Model of a bacterial cell (*Escherichia coli*). **Envelope:** The cell membrane contains embedded proteins for structure and transport. The cell membrane is supported by the cell wall. In this gram-negative cell, the cell wall is coated by the outer membrane, whose sugar chain extensions protect the cell from attack by the immune system or by predators. Plugged into the membranes is the rotary motor of a flagellum. **Cytoplasm:** Molecules of nascent messenger RNA (mRNA) extend out of the nucleoid to the region of the cytoplasm rich in ribosomes. Ribosomes translate the mRNA to make proteins, which are folded by chaperones. **Nucleoid:** The chromosomal DNA is wrapped around binding proteins. Replication by DNA polymerase and transcription by RNA polymerase occur at the same time within the nucleoid. (PDB codes: ribosome, 1GIX,1GIY; DNA-binding protein, 1P78; RNA polymerase, 1MSW)

Bacterial Cell Components

Outer membrane proteins:

- Sugar porin (10 nm)
- Braun lipoprotein (8 nm)

Inner membrane proteins:

- Glycerol porin
- Secretory complex (Sec)
- ATP synthase (20 nm diameter in inner membrane; 32 nm total height)

Periplasmic proteins:

- Arabinose-binding protein (3 nm x 3 nm x 6 nm)
- Acid resistance chaperone (HdeA) (3 nm x 3 nm x 6 nm)
- Disulfide bond protein (DsbA) (3 nm x 3 nm x 6 nm)

Cytoplasmic proteins:

- Pyruvate kinase (5 nm x 10 nm x 10 nm)
- Phosphofructokinase (4 nm x 7 nm x 7 nm)
- Proteasome (12 nm x 12 nm x 15 nm)
- Chaperonin GroEL (18 nm x 14 nm)
- Other proteins

Transcription and translation complexes:

- RNA polymerase (10 x 10 x 16 nm)
- Ribosome (21 x 21 x 21 nm)

Nucleoid components:

- DNA (2.4 nm wide x 3.4 nm/10 bp)
- DNA-binding protein (3 x 3 x 5 nm)
- DNA-bridging protein (3 x 3 x 5 nm)

W • W • NORTON
NEW YORK • LONDON

W. W. Norton & Company has been independent since its founding in 1923, when William Warder Norton and Mary D. Herter Norton first published lectures delivered at the People's Institute, the adult education division of New York City's Cooper Union. The Nortons soon expanded their program beyond the Institute, publishing books by celebrated academics from America and abroad. By mid-century, the two major pillars of Norton's publishing program—trade books and college texts—were firmly established. In the 1950s, the Norton family transferred control of the company to its employees, and today—with a staff of four hundred and a comparable number of trade, college, and professional titles published each year—W. W. Norton & Company stands as the largest and oldest publishing house owned wholly by its employees.

DEDICATION

We dedicate this book to the memory of our doctoral research mentors. Joan's doctoral mentor, Bob Macnab, offered an unfailingly rigorous pursuit of bacterial chemotaxis and physiology, and lasting friendship. John was mentored by Al Moat, a gifted microbial physiologist and humorist who instilled in his neophyte students an appreciation for critical thinking and a love for the science of microbiology.

Brief Contents

Preface xvii

About the Authors xxviii

Part 1: The Microbial Cell 2

1 Microbial Life: Origin and Discovery 5
2 Observing the Microbial Cell 39
3 Cell Structure and Function 73
4 Bacterial Culture, Growth, and Development 115
5 Environmental Influences and Control of Microbial Growth 149
6 Virus Structure and Function 181

Part 2: Genes and Genomes 218

7 Genomes and Chromosomes 221
8 Transcription, Translation, and Bioinformatics 257
9 Gene Transfer, Mutations, and Genome Evolution 303
10 Molecular Regulation 345
11 Viral Molecular Biology 389
12 Molecular Techniques and Biotechnology 431

Part 3: Metabolism and Biochemistry 458

13 Energetics and Catabolism 461
14 Respiration, Lithotrophy, and Photolysis 505
15 Biosynthesis 547
16 Food and Industrial Microbiology 589

Part 4: Microbial Diversity and Ecology 626

17 Origins and Evolution 629
18 Bacterial Diversity 675
19 Archaeal Diversity 721
20 Eukaryotic Diversity 755
21 Microbial Ecology 793
22 Microbes and the Global Environment 831

Part 5: Medicine and Immunology 860

23 Human Microflora and Nonspecific Host Defenses 863
24 The Adaptive Immune Response 895
25 Microbial Pathogenesis 937
26 Microbial Diseases 979
27 Antimicrobial Chemotherapy 1029
28 Clinical Microbiology and Epidemiology 1063

PART 1
The Microbial Cell 2

AN INTERVIEW WITH RITA COLWELL: THE GLOBAL IMPACT OF MICROBIOLOGY

CHAPTER 1
Microbial Life: Origin and Discovery 5

1.1 From Germ to Genome: What Is a Microbe? 6
1.2 Microbes Shape Human History 11
1.3 Medical Microbiology 17
  Special Topic 1.1 How Did Life Originate? 18
  Special Topic 1.2 The Discovery of Viruses 22
1.4 Microbial Ecology 26
  Special Topic 1.3 Microbial Endosymbionts of Animals 28
1.5 The Microbial Family Tree 29
1.6 Cell Biology and the DNA Revolution 32

CHAPTER 2
Observing the Microbial Cell 39

2.1 Observing Microbes 40
2.2 Optics and Properties of Light 44
2.3 Bright-Field Microscopy 48
2.4 Dark-Field, Phase-Contrast, and Interference Microscopy 55
2.5 Fluorescence Microscopy 58
  Special Topic 2.1 Confocal Fluorescence Microscopy 60
2.6 Electron Microscopy 62
  Special Topic 2.2 Three-Dimensional Electron Microscopy Solves the Structure of a Major Agricultural Virus 66
2.7 Visualizing Molecules 68

CHAPTER 3

Cell Structure and Function 73

3.1 The Bacterial Cell: An Overview 75
3.2 How We Study the Parts of Cells 78
3.3 The Cell Membrane and Transport 82
3.4 The Cell Wall and Outer Layers 88
Special Topic 3.1 The Unique Cell Envelope of Mycobacteria 92
3.5 The Nucleoid and Gene Expression 98
3.6 Cell Division 101
Special Topic 3.2 Bacteria Have a Cytoskeleton 105
3.7 Specialized Structures 106
Special Topic 3.3 Two Kinds of Progeny: One Stays, One Swims 108

CHAPTER 4

Bacterial Culture, Growth, and Development 115

4.1 Microbial Nutrition 116
4.2 Nutrient Uptake 121
4.3 Culturing Bacteria 127
4.4 Counting Bacteria 131
4.5 The Growth Cycle 134
4.6 Biofilms 140
Special Topic 4.1 Biofilms, Disease, and Antibiotic Resistance 141
4.7 Cell Differentiation 142

CHAPTER 5

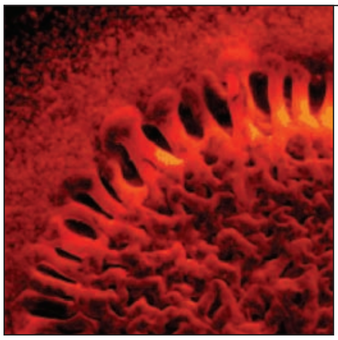
Environmental Influences and Control of Microbial Growth 149

5.1 Environmental Limits on Microbial Growth 150
5.2 Microbial Responses to Changes in Temperature 152
5.3 Microbial Adaptation to Variations in Pressure 155
5.4 Microbial Responses to Changes in Water Activity and Salt Concentration 157
5.5 Microbial Responses to Changes in pH 158
Special Topic 5.1 Signaling Virulence 164
5.6 Microbial Responses to Oxygen and Other Electron Acceptors 164
5.7 Microbial Responses to Nutrient Deprivation and Starvation 168
5.8 Physical and Chemical Methods of Controlling Microbial Growth 170
5.9 Biological Control of Microbes 178

CHAPTER 6

Virus Structure and Function 181
6.1 What Is a Virus? 182
6.2 Virus Structure 187
6.3 Viral Genomes and Classification 191
6.4 Bacteriophage Life Cycles 198
6.5 Animal and Plant Virus Life Cycles 201
6.6 Culturing Viruses 208
6.7 Viral Ecology 212
Special Topic 6.1 West Nile Virus, an Emerging Pathogen 214

PART 2
Genes and Genomes 218



AN INTERVIEW WITH RICHARD LOSICK:
THE THRILL OF DISCOVERY IN MOLECULAR MICROBIOLOGY

CHAPTER 7
Genomes and Chromosomes 221
7.1 DNA: The Genetic Material 222
7.2 Genome Organization 223
7.3 DNA Replication 232
Special Topic 7.1 Trapping a Sliding Clamp 237
7.4 Plasmids and Bacteriophages 243
Special Topic 7.2 Plasmid Partitioning and Addiction 245
7.5 Eukaryotic Chromosomes: Comparison with Prokaryotes 246
7.6 DNA Sequence Analysis 248
Special Topic 7.3 The Polymerase Chain Reaction 250

CHAPTER 8
Transcription, Translation, and Bioinformatics 257
8.1 RNA Polymerases and Sigma Factors 258
8.2 Transcription Initiation, Elongation, and Termination 263
8.3 Translation of RNA to Protein 267
Special Topic 8.1 Antibiotics That Affect Transcription 268
Special Topic 8.2 Antibiotics That Affect Translation 281
8.4 Protein Modification and Folding 283
8.5 Secretion: Protein Traffic Control 285
8.6 Protein Degradation: Cleaning House 290
Special Topic 8.3 Ubiquitination: A Ticket to the Proteasome 292
8.7 Bioinformatics: Mining the Genomes 293
Special Topic 8.4 What Is the Minimal Genome? 297

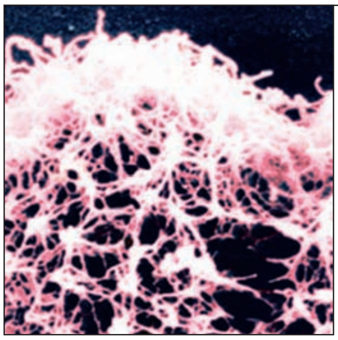
CHAPTER 9
Gene Transfer, Mutations, and Genome Evolution 303
9.1 The Mosaic Nature of Genomes 304
9.2 Gene Transfer: Transformation, Conjugation, and Transduction 304
9.3 Recombination 316
9.4 Mutations 320
9.5 DNA Repair 327
9.6 Mobile Genetic Elements 333
9.7 Genome Evolution 336
Special Topic 9.1 Integrons and Gene Capture 338

CHAPTER 10
Molecular Regulation 345
10.1 Regulating Gene Expression 346
10.2 Paradigm of the Lactose Operon 349
10.3 Other Systems of Operon Control 355
Special Topic 10.1 How Do We Study Protein-DNA Binding? 356
10.4 Sigma Factor Regulation 365
10.5 Small Regulatory RNAs 368
10.6 DNA Rearrangements: Phase Variation by Shifty Pathogens 370
10.7 Integrated Control Circuits 373
10.8 Quorum Sensing: Chemical Conversations 378
Special Topic 10.2 The Role of Quorum Sensing in Pathogenesis and in Interspecies Communications 380
10.9 Genomics and Proteomics: Tools of the Future 381

CHAPTER 11
Viral Molecular Biology 389
11.1 Phage T4: The Classic Molecular Model 391
11.2 The Filamentous Phage M13 397
11.3 A (+) Strand RNA Virus: Polio 400
11.4 A Segmented (–) Strand RNA Virus: Influenza 406
11.5 A Retrovirus: Human Immunodeficiency Virus 412
11.6 A DNA Virus: Herpes Simplex 423
Special Topic 11.1 How Did Viruses Originate? 424

CHAPTER 12
Molecular Techniques and Biotechnology 431
12.1 Basic Tools of Biotech: A Research Case Study 432
12.2 Genetic Analyses 432
12.3 Molecular Analyses 436
12.4 “Global” Questions of Cell Physiology 444
12.5 Biotechniques of Artificial Evolution 446
12.6 Applied Microbial Biotechnology 450
Special Topic 12.1 DNA Vaccines 452

PART 3
Metabolism and Biochemistry 458



AN INTERVIEW WITH CAROLINE HARWOOD: BACTERIAL METABOLISM DEGRADES POLLUTANTS AND PRODUCES HYDROGEN

CHAPTER 13

Energetics and Catabolism 461

13.1 Energy and Entropy: Building a Cell 463
13.2 Energy and Entropy in Biochemical Reactions 465
13.3 Energy Carriers and Electron Transfer 469
Special Topic 13.1 Observing Energy Carriers in Living Cells 475
13.4 Catabolism: The Microbial Buffet 476
Special Topic 13.2 Swiss Cheese: A Product of Bacterial Catabolism 480
13.5 Glucose Breakdown and Fermentation 482
13.6 The Tricarboxylic Acid (TCA) Cycle 491
13.7 Aromatic Catabolism 496
Special Topic 13.3 Genomic Analysis of Metabolism 498

CHAPTER 14

Respiration, Lithotrophy, and Photolysis 505

14.1 Electron Transport Systems 506
14.2 The Proton Motive Force 511
Special Topic 14.1 Testing the Chemiosmotic Hypothesis 512
14.3 The Respiratory ETS and ATP Synthase 516
14.4 Anaerobic Respiration 525
Special Topic 14.2 ATP Synthesis at High pH 526
14.5 Lithotrophy and Methanogenesis 529
14.6 Phototrophy 534

CHAPTER 15

Biosynthesis 547

15.1 Overview of Biosynthesis 548
15.2 CO_2 Fixation: The Calvin Cycle 550
Special Topic 15.1 The Discovery of ^{14}C 554
15.3 CO_2 Fixation in Anaerobes and Archaea 560
15.4 Biosynthesis of Fatty Acids and Polyesters 564
Special Topic 15.2 Polyketide Drugs Are Synthesized by Multienzyme Factories 567
15.5 Nitrogen Fixation 570
15.6 Biosynthesis of Amino Acids and Nitrogenous Bases 575
15.7 Biosynthesis of Tetrapyrroles 581
Special Topic 15.3 Modular Biosynthesis of Vancomycin 584

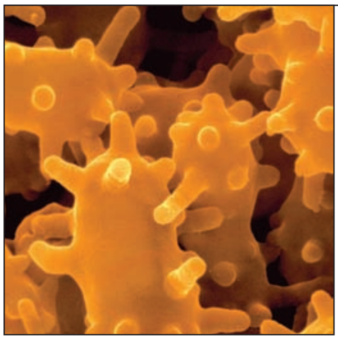
CHAPTER 16

Food and Industrial Microbiology 589

16.1 Microbes as Food 590
16.2 Fermented Foods: An Overview 592
16.3 Acidic and Alkaline Fermented Foods 595
Special Topic 16.1 Chocolate: The Mystery Fermentation 600
16.4 Ethanolic Fermentation: Bread and Wine 602
Special Topic 16.2 Beer Is Made from Barley and Hops 606
16.5 Food Spoilage and Preservation 608
16.6 Industrial Microbiology 615
Special Topic 16.3 Start-Up Companies Take On Tuberculosis 616

PART 4

Microbial Diversity and Ecology 626



AN INTERVIEW WITH KARL STETTER: ADVENTURES IN MICROBIAL DIVERSITY LEAD TO PRODUCTS IN INDUSTRY

CHAPTER 17

Origins and Evolution 629

17.1 Origins of Life 631
17.2 Models for Early Life 641
Special Topic 17.1 The RNA World: Clues for Modern Medicine 644
17.3 Microbial Taxonomy 647
17.4 Microbial Divergence and Phylogeny 651
Special Topic 17.2 Phylogeny of a Shower Curtain Biofilm 658
17.5 Horizontal Gene Transfer 661
Special Topic 17.3 Horizontal Transfer in *E. coli* O157:H7 664
17.6 Symbiosis and the Origin of Mitochondria and Chloroplasts 666

CHAPTER 18

Bacterial Diversity 675

18.1 Bacterial Diversity at a Glance 677
18.2 Deep-Branching Thermophiles 685
18.3 Cyanobacteria: Oxygenic Phototrophs 688
Special Topic 18.1 Cyanobacterial Communities: From Ocean to Animal 691
18.4 Gram-Positive Firmicutes and Actinobacteria 692
18.5 Gram-Negative Proteobacteria and Nitrospirae 703
18.6 Bacteroidetes and Chlorobi 714
18.7 Spirochetes: Sheathed Spiral Cells with Internalized Flagella 715
18.8 Chlamydiae, Planctomycetes, and Verrucomicrobia: Irregular Cells 716

CHAPTER 19

Archaeal Diversity 721

19.1 Archaeal Traits and Diversity 723
19.2 Crenarchaeota: Hyperthermophiles 730
Special Topic 19.1 Research on Deep-Sea Hyperthermophiles 733
19.3 Crenarchaeota: Mesophiles and Psychrophiles 735
19.4 Euryarchaeota: Methanogens 738
19.5 Euryarchaeota: Halophiles 744
Special Topic 19.2 Haloarchaea in the High School Classroom 746
19.6 Euryarchaeota: Thermophiles and Acidophiles 750
19.7 Nanoarchaeota and Other Emerging Divisions 753

CHAPTER 20

Eukaryotic Diversity 755

20.1 Phylogeny of Eukaryotes 756
20.2 Fungi 765
Special Topic 20.1 Mold after Hurricane Katrina 772
20.3 Algae 774
20.4 Amebas and Slime Molds 780
20.5 Alveolates: Ciliates, Dinoflagellates, and Apicomplexans 783
Special Topic 20.2 A Ciliate Model for Human Aging 785
20.6 Trypanosomes, Microsporidia, and Excavates 791

CHAPTER 21

Microbial Ecology 793

21.1 Microbes in Ecosystems 794
21.2 Microbial Symbiosis 798
21.3 Marine and Aquatic Microbiology 801
21.4 Soil and Subsurface Microbiology 812
21.5 Microbial Communities within Plants 820
21.6 Microbial Communities within Animals 824
Special Topic 21.1 A Veterinary Experiment: The Fistulated Cow 828

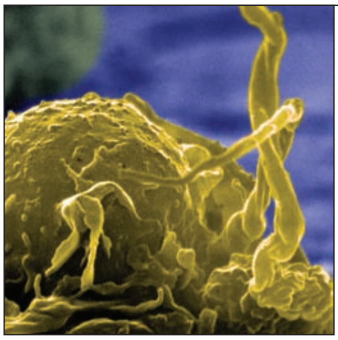
CHAPTER 22

Microbes and the Global Environment 831

22.1 Biogeochemical Cycles 832
22.2 The Carbon Cycle 835
Special Topic 22.1 Wetlands: Disappearing Microbial Ecosystems 838
22.3 The Hydrologic Cycle and Wastewater Treatment 839
22.4 The Nitrogen Cycle 842
22.5 Sulfur, Phosphorus, and Metals 847
22.6 Astrobiology 854

PART 5

Medicine and Immunology 860



AN INTERVIEW WITH CLIFFORD W. HOUSTON: AN AQUATIC BACTERIUM CAUSES FATAL WOUND INFECTIONS

CHAPTER 23

Human Microflora and Nonspecific Host Defenses 863

23.1 Human Microflora: Location and Shifting Composition 864
23.2 Risks and Benefits of Harboring Microbial Populations 871
23.3 Overview of the Immune System 872
23.4 Barbarians at the Gate: Innate Host Defenses 877
23.5 Innate Immunity: The Acute Inflammatory Response 880
Special Topic 23.1 Do Defensins Have a Role in Determining Species Specificity for Infection? 881
23.6 Phagocytosis 884
23.7 Innate Defenses by Interferon and Natural Killer Cells 886
Special Topic 23.2 Immune Avoidance: Outsmarting the Host's Innate Immune System 888
23.8 Complement's Role in Innate Immunity 889
23.9 Fever 891

CHAPTER 24

The Adaptive Immune Response 895

24.1 Adaptive Immunity 896
24.2 Factors That Influence Immunogenicity 898
24.3 Antibody Structure and Diversity 902
Special Topic 24.1 Applications Based on Antigen-Antibody Interactions 906
24.4 Humoral Immunity: Primary and Secondary Antibody Responses 908
24.5 Genetics of Antibody Production 911
24.6 T Cells, Major Histocompatibility Complex, and Antigen Processing 915
Special Topic 24.2 T Cells That Recognize Self Too Strongly Are Weeded Out in the Thymus 918
24.7 Complement as Part of Adaptive Immunity 925
24.8 Failures of Immune System Regulation: Hypersensitivity and Autoimmunity 926
Special Topic 24.3 Organ Donation and Transplantation Rejection 933

CHAPTER 25

Microbial Pathogenesis 937

25.1 Host-Pathogen Interactions 938
25.2 Virulence Factors and Pathogenicity Islands: The Tools and Toolkits of Microbial Pathogens 942
25.3 Virulence Factors: Microbial Attachment 944
25.4 Toxins: A Way to Subvert Host Cell Function 948
25.5 Protein Secretion and Pathogenesis 959
Special Topic 25.1 The Bacterial Trojan Horse: Bacteria That Deliver Their Own Receptor 963
25.6 Finding Virulence Genes 964
Special Topic 25.2 Signature-Tagged Mutagenesis 966
25.7 Surviving within the Host 969
25.8 Viral Pathogenesis 971

CHAPTER 26

Microbial Diseases 979

26.1 Characterizing and Diagnosing Microbial Diseases 980
26.2 Skin and Soft-Tissue Infections 982
26.3 Respiratory Tract Infections 986
26.4 Gastrointestinal Tract Infections 992
26.5 Genitourinary Tract Infections 997
Special Topic 26.1 Intracellular Biofilm Pods Are Reservoirs of Infection 1000
26.6 Infections of the Central Nervous System 1007
26.7 Infections of the Cardiovascular System 1014
28.8 Systemic Infections 1017
26.9 Immunization 1023

CHAPTER 27

Antimicrobial Chemotherapy 1029

27.1 The Golden Age of Antibiotic Discovery 1030
27.2 Basic Concepts of Antimicrobial Therapy 1032
27.3 Measuring Drug Susceptibility 1034
27.4 Mechanisms of Action 1037
27.5 Antibiotic Biosynthesis 1046
27.6 The Challenges of Antibiotic Resistance 1047
27.7 The Future of Drug Discovery 1052
27.8 Antiviral Agents 1054
Special Topic 27.1 Poking Holes with Nanotubes: A New Antibiotic Therapy 1055
Special Topic 27.2 Critical Virulence Factors Found in the 1918 Strain of Influenza Virus 1057
27.9 Antifungal Agents 1059

CHAPTER 28

Clinical Microbiology and Epidemiology 1063

28.1 Principles of Clinical Microbiology 1064
28.2 Approaches to Pathogen Identification 1065
28.3 Specimen Collection 1081
28.4 Biosafety Containment Procedures 1083
28.5 Principles of Epidemiology 1085
Special Topic 28.1 Microbial Pathogen Detection Gets Wired Up 1092
28.6 Detecting Emerging Microbial Diseases 1092

APPENDIX 1

Biological Molecules A-1

A1.1 Elements, Bonding, and Water A-2
A1.2 Common Features of Organic Molecules A-5
A1.3 Proteins A-6
A1.4 Polysaccharides A-10
A1.5 Nucleic Acids A-12
A1.6 Lipids A-14
A1.7 Chemical Principles in Biological Chemistry A-16

APPENDIX 2

Introductory Cell Biology: Eukaryotic Cells A-21

A2.1 The Cell Membrane A-22
A2.2 The Nucleus and Mitosis A-29
A2.3 Problems Faced by Large Cells A-30
A2.4 The Endomembrane System A-32
A2.5 The Cytoskeleton A-35
A2.6 Mitochondria and Chloroplasts A-37

Answers to Thought Questions AQ-1

Glossary G-1

Index I-1

Preface

Among civilization's greatest achievements are the discovery of microbes and learning how they function. Today, microbiology as a science is evolving rapidly. Emerging species, from *Helicobacter pylori* to ammonia oxidizers, challenge our vision of where microbes can grow, while emerging technologies, from atomic force microscopy to metagenomic sequencing, expand the frontiers of what we can study. As our understanding of microbes and our ability to study them has evolved, what is taught must also evolve. This textbook was designed to present core topics of microbiology in the context of new challenges and opportunities.

Our book gives students and faculty a fresh approach to learning the science of microbiology. A major aim is to balance the coverage of microbial ecology and medical microbiology. We explore the origin of life as a dynamic story of discovery that integrates microfossil data with physiology and molecular biology. This story provides surprising applications in both biotechnology and medicine (Chapter 17, Origins and Evolution). Microbial–host interactions are presented in the context of evolution and ecology, reflecting current discoveries in microbial diversity. For example, *Vibrio cholerae*, the causative agent of cholera, is discussed as part of a complex ecosystem involving invertebrates as well as human hosts (Part 1, Interview with Rita Colwell). Principles of disease are explained in terms of molecular virulence factors that act upon the host cell, including the horizontal transfer of virulence genes that make a pathogen (Chapter 25, Microbial Pathogenesis). Throughout our book, we present the tools of scientific investigation (emphasizing their strengths and limitations) and the excitement of pursuing questions yet to be answered.

We were students when the first exciting reports of gene cloning and the descriptions of molecular machines that compose cells were published. We shared in the excitement surrounding these extraordinary advances, witnessed their impact on the field, and recall how profoundly they inspired us as aspiring scientists. As a result, we believe that conveying the story of scientific advancement and its influence on the way scientists approach research questions, whether classical or modern, is an important motivational and pedagogical tool in presenting fundamental concepts. We present the story of molecular microbiology and microbial ecology in the same spirit as the classical history of Koch and Pasteur, and of Winogradsky and Beijerinck. We drew on all our experience as researchers and educators (and on the input of dozens of colleagues over the past seven years) to create a microbiology text for the twenty-first century.

Major Features

Our book targets the science major in biology, microbiology, or biochemistry. We offer several important improvements over other books written for this audience:

- **Genetics and genomics are presented as the foundation of microbiology.** Molecular genetics and genomics are thoroughly integrated with core topics throughout the book. This approach gives students many advantages, including an understanding of how genomes reveal potential metabolic pathways in diverse organisms, and how genomics and metagenomics reveal the character of microbial communities. Molecular structures and chemical diagrams presented throughout the art program clearly illustrate the connections between molecular genetics, physiology, and pathogenesis.
- **Microbial ecology and medical microbiology receive equal emphasis**, with particular attention paid to the merging of these fields. Throughout the book, phenomena are presented with examples from both ecology and medicine; for example, when discussing horizontal transfer of "genomic islands" we present symbiosis islands associated with nitrogen fixation, as well as pathogenicity islands associated with disease (Chapter 9).
- **Current research examples and tools throughout the text enrich students' understanding of foundational topics.** Every chapter presents numerous current research examples within the up-to-date framework of molecular biology, showing how the latest research extends our knowledge of fundamental topics. For example, in the past two decades, advances in microscopy have reshaped our vision of microbial cells. Chapter 2 is devoted to visualization techniques, from an in-depth treatment of the student's microscope to advanced methods such as atomic force microscopy. Unlike most microbiology textbooks, our text provides size scale information for nearly every micrograph, which is critical when trying to visualize the relationship between different organisms and structures. Examples of current research range from the use of two-hybrid assays to study *Salmonella* virulence proteins to the spectroscopic measurement of carbon flux from microbial communities.
- **Viruses are presented in molecular detail and in ecological perspective.** For example, in marine ecosystems, viruses play key roles in limiting algal populations while selecting for species diversity (Chapter 6). Similarly, a constellation of bacteriophages influences enteric flora. Our coverage of human virology includes the molecular reproductive cycles of herpes, avian influenza, and HIV, including emerging topics such as the role of regulatory proteins in HIV virulence (Chapter 11).
- **Microbial diversity that students can grasp.** We present microbial diversity in a manageable framework that enables students to grasp the essentials of the most commonly presented taxa, devoting one chapter each to bacteria, archaea, and the microbial eukaryotes. At the same time, we emphasize the continual discovery of previously unknown forms such as the nanoarchaea and the marine prochlorophytes. Our book is supported by the on-line *Microbial Biorealm*, an innovative resource on microbial diversity authored by students and their teachers.
- **The physician-scientist's approach to microbial diseases.** Case histories are used to present how a physician-scientist approaches the interplay between the

human immune response and microbial diseases. By taking an organ systems approach, we show how a physician actually interacts with the patient, recognizing that patients complain of symptoms, not a species. Ultimately, we let the student in on the clues used to identify infective microbes. The approach stresses the concepts of infectious disease rather than presenting an exhaustive recitation of diseases and microbes.

- **Scientists pursuing research today are presented alongside the traditional icons.** This approach helps students see that microbiology is an extremely dynamic field of science, full of opportunities for them to do important research as undergraduates or as future graduate students. For example, Chapter 1 not only introduces historical figures such as Koch and Pasteur, but also features genome sequencer Claire Fraser-Liggett, postdoctoral researcher Kazem Kashefi growing a hyperthermophile in an autoclave, and undergraduate students studying acid stress in *E. coli*.
- **Appendices for students in need of review.** Our book assumes a sophomore-level understanding of introductory biology and chemistry. For those in need of review, two appendices summarize the fundamental structure and function of biological molecules and cells.

Organization

The topics of this book are arranged so that students can progressively develop an understanding of microbiology from key concepts and research tools. The chapters of Part 1 present key foundational topics: history, visualization, the bacterial cell, microbial growth and control, and virology. Chapter 1 discusses the nature of microbes and the history of their discovery, including the key role of microbial genomes. In Chapter 2, basic tools of visualization, from the student's microscope to cryo-EM, provide the foundation for understanding how scientists reveal microbial structure. The basic form and function of bacterial cells emerges in Chapter 3, while Chapters 4 and 5 present core concepts of microbial growth in relation to the environment. Chapter 6 introduces virus structure and culture.

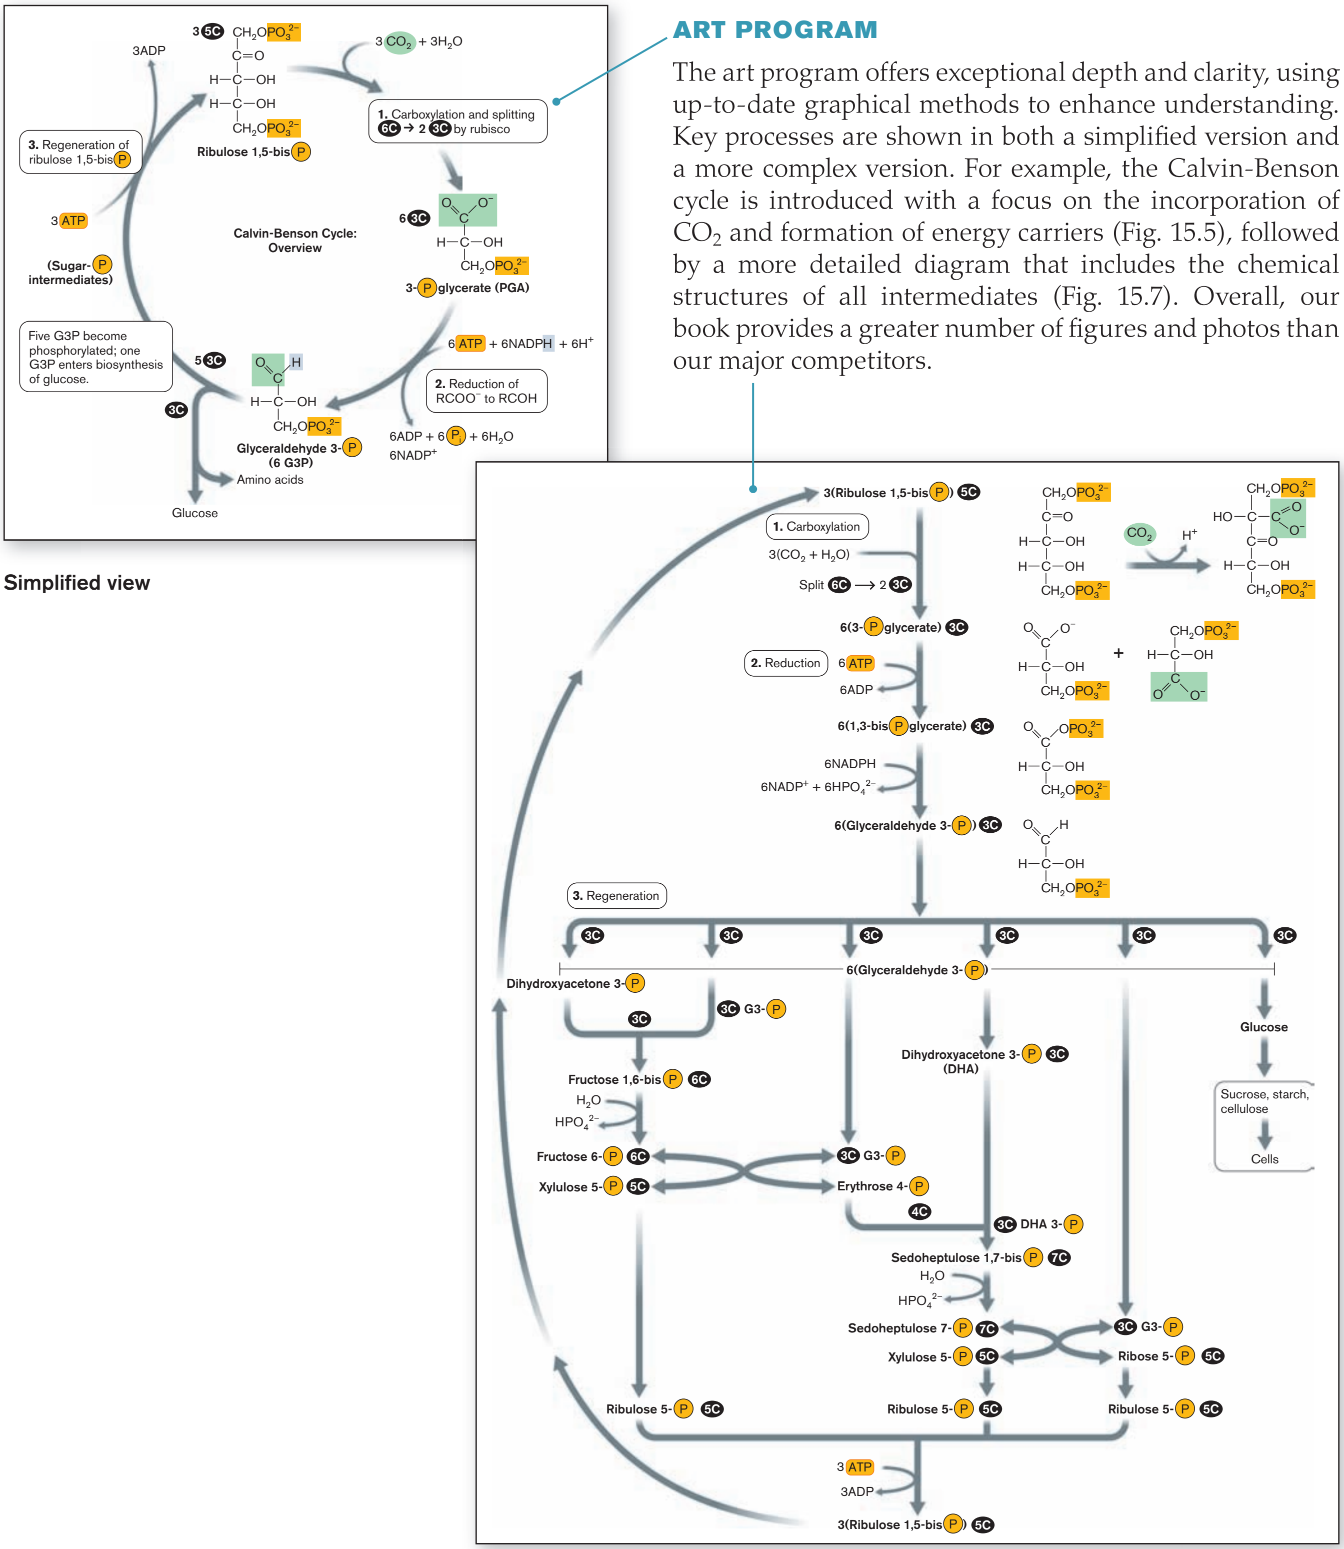
The six chapters in Part 1 present topics treated in more detail in Parts 2 through 5. The topics of nucleoid structure and virus replication introduced in Chapters 3 and 6 lead into Part 2, where Chapters 7 through 12 present modern genetics and genomics. Chapter 11 presents the life cycles of selected viruses in molecular detail. The topics of cell growth and nutrition introduced in Chapter 4 lead into Part 3 (Chapters 13–16), which presents cell metabolism and biochemistry. Diverse forms of metabolism, such as phototrophy and lithotrophy, are explained on a common basis, the fundamental principles of electron transport and energy conservation. These chapters are written in such a way that they can be presented before the genetics material if so desired. Chapter 16 presents food and industrial microbiology, showing how these fields are founded on microbial metabolism. The principles of environmental responses and growth limits introduced in Chapter 5 lead into Part 4 (Chapters 17–22), which explores microbial ecology and diversity. The roles of microbial communities in local ecosystems and global cycling, introduced in Chapter 4, are presented in greater depth in Chapters 21 and 22. And the chapters of Part 5 (Chapters 23–28) present medical and disease microbiology from an investigative perspective, founded on the principles of genetics, metabolism, and microbial ecology.

Special Features

Throughout our book, special features aid student understanding and stimulate inquiry.

ART PROGRAM

The art program offers exceptional depth and clarity, using up-to-date graphical methods to enhance understanding. Key processes are shown in both a simplified version and a more complex version. For example, the Calvin-Benson cycle is introduced with a focus on the incorporation of CO_2 and formation of energy carriers (Fig. 15.5), followed by a more detailed diagram that includes the chemical structures of all intermediates (Fig. 15.7). Overall, our book provides a greater number of figures and photos than our major competitors.



Calvin-Benson Cycle: Overview

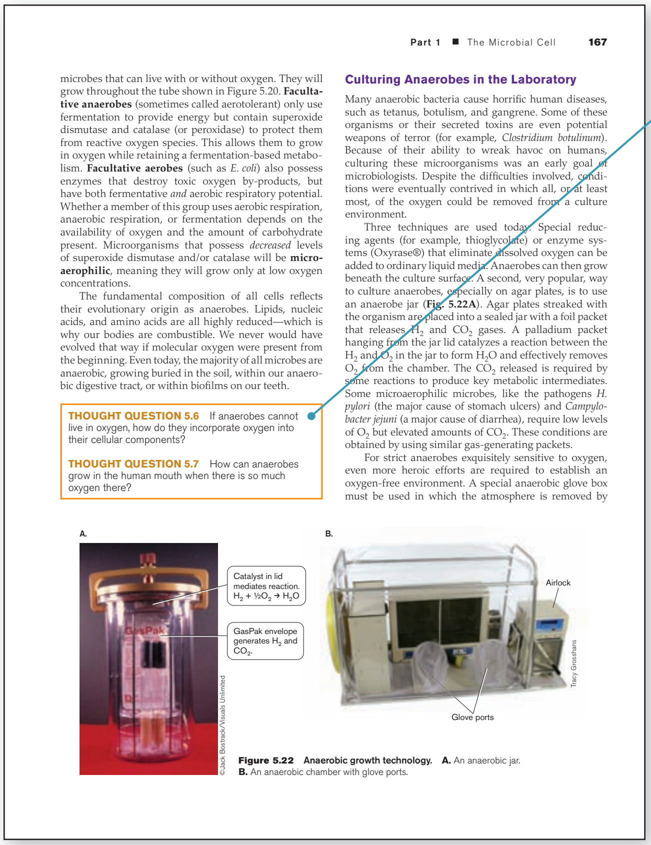
THOUGHT QUESTIONS

"Thought Questions" throughout the text stimulate students to think critically about their reading. For example, a Thought Question in Chapter 5 (p. 167) asks students to consider how anaerobes incorporate oxygen into their cellular components in spite of their inability to live in oxygen. The question is posed in the context of a discussion of the different levels of oxygen tolerated or required by different types of microbes.

Answers to each Thought Question are provided at the back of the book.



Part 1 ■ The Microbial Cell 167

microbes that can live with or without oxygen. They will grow throughout the tube shown in Figure 5.20. **Facultative anaerobes** (sometimes called aerotolerant) only use fermentation to provide energy but contain superoxide dismutase and catalase (or peroxidase) to protect them from reactive oxygen species. This allows them to grow in oxygen while retaining a fermentation-based metabolism. **Facultative aerobes** (such as *E. coli*) also possess enzymes that destroy toxic oxygen by-products, but have both fermentative *and* aerobic respiratory potential. Whether a member of this group uses aerobic respiration, anaerobic respiration, or fermentation depends on the availability of oxygen and the amount of carbohydrate present. Microorganisms that possess *decreased* levels of superoxide dismutase and/or catalase will be **microaerophilic**, meaning they will grow only at low oxygen concentrations.

The fundamental composition of all cells reflects their evolutionary origin as anaerobes. Lipids, nucleic acids, and amino acids are all highly reduced—which is why our bodies are combustible. We never would have evolved that way if molecular oxygen were present from the beginning. Even today, the majority of all microbes are anaerobic, growing buried in the soil, within our anaerobic digestive tract, or within biofilms on our teeth.

THOUGHT QUESTION 5.6 If anaerobes cannot live in oxygen, how do they incorporate oxygen into their cellular components?

THOUGHT QUESTION 5.7 How can anaerobes grow in the human mouth when there is so much oxygen there?

Culturing Anaerobes in the Laboratory

Many anaerobic bacteria cause horrific human diseases, such as tetanus, botulism, and gangrene. Some of these organisms or their secreted toxins are even potential weapons of terror (for example, *Clostridium botulinum*). Because of their ability to wreak havoc on humans, culturing these microorganisms was an early goal of microbiologists. Despite the difficulties involved, conditions were eventually contrived in which all, or at least most, of the oxygen could be removed from a culture environment.

Three techniques are used today. Special reducing agents (for example, thioglycolate) or enzyme systems (Oxyrase®) that eliminate dissolved oxygen can be added to ordinary liquid media. Anaerobes can then grow beneath the culture surface. A second, very popular, way to culture anaerobes, especially on agar plates, is to use an anaerobe jar (**Fig. 5.22A**). Agar plates streaked with the organism are placed into a sealed jar with a foil packet that releases H_2 and CO_2 gases. A palladium packet hanging from the jar lid catalyzes a reaction between the H_2 and O_2 in the jar to form H_2O and effectively removes O_2 from the chamber. The CO_2 released is required by some reactions to produce key metabolic intermediates. Some microaerophilic microbes, like the pathogens *H. pylori* (the major cause of stomach ulcers) and *Campylobacter jejuni* (a major cause of diarrhea), require low levels of O_2 but elevated amounts of CO_2. These conditions are obtained by using similar gas-generating packets.

For strict anaerobes exquisitely sensitive to oxygen, even more heroic efforts are required to establish an oxygen-free environment. A special anaerobic glove box must be used in which the atmosphere is removed by

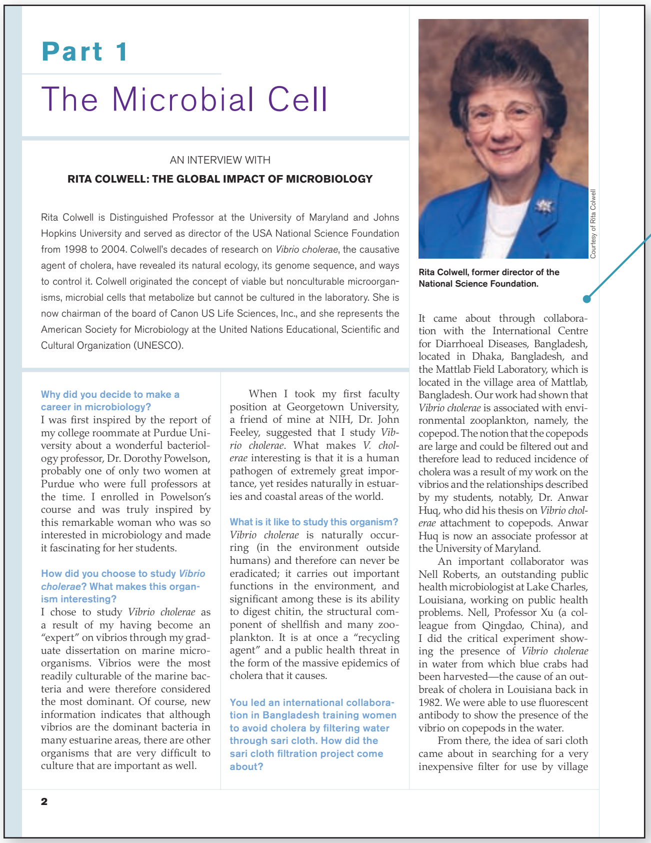
INTERVIEWS WITH PROMINENT SCIENTISTS

Each Part of the book opens with an interview of a prominent microbiologist working today. In each interview, the authors ask the featured scientist questions about everything from how they first became interested in microbiology to how their thought processes and experiments allowed them to make important discoveries. Interviewees include Karl Stetter, the first person to discover living organisms growing at temperatures above 100°C, and Rita Colwell, past director of the National Science Foundation, who used her understanding of the marine ecology of *Vibrio cholerae* to help develop public health measures against cholera in developing countries.



Part 1

The Microbial Cell

AN INTERVIEW WITH

RITA COLWELL: THE GLOBAL IMPACT OF MICROBIOLOGY

Rita Colwell is Distinguished Professor at the University of Maryland and Johns Hopkins University and served as director of the USA National Science Foundation from 1998 to 2004. Colwell's decades of research on *Vibrio cholerae*, the causative agent of cholera, have revealed its natural ecology, its genome sequence, and ways to control it. Colwell originated the concept of viable but nonculturable microorganisms, microbial cells that metabolize but cannot be cultured in the laboratory. She is now chairman of the board of Canon US Life Sciences, Inc., and she represents the American Society for Microbiology at the United Nations Educational, Scientific and Cultural Organization (UNESCO).

Why did you decide to make a career in microbiology?
I was first inspired by the report of my college roommate at Purdue University about a wonderful bacteriology professor, Dr. Dorothy Powelson, probably one of only two women at Purdue who were full professors at the time. I enrolled in Powelson's course and was truly inspired by this remarkable woman who was so interested in microbiology and made it fascinating for her students.

How did you choose to study *Vibrio cholerae*? What makes this organism interesting?
I chose to study *Vibrio cholerae* as a result of my having become an "expert" on vibrios through my graduate dissertation on marine microorganisms. Vibrios were the most readily culturable of the marine bacteria and were therefore considered the most dominant. Of course, new information indicates that although vibrios are the dominant bacteria in many estuarine areas, there are other organisms that are very difficult to culture that are important as well.

When I took my first faculty position at Georgetown University, a friend of mine at NIH, Dr. John Feeley, suggested that I study *Vibrio cholerae*. What makes *V. cholerae* interesting is that it is a human pathogen of extremely great importance, yet resides naturally in estuaries and coastal areas of the world.

What is it like to study this organism?
Vibrio cholerae is naturally occurring (in the environment outside humans) and therefore can never be eradicated; it carries out important functions in the environment, and significant among these is its ability to digest chitin, the structural component of shellfish and many zooplankton. It is at once a "recycling agent" and a public health threat in the form of the massive epidemics of cholera that it causes.

You led an international collaboration in Bangladesh training women to avoid cholera by filtering water through sari cloth. How did the sari cloth filtration project come about?

Courtesy of Rita Colwell

Rita Colwell, former director of the National Science Foundation.

It came about through collaboration with the International Centre for Diarrhoeal Diseases, Bangladesh, located in Dhaka, Bangladesh, and the Mattlab Field Laboratory, which is located in the village area of Mattlab, Bangladesh. Our work had shown that *Vibrio cholerae* is associated with environmental zooplankton, namely, the copepod. The notion that the copepods are large and could be filtered out and therefore lead to reduced incidence of cholera was a result of my work on the vibrios and the relationships described by my students, notably, Dr. Anwar Huq, who did his thesis on *Vibrio cholerae* attachment to copepods. Anwar Huq is now an associate professor at the University of Maryland.

An important collaborator was Nell Roberts, an outstanding public health microbiologist at Lake Charles, Louisiana, working on public health problems. Nell, Professor Xu (a colleague from Qingdao, China), and I did the critical experiment showing the presence of *Vibrio cholerae* in water from which blue crabs had been harvested—the cause of an outbreak of cholera in Louisiana back in 1982. We were able to use fluorescent antibody to show the presence of the vibrio on copepods in the water.

From there, the idea of sari cloth came about in searching for a very inexpensive filter for use by village

380 **Chapter 10** ■ Molecular Regulation

Part 2 ■ Genes and Genomes **381**

Special Topic 10.2 **The Role of Quorum Sensing in Pathogenesis and in Interspecies Communications**

Pseudomonas aeruginosa is a human pathogen that commonly infects patients with cystic fibrosis, a genetic disease of the lung. The organism forms a biofilm over affected areas and interferes with lung function. Key to the destruction of host tissues by *P. aeruginosa* are virulence factors such as proteases and other degradative enzymes. But these proteins are not made until cell density is fairly high, a point where the organism might have a chance of overwhelming its host. The organism would not want to make the virulence proteins too early and alert the host to launch an immune response. The induction mechanism involves two interconnected quorum-sensing systems called Las and Rhl, both comprised of regulatory proteins homologous to LuxR and LuxI of *V. fischeri*. Many pathogens besides *Pseudomonas* appear to use chemical signaling to control virulence genes. Genomic analysis has revealed homologs of known quorum-sensing genes in *Salmonella*, *Escherichia*, *Vibrio cholerae*, the plant symbiote *Rhizobium*, and many other microbes.

Some microbial species not only chemically talk among themselves, but appear capable of communicating with other species. *V. harveyi*, for example, uses two different, but converging, quorum-sensing systems to coordinate control of its luciferase. Both sensing pathways are very different from the *V. fischeri* system. One utilizes an acyl homoserine lactone (AHL) as an autoinducer (AI-1) to communicate with other *V. harveyi* cells. The second system involves production of a different autoinducer (AI-2) that contains borate. Because many species appear to produce this second signal molecule, it is thought that mixed populations of microbes use it to "talk" to each other. In the case of *V. harveyi*, specific membrane sensor kinase proteins are used to sense each autoinducer (**Fig. 1**). At low cell densities (no autoinducer), both sensor kinases initiate phosphorylation cascades that converge on a shared response regulator, LuxO, to produce phosphorylated LuxO. Phosphorylated LuxO appears to activate a repressor of the *lux* genes. Thus, at low cell densities, the culture does not display bioluminescence. At high cell density, the autoinducers prevent signal transmission by inhibiting phosphorylation. The cell stops making repressor, which allows another protein, LuxR (*not* a homolog of the *V. fischeri* LuxR), to activate the *lux* operon. The "lights" are turned on. Bonnie Bassler (**Fig. 2**) and Pete Greenberg (**Fig. 3**) are two of the leading scientists whose studies revealed the complex elegance of quorum sensing in *Vibrio* and *Pseudomonas* species. Other organisms, such as *Salmonella*, have been shown to activate the AI-2 pathway of *V. harveyi*, dramatically supporting the concept of cross-species communication.

A recent report by Ian Joint and his colleagues has shown that bacteria can even communicate across the prokaryotic-eukaryotic boundary. The green seaweed *Enteromorpha* (a eukaryote) produces motile zoospores that explore and attach to *Vibrio anguillarum* bacterial cells in biofilms (**Fig. 4**). They attach and remain there because the bacterial cells produce acetyl homoserine lactone molecules that the zoospores sense. Part of the evidence for this interkingdom communication involved showing that the zoospores would even attach to biofilms of *E. coli* carrying the *Vibrio* genes for the synthesis of acetyl homoserine lactone. The implications of possible interkingdom conversations are staggering. Do our normal flora "speak" to us? Do we "speak" back?

For further discussion of molecular communication between prokaryotes and eukaryotes, see Chapter 21.

Figure 1 **The two quorum-sensing systems of *V. harveyi*.** In the absence of autoinducers (AI-1 and AI-2), both sensor kinases trigger converging phosphorylation cascades that end with the phosphorylation of LuxO. Phosphorylated LuxO (LuxO-P) activates a repressor that inhibits expression of the luciferase genes. As autoinducer concentrations increase, they inhibit autophosphorylation of the sensor kinases and the phosphorylation cascade. As a result, repressor levels decrease, which allows the LuxR protein to activate the *lux* operon.

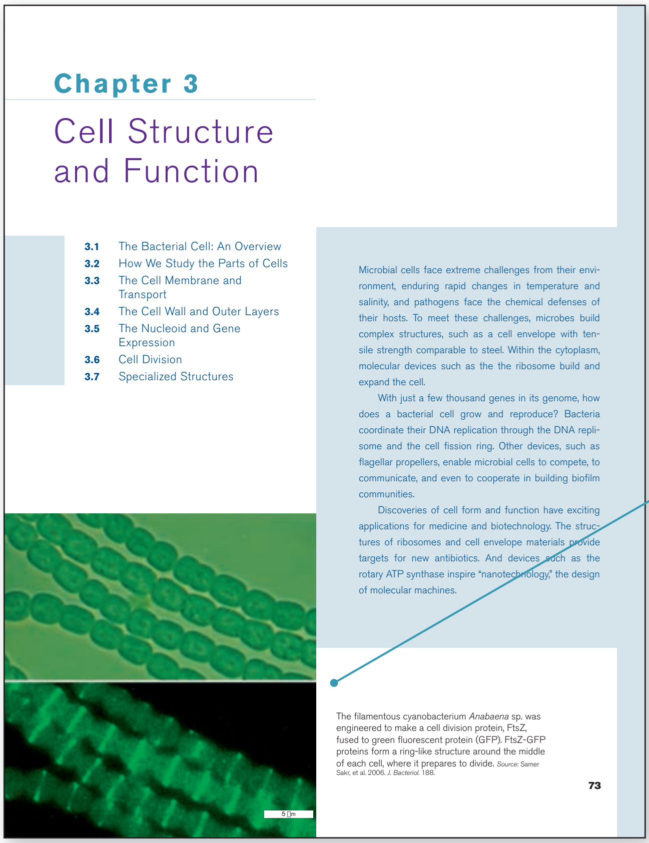
SPECIAL TOPICS

Optional "Special Topics" boxes show the process of science and give a human face to the research. Topics are as diverse as scientists discovering "quorum sensing" in pathogenesis (ST 10.2) and undergraduate researchers investigating mycorrhizae in wetland soil (ST 22.1). Whether historical in focus or providing more detail about cutting-edge science, "Special Topics" give students extra background and detail to help them appreciate the dynamic nature of microbiology.



Chapter 3

Cell Structure and Function

3.1 The Bacterial Cell: An Overview
3.2 How We Study the Parts of Cells
3.3 The Cell Membrane and Transport
3.4 The Cell Wall and Outer Layers
3.5 The Nucleoid and Gene Expression
3.6 Cell Division
3.7 Specialized Structures

Microbial cells face extreme challenges from their environment, enduring rapid changes in temperature and salinity, and pathogens face the chemical defenses of their hosts. To meet these challenges, microbes build complex structures, such as a cell envelope with tensile strength comparable to steel. Within the cytoplasm, molecular devices such as the the ribosome build and expand the cell.

With just a few thousand genes in its genome, how does a bacterial cell grow and reproduce? Bacteria coordinate their DNA replication through the DNA replisome and the cell fission ring. Other devices, such as flagellar propellers, enable microbial cells to compete, to communicate, and even to cooperate in building biofilm communities.

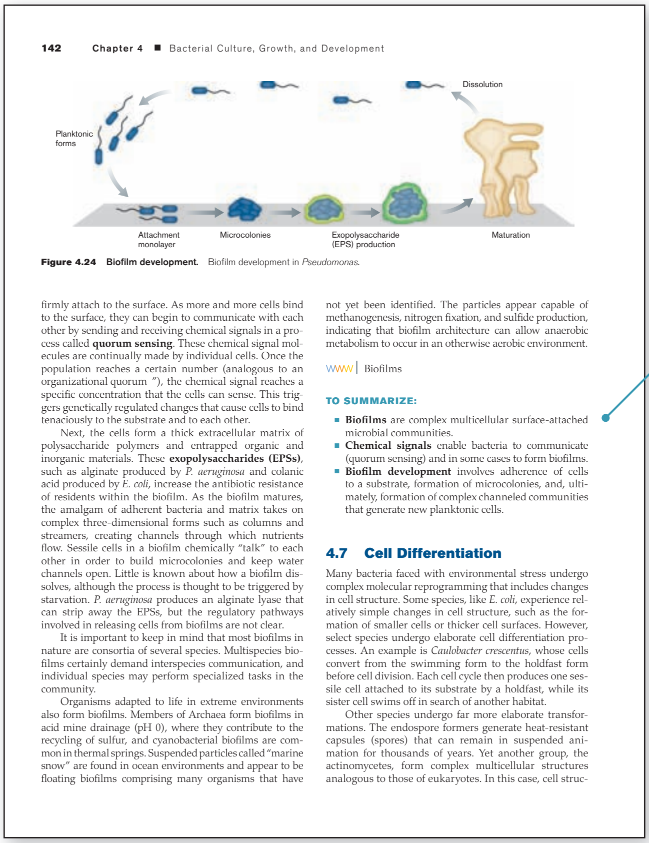
Discoveries of cell form and function have exciting applications for medicine and biotechnology. The structures of ribosomes and cell envelope materials provide targets for new antibiotics. And devices such as the rotary ATP synthase inspire "nanotechnology," the design of molecular machines.

The filamentous cyanobacterium *Anabaena* sp. was engineered to make a cell division protein, FtsZ, fused to green fluorescent protein (GFP). FtsZ-GFP proteins form a ring-like structure around the middle of each cell, where it prepares to divide. *Source*: Samer Sakr, et al. 2006. *J. Bacteriol.* 188.

73

CHAPTER OPENERS

The title page of each chapter presents an intriguing photo related to a recent research article or current application of the chapter topic. For example, Chapter 3 opens with a fluorescence micrograph of *Anabaena* in which the cell division protein FtsZ fused to "green fluorescent protein" (GFP) fluoresces around the division plane of each cell.



142 Chapter 4 ■ Bacterial Culture, Growth, and Development

Figure 4.24 **Biofilm development.** Biofilm development in *Pseudomonas.*

firmly attach to the surface. As more and more cells bind to the surface, they can begin to communicate with each other by sending and receiving chemical signals in a process called **quorum sensing**. These chemical signal molecules are continually made by individual cells. Once the population reaches a certain number (analogous to an organizational quorum ”), the chemical signal reaches a specific concentration that the cells can sense. This triggers genetically regulated changes that cause cells to bind tenaciously to the substrate and to each other.

Next, the cells form a thick extracellular matrix of polysaccharide polymers and entrapped organic and inorganic materials. These **exopolysaccharides (EPSs)**, such as alginate produced by *P. aeruginosa* and colanic acid produced by *E. coli*, increase the antibiotic resistance of residents within the biofilm. As the biofilm matures, the amalgam of adherent bacteria and matrix takes on complex three-dimensional forms such as columns and streamers, creating channels through which nutrients flow. Sessile cells in a biofilm chemically “talk” to each other in order to build microcolonies and keep water channels open. Little is known about how a biofilm dissolves, although the process is thought to be triggered by starvation. *P. aeruginosa* produces an alginate lyase that can strip away the EPSs, but the regulatory pathways involved in releasing cells from biofilms are not clear.

It is important to keep in mind that most biofilms in nature are consortia of several species. Multispecies biofilms certainly demand interspecies communication, and individual species may perform specialized tasks in the community.

Organisms adapted to life in extreme environments also form biofilms. Members of Archaea form biofilms in acid mine drainage (pH 0), where they contribute to the recycling of sulfur, and cyanobacterial biofilms are common in thermal springs. Suspended particles called “marine snow” are found in ocean environments and appear to be floating biofilms comprising many organisms that have not yet been identified. The particles appear capable of methanogenesis, nitrogen fixation, and sulfide production, indicating that biofilm architecture can allow anaerobic metabolism to occur in an otherwise aerobic environment.

WWW | Biofilms

TO SUMMARIZE:

- **Biofilms** are complex multicellular surface-attached microbial communities.
- **Chemical signals** enable bacteria to communicate (quorum sensing) and in some cases to form biofilms.
- **Biofilm development** involves adherence of cells to a substrate, formation of microcolonies, and, ultimately, formation of complex channeled communities that generate new planktonic cells.

4.7 Cell Differentiation

Many bacteria faced with environmental stress undergo complex molecular reprogramming that includes changes in cell structure. Some species, like *E. coli*, experience relatively simple changes in cell structure, such as the formation of smaller cells or thicker cell surfaces. However, select species undergo elaborate cell differentiation processes. An example is *Caulobacter crescentus*, whose cells convert from the swimming form to the holdfast form before cell division. Each cell cycle then produces one sessile cell attached to its substrate by a holdfast, while its sister cell swims off in search of another habitat.

Other species undergo far more elaborate transformations. The endospore formers generate heat-resistant capsules (spores) that can remain in suspended animation for thousands of years. Yet another group, the actinomycetes, form complex multicellular structures analogous to those of eukaryotes. In this case, cell struc-

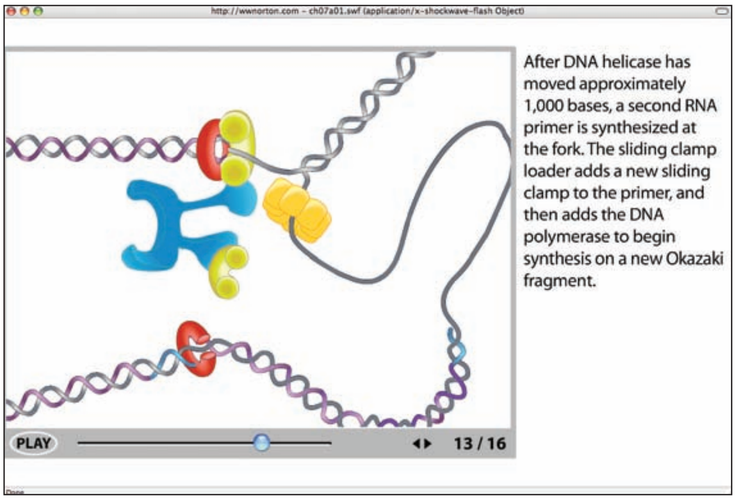
Student Resources

- **StudySpace.** wwnorton.com/studyspace This student website includes multiple-choice quizzes, process animations, vocabulary flashcards, indices of the Weblink reference sites from the text, and prominent links to *Microbial Biorealm*.
- **Process Animations.** Developed specifically for *Microbiology: An Evolving Science*, these animations bring key figures from the text to life, presenting key microbial processes in a dynamic format. The animations can be enlarged to full-screen view, and include VCR-like controls that make it easy to control the pace of animation.
- WWW | **Weblink Icons** throughout the text point students to the student website, which serves as a portal to websites where they can find more information on a host of topics. Each link was reviewed and approved by the authors to ensure that only high-interest, high-quality sites were selected.
- **Microbial Biorealm and Viral Biorealm.** A website maintained at Kenyon College provides information on several hundred genera of microbes and viruses, to which interested students have the opportunity to contribute. Pages are monitored and edited by microbiologists at Kenyon.
- **Ebook.** Same great book at half the price. *Microbiology: An Evolving Science* is also available as an ebook from norton**ebooks**.com. With a Norton ebook, students can electronically highlight text, use sticky notes, and work with fully zoomable images from the book.



http://wwnorton.com – ch07a01.swf (application/x-shockwave-flash Object)

After DNA helicase has moved approximately 1,000 bases, a second RNA primer is synthesized at the fork. The sliding clamp loader adds a new sliding clamp to the primer, and then adds the DNA polymerase to begin synthesis on a new Okazaki fragment.

Instructor Resources

- **Norton Media Library Instructor's CD-ROM:**
  - **Drawn Art and Photographs.** Digital files of all drawn art and most photographs are available to adopters of the text.
  - **Process Animations.** Developed specifically for *Microbiology: An Evolving Science*, these animations bring key figures from the text to life, presenting key microbial processes in a dynamic format. The animations can be enlarged to full-screen view and include VCR-like controls that make it easy for instructors to control the pace of animation during lecture.
  - **Editable PowerPoint Lectures** for each chapter.
- **Norton Resource Library Instructor's Website.** wwnorton.com/instructors Maintained as a service to our adopters, this password-protected instructor website offers book-specific materials for use in class or within WebCT, Blackboard, or course websites. The resources available online are the same as those offered on the Norton Media Library CD-ROM.
- **Instructor's Manual.** The manual includes chapter overviews, answers to end-of-chapter questions, and a test bank of 2,000 questions. Authored by Kathleen Campbell at Emory University.
- **Electronic Test Bank.** The Test Bank includes 2,000 questions in *ExamView Assessment Suite* format.
- **Blackboard Learning System Coursepacks.** These coursepacks include classroom-ready content.
- **Transparencies.** A subset of the figures in the text are available as color acetates.

Acknowledgments

We are very grateful for the help of many people in developing and completing the book. Our first editor at Norton, John Byram, helped us define the aims and scope of the project. Vanessa Drake-Johnson helped us shape the text, supported us in developing a strong art program, and conceived the title. Mike Wright spared no effort to bring the project to completion and to the attention of our colleagues. Our developmental editors, Philippa Solomon and Carol Pritchard-Martinez, contributed greatly to the clarity of presentation. Philippa's strength in chemistry was invaluable in improving our presentation of metabolism. Trish Marx and the photo researchers did a heroic job of tracking down all kinds of images from sources all over the world. Our colleague Kathy Gillen provided exceptional expertise on review topics for the appendices and wrote outstanding review questions for the student website. April Lange's coordination of electronic media development has resulted in a superb suite of resources for students and instructors alike. We thank Kathleen Campbell for authoring an instructor's manual that demonstrates a clear understanding of our goals for the book, and Lisa Rand for editing it. Without Thom Foley's incredible attention to detail, the innumerable moving parts of this book would never have become a finished book. Marian Johnson, Norton's managing editor in the college department, helped coordinate the complex process involved in shaping the manuscript over the years. Chris Granville ably and calmly managed the transformation of manuscript to finished product in record time. Matthew Freeman coordinated the transfer of many drafts among many people. Steve Dunn and Betsy Twitchell have been effective advocates for the book in the marketplace. Finally, we thank Roby Harrington, Drake McFeely, and Julia Reidhead for their support of this book over its many years of development.

For the quality of our illustrations we thank the many artists at Precision Graphics, who developed attractive and accurate representations and showed immense patience in getting the details right. We especially thank Kirsten Dennison for project management; Karen Hawk for the layout of every page in the book; Kim Brucker and Becky Oles for developing the art style and leading the art team; and Simon Shak for his rendering of the molecular models based on PDB files, including some near-impossible structures that we requested.

We thank the numerous colleagues over the years who encouraged us in our project, especially the many attendees at the Microbial Stress Gordon Conferences. We greatly appreciate the insightful reviews and discussions of the manuscript provided by our colleagues, and the many researchers who contributed their micrographs and personal photos. We especially thank the American Society for Microbiology journals for providing many valuable resources. Reviewers Bob Bender, Bob Kadner, and Caroline Harwood offered particularly insightful comments on the metabolism and genetics sections, and James Brown offered invaluable assistance in improving the coverage of microbial evolution. Peter Rich was especially thoughtful in providing materials from the archive of Peter Mitchell. We also thank the following reviewers:

Finally, we offer special thanks to our families for their support. Joan's husband Michael Barich offered unfailing support, and her son Daniel Barich contributed photo research, as well as filling the indispensable role of technical director for the *Microbial Biorealm* website. John's wife Zarrintaj ("Zari") Aliabadi contributed to the text development, especially the sections on medical microbiology and public health.

To the Reader: Thanks!

We greatly appreciate your selection of this book as your introduction to the science of microbiology. This is a first edition, and as such can certainly benefit from the input of readers. We welcome your comments, especially if you find text or figures that are in error or unclear. Feel free to contact us at the addresses listed below.

About the **Authors**

JOAN L. SLONCZEWSKI received her B.A. from Bryn Mawr College and her Ph.D. in Molecular Biophysics and Biochemistry from Yale University, where she studied bacterial motility with Robert M. Macnab. After postdoctoral work at the University of Pennsylvania, she has since taught undergraduate microbiology in the Department of Biology at Kenyon College, where she earned a Silver Medal in the National Professor of the Year program of the Council for the Advancement and Support of Education. She has published numerous research articles with undergraduate coauthors on bacterial pH regulation, and has published five science fiction novels including *A Door into Ocean*, which earned the John W. Campbell Memorial Award. She serves as At-large Member representing Divisions on the Council Policy Committee of the American Society for Microbiology, and is a member of the Editorial Board of the journal *Applied and Environmental Microbiology.*

JOHN W. FOSTER received his B.S. from the Philadelphia College of Pharmacy and Science (now the University of the Sciences in Philadelphia), and his Ph.D. from Hahnemann University (now Drexel University School of Medicine), also in Philadelphia, where he worked with Albert G. Moat. After postdoctoral work at Georgetown University, he joined the Marshall University School of Medicine in West Virginia; he is currently teaching in the Department of Microbiology and Immunology at the University of South Alabama College of Medicine in Mobile, Alabama. Dr. Foster has coauthored three editions of the textbook *Microbial Physiology* and has published over 100 journal articles describing the physiology and genetics of microbial stress responses. He has served as Chair of the Microbial Physiology and Metabolism division of the American Society for Microbiology and is a member of the editorial advisory board of the journal *Molecular Microbiology.*

Microbiology

An Evolving Science

Part 1

The Microbial Cell

AN INTERVIEW WITH

RITA COLWELL: THE GLOBAL IMPACT OF MICROBIOLOGY

Rita Colwell is Distinguished Professor at the University of Maryland and Johns Hopkins University and served as director of the USA National Science Foundation from 1998 to 2004. Colwell's decades of research on *Vibrio cholerae*, the causative agent of cholera, have revealed its natural ecology, its genome sequence, and ways to control it. Colwell originated the concept of viable but nonculturable microorganisms, microbial cells that metabolize but cannot be cultured in the laboratory. She is now chairman of the board of Canon US Life Sciences, Inc., and she represents the American Society for Microbiology at the United Nations Educational, Scientific and Cultural Organization (UNESCO).

Courtesy of Rita Colwell

Rita Colwell, former director of the National Science Foundation.

Why did you decide to make a career in microbiology?

I was first inspired by the report of my college roommate at Purdue University about a wonderful bacteriology professor, Dr. Dorothy Powelson, probably one of only two women at Purdue who were full professors at the time. I enrolled in Powelson's course and was truly inspired by this remarkable woman who was so interested in microbiology and made it fascinating for her students.

How did you choose to study *Vibrio cholerae*? What makes this organism interesting?

I chose to study *Vibrio cholerae* as a result of my having become an "expert" on vibrios through my graduate dissertation on marine microorganisms. Vibrios were the most readily culturable of the marine bacteria and were therefore considered the most dominant. Of course, new information indicates that although vibrios are the dominant bacteria in many estuarine areas, there are other organisms that are very difficult to culture that are important as well.

When I took my first faculty position at Georgetown University, a friend of mine at NIH, Dr. John Feeley, suggested that I study *Vibrio cholerae*. What makes *V. cholerae* interesting is that it is a human pathogen of extremely great importance, yet resides naturally in estuaries and coastal areas of the world.

What is it like to study this organism?

Vibrio cholerae is naturally occurring (in the environment outside humans) and therefore can never be eradicated; it carries out important functions in the environment, and significant among these is its ability to digest chitin, the structural component of shellfish and many zooplankton. It is at once a "recycling agent" and a public health threat in the form of the massive epidemics of cholera that it causes.

You led an international collaboration in Bangladesh training women to avoid cholera by filtering water through sari cloth. How did the sari cloth filtration project come about?

It came about through collaboration with the International Centre for Diarrhoeal Diseases, Bangladesh, located in Dhaka, Bangladesh, and the Mattlab Field Laboratory, which is located in the village area of Mattlab, Bangladesh. Our work had shown that *Vibrio cholerae* is associated with environmental zooplankton, namely, the copepod. The notion that the copepods are large and could be filtered out and therefore lead to reduced incidence of cholera was a result of my work on the vibrios and the relationships described by my students, notably, Dr. Anwar Huq, who did his thesis on *Vibrio cholerae* attachment to copepods. Anwar Huq is now an associate professor at the University of Maryland.

An important collaborator was Nell Roberts, an outstanding public health microbiologist at Lake Charles, Louisiana, working on public health problems. Nell, Professor Xu (a colleague from Qingdao, China), and I did the critical experiment showing the presence of *Vibrio cholerae* in water from which blue crabs had been harvested—the cause of an outbreak of cholera in Louisiana back in 1982. We were able to use fluorescent antibody to show the presence of the vibrio on copepods in the water.

From there, the idea of sari cloth came about in searching for a very inexpensive filter for use by village

Vibrio cholerae **bacteria (left) colonize copepods such as this one (right).**

women in Bangladesh. We were able to show that folded sari cloth yielded a 20-micrometer (μm) mesh net. Because plankton are 200 μm or more in size, we could filter them out. The hypothesis that I came up with was that by removing the copepods and associated particulates, we could reduce cholera, which proved to be the case.

What are "viable but nonculturable" organisms?

Viable but nonculturable is a state into which gram-negative microorganisms transform under adverse conditions in the environment. In this state, the bacteria are unable to be cultured, even though they remain viable and potentially pathogenic. Hence, they pose a public health risk, since routine tests done in a bacteriology laboratory would be negative for their presence.

Courtesy of Rita Colwell

A Bangladeshi woman filters water through sari cloth. Colwell's graduate student Anwar Huq compares the filtered and unfiltered water.

What are the challenges of marine microbiology today? How does marine microbiology impact human health?

The challenges of marine microbiology today are to understand and catalog the extraordinary diversity of marine microorganisms. The world's oceans function in large part as a result of the activities of marine organisms. Marine microbiology impacts human health because of the many pathogens naturally occurring in the environment. But more than that, marine microorganisms may well be the cycling agent that keeps the blue planet inhabitable for humans. Marine microorganisms actively cycle carbon, nitrogen, phosphorus, and other elements in our oceans and even play a role in the weather by producing dimethyl sulfoxide (DMSO), which is involved in cloud formation and moisture condensation.

Why did you move to the National Science Foundation? What difference did you make as a microbiologist heading NSF?

I was asked by the president of the United States to serve as director of the National Science Foundation (NSF). It is a position appointed by the president and confirmed by the U.S. Senate. As a microbiologist, I was able to bring a molecular understanding of biology to the NSF, while as an interdisciplinary researcher, I was attuned to the needs of all aspects of science, from astronomy to physics. In the biological sciences, my major impact was in launching the Biocomplexity Initiative, which has been enormously productive and continues to yield new information on biological systems, including those of microbiology.

What do you think are the most exciting areas for students entering microbiology today?

Microbial diversity and microbial population studies are two emerging areas of huge interest that will lead to a better understanding of microbial evolution and development.

What advice do you have for today's students?

Develop an expertise as an undergraduate in some area of science, whether it be biology, chemistry, mathematics, physics, or some other area of science or engineering, and be creative and curious about other disciplines. The world of the future will be interdisciplinary and multidisciplinary.

How does your family relate to your work?

I have been happily married ever since I graduated from college! We have two daughters. One is a medical doctor (pediatrician). She recently was named an outstanding physician scholar and voted the best physician in her fellowship class by her colleagues. She also worked in Africa on delivery of health care to women in Tanzania for her PhD. We are equally proud of our other daughter, who earned a PhD in evolutionary biology and now works for the U.S. Geological Survey, cataloging rare plants in Yosemite National Park and Forest.

Chapter 1

Microbial Life: Origin and Discovery

1.1 From Germ to Genome: What Is a Microbe?
1.2 Microbes Shape Human History
1.3 Medical Microbiology
1.4 Microbial Ecology
1.5 The Microbial Family Tree
1.6 Cell Biology and the DNA Revolution

Life on Earth began early in our planet's history with microscopic organisms, or microbes. Microbial life has since shaped our atmosphere, our geology, and the energy cycles of all ecosystems. A human body contains ten times as many microbes as it does human cells, including numerous tiny bacteria on the skin and in the digestive tract. Throughout history, humans have had a hidden partnership with microbes ranging from food production and preservation to mining for precious minerals.

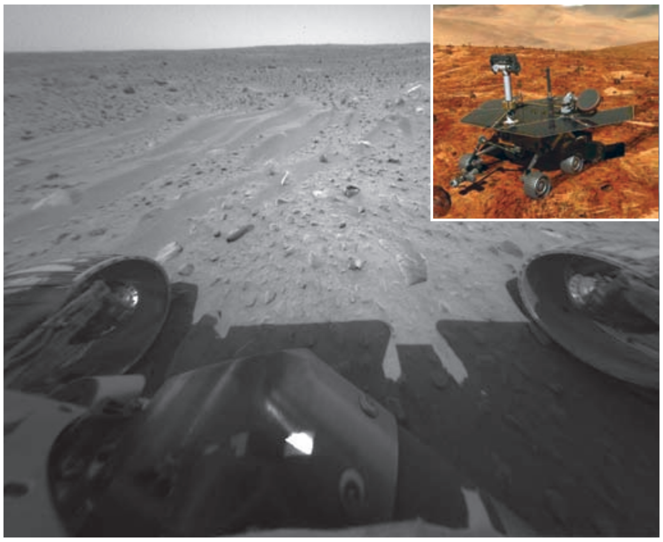
Yet throughout most of our history, humans were unaware that microbes even existed. To study these unseen organisms required a microscope, first developed in the 1600s. In the nineteenth century—the "golden age" of microbiology—microscopes revealed the tiny organisms at work in our bodies and in our ecosystems. The twentieth century saw the rise of microbes as the engines of biotechnology. Microbial discoveries led to recombinant DNA and revealed the secrets of the first sequenced genomes.

Lactobacillus salivarius bacteria grow normally in human skin, where they produce bacteriocins, compounds that protect us from disease-causing bacteria. Their multi-part genome was sequenced by Marcus Claesson and colleagues. (Claesson, et al. 2006. *Proceedings of the National Academy of Sciences* 103:6718.) Scanning electron micrograph is from Sinead Leahy and D. John, Trinity College, Dublin. Cell length, 1–2 μm.

In 2004, the two Mars Exploration Rovers, *Spirit* and *Opportunity*, landed on the planet Mars (**Fig. 1.1**). The rovers carried scientific instruments to test Martian rocks, to identify minerals and to assess the size and shape of sedimentary particles. The identity of the minerals, as well as their particle structure, could yield clues as to whether the Martian surface had ever been shaped by liquid water. Evidence for water would support the possible existence of living microbes.

Why do we care whether microbes exist on Mars? The discovery of life beyond Earth would fundamentally change how we see our place in the universe. The observation of Martian life could yield clues as to the origin of our own biosphere and expand our knowledge of the capabilities of living cells on our own planet. As of this writing, the existence of microbial life on Mars remains unknown, but here on Earth, many terrestrial microbes remain as mysterious as Mars. Barely 0.1% of the microbes in our biosphere can be cultured in the laboratory; even the digestive tract of a newborn infant contains species of bacteria unknown to science. Our "exploration rovers" for microbiology include, for example, new tools of microscopy and the sequencing of microbial DNA.

On Earth, the microscope reveals microbes throughout our biosphere, from the superheated black smoker vents at the ocean floor to the subzero ice fields of Antarctica. Bacteria such as *Escherichia coli* live in our intestinal tract, while algae and cyanobacteria turn ponds green (**Fig. 1.2**). Protists are the predators of the microscopic world. And viruses such as papillomavirus cause disease, as do many bacteria and protists.



NASA

Figure 1.1 Is there microbial life on Mars? On February 9, 2004, the Mars Exploration Rover *Spirit* (inset) photographed this windswept surface of the planet Mars. Rock samples were tested for distinctive minerals that are formed by the action of water. The presence of liquid water today would increase the chance that microbial life exists on Mars.

Yet before microscopes were developed in the seventeenth century, we humans were unaware of the unseen living organisms that surround us, that float in the air we breathe and the water we drink, and that inhabit our own bodies. Microbes generate the very air we breathe, including nitrogen gas and much of the oxygen and carbon dioxide. They fix nitrogen into forms used by plants, and they make essential vitamins, such as vitamin B_{12}. Microbes are the primary producers of major food webs, particularly in the oceans; when we eat fish, we indirectly consume tons of algae at the base of the food chain. At the same time, virulent pathogens take our lives. Despite all the advances of modern medicine and public health, microbial disease remains the number one cause of human mortality.

In the twentieth century, the science of microbiology exploded with discoveries, creating entire new fields such as genetic engineering. The promise—and pitfalls—were dramatized by Michael Crichton's best-selling science fiction novel and film, *The Andromeda Strain* (1969; filmed in 1971). In *The Andromeda Strain*, scientists at a top-secret laboratory race to identify a deadly pathogen from outer space—or perhaps from a biowarfare lab (**Fig. 1.3A**). The film prophetically depicts the computerization of medical research, as well as the emergence of pathogens, such as the human immunodeficiency virus (HIV), that can yet defeat the efforts of advanced science.

Today, we discover surprising new kinds of microbes deep underground and in places previously thought uninhabitable, such as the hot springs of Yellowstone National Park (**Fig. 1.3B**). These microbes shape our biosphere and provide new tools that impact human society. For example, the use of heat-resistant bacterial DNA polymerase (a DNA-replicating enzyme) in a technique called the polymerase chain reaction (PCR) allows us to detect minute amounts of DNA in traces of blood or fossil bone. Microbial technologies led us from the discovery of the double helix to the sequence of the human genome, the total genetic information that defines our species.

In this chapter, we introduce the concept of a microbe and the question of how microbial life originated. We then survey the history of human discovery of the role microbes play in disease and in our ecosystems. Finally, we address the exciting century of molecular microbiology, in which microbial genetics and genomics have transformed the face of modern biology and medicine.

1.1 From Germ to Genome: What Is a Microbe?

From early childhood, we hear that we are surrounded by microscopic organisms, or "germs," that we cannot see. What are microbes? Our modern concept of a

Figure 1.3 Microbial discovery: science fiction and science fact. **A.** In *The Andromeda Strain*, medical scientists try to feed a baby who was infected by a deadly pathogen from outer space. While the details of the pathogen are imaginary, the film's approach to identifying the mystery organism captures the spirit of actual investigations of emerging diseases. **B.** Yellowstone National Park hot springs are surrounded by mats of colorful microbes that grow above 80°C in waters containing sulfuric acid. Bacteria discovered at Yellowstone produce enzymes used in polymerase chain reaction (PCR), a technique of DNA amplification.

microbe has deepened through two major research tools: advanced microscopy and the sequencing of genomic DNA. Modern microscopy is covered in Chapter 2, and microbial genetics and genomics are presented in Chapters 6–12.

A Microbe Is a Microscopic Organism

A **microbe** is commonly defined as a living organism that requires a microscope to be seen. Microbial cells range in size from millimeters (mm) down to 0.2 micrometers (μm), and viruses may be tenfold smaller (**Table 1.1**). Some microbes consist of a single cell, the smallest unit of life, a membrane-enclosed compartment of water solution containing molecules that carry out metabolism. Each microbe contains in its genome the capacity to reproduce its own kind.

Our simple definition of a microbe, however, leaves us with contradictions.

- **Super-size microbial cells.** Most single-celled organisms require a microscope to render them visible and thus fit the definition of "microbe." Nevertheless, some species of protists and algae, and even some bacterial cells are large enough to see with the naked eye (**Fig. 1.4**). The marine sulfur bacterium *Thiomargarita namibiensis*, called the sulfur pearl of Namibia, grows as large as the head of a fruit fly. Even more surprising, a single-celled plant, the "killer algae" *Caulerpa taxifolia*, spreads through the coastal waters of California. The single cell covers many acres with its leaf-like cell parts.
- **Microbial communities.** Many microbes form complex multicellular assemblages, such as mushrooms, kelps, and biofilms. In these structures, cells are differentiated into distinct types that complement each other's function, as in multicellular organisms. And yet, some multicellular worms and arthropods require a microscope to see but are *not* considered microbes.
- **Viruses.** A **virus** consists of a noncellular particle containing genetic material that takes over the metabolism of a cell to generate more virus particles. Although viruses are considered microbes, they are not fully functional cells. Some viruses consist of only a few molecular parts, whereas others, such as the Mimivirus infecting amebas (also spelled amoebae) show the size and complexity of a cell.

NOTE: Each section contains questions to think about. These thought questions may have various answers. Possible responses are posted at the back of the book.

THOUGHT QUESTION 1.1 The minimum size of known microbial cells is about 0.2 μm. Could even smaller cells be discovered? What factors may determine the minimum size of a cell?

THOUGHT QUESTION 1.2 If viruses are not functional cells, are they truly "alive"?

In practice, our definition of a microbe derives from tradition as well as genetic considerations. In this book, we consider microbes to include **prokaryotes** (cells lacking a nucleus, including bacteria and archaea) as well as certain classes of **eukaryotes** (cells with a nucleus) that

Table 1.1 Sizes of some microbes.

Microbe	Description	Approximate size
Varicella-zoster virus 1	Virus that causes chicken pox and shingles	100 nanometers (nm) = 10^{-7} meter (m)
Prochlorococcus	Photosynthetic marine bacteria	500 nm = 5×10^{-7} m
Rhizobium	Bacteria that fix N_2 in symbiosis with leguminous plants	1 micrometer (μm) = 10^{-6} m
Spirogyra	Filamentous algae found in aquatic habitat	40 μm = 4×10^{-5} m (cell width)
Pelomyxa (an ameba)	Protists found in solid or aquatic habitat	5 millimeters (mm)

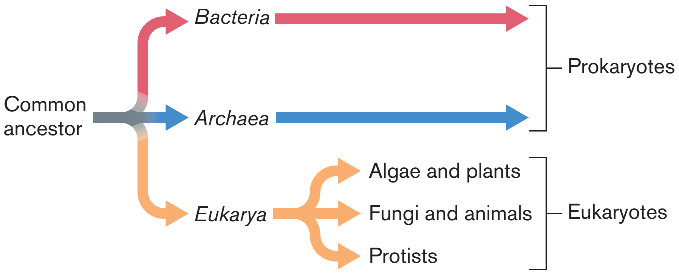

Figure 1.5 Three domains of life. Analysis of DNA sequence reveals the ancient divergence of three domains of living organisms: *Bacteria* and *Archaea* (both prokaryotes) and *Eukarya* (eukaryotes). The color code shown here is used throughout this book to indicate the three domains.

include simple multicellular forms: algae, fungi, and protists (**Fig. 1.5**). The bacteria, archaea, and eukaryotes—known as the three domains—diverged from a common ancestral cell. We also discuss viruses and related infectious particles (Chapters 6 and 11).

NOTE: The formal names of the three domains are ***Bacteria***, ***Archaea***, and ***Eukarya***. Members of these domains are called **bacteria** (singular, **bacterium**), **archaea** (singular, **archaeon**), and **eukaryotes** (singular, **eukaryote**), respectively. The microbiology literature includes alternative spellings for some of these terms, such as "archaean" and "eucaryote."

Microbial Genomes Are Sequenced

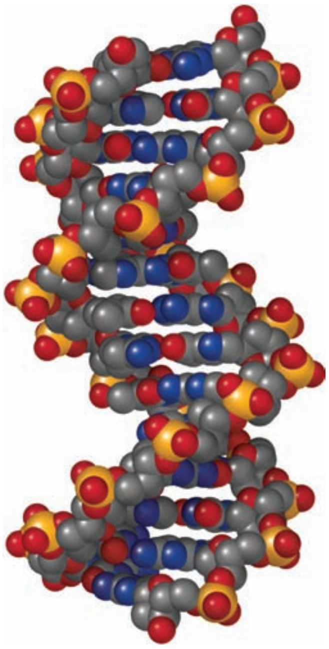

Figure 1.6 DNA. The sequence of base pairs in DNA encodes all the genetic information of an organism.

Our understanding of microbes has grown tremendously through the study of their genomes. A **genome** is the total genetic information contained in an organism's chromosomal DNA (**Fig. 1.6**). By determining the sequence of genes in a microbe's genome, we learn a lot about how that microbe grows and associates with other species. For example, if a microbe's genome includes genes for nitrogenase, a nitrogen-fixing enzyme, that microbe probably can fix nitrogen from the atmosphere into compounds that plants can assimilate into protein. And by comparing DNA sequences, we can measure the degree of relatedness between different species based on the time since they diverged from a common ancestor.

Historically, the first genomes to be sequenced were those of viruses. The first genome whose complete DNA sequence was determined was that of a bacteriophage (a virus that infects bacteria), bacteriophage φX174. The DNA sequence of φX174 was determined in 1977 by Fred Sanger (**Fig. 1.7A**), who shared the 1980 Nobel Prize in Chemistry with Walter Gilbert and Paul Berg for developing the method of DNA sequence analysis. The

Figure 1.8 The first sequenced genomes. A. The first organism whose genome sequence was determined was bacteriophage φX174, a virus that grows in *Escherichia coli* (virus diameter, 27 nm). The entire DNA sequence of φX174 contains 5,386 base pairs specifying only ten genes (here labeled A–H and J–K), nine of whose functions have since been determined. Note the highly compact genome, with several overlapping genes. **B.** The genome of *Haemophilus influenzae* Rd, a bacterium that causes ear infections and meningitis, was the first DNA sequence completed for a cellular organism (inset, colorized electron micrograph). The genome of *H. influenzae* contains nearly 2 million base pairs specifying approximately 1,743 genes, which are expressed to make protein and RNA products. The annotated sequence of the genome appears on the website of the National Center for Biotechnology Information. Colored bars indicate gene sequences throughout.

Nearly two decades passed before scientists completed the first genome sequence of a cellular microbe, *Haemophilus influenzae*, a bacterium that causes ear infections and meningitis in children (**Fig. 1.8B**). The strain of *H. influenzae* sequenced has nearly 2 million base pairs, which specify about 1,700 genes. The sequence of *H. influenzae* was determined by a large team of scientists at The Institute for Genomic Research (TIGR) led by Hamilton Smith and Craig Venter, who devised a special computational strategy for assembling large amounts of sequence data. This strategy was later applied to sequencing the human genome. Led by president Claire Fraser-Liggett, (**Fig. 1.7B**), TIGR sequenced the genomes of numerous microbes, such as *Bacillus anthracis*, the bacterium that causes anthrax, and *Colwellia psychrerythraea*, a cold-loving bacterium growing in Antarctic sea ice.

WWW The National Center for Biotechnology Information (NCBI) provides free access to all published genome sequences.

The growing availability of sequenced genomes at universities and in industry has generated the new field of comparative genomics, which involves the systematic comparison of all genomic sequences of living species, ranging from microbes to *Homo sapiens*. Comparative genomics reveals a set of core genes shared by all organisms, further evidence that all life on Earth shares a common ancestry.

1.2 Microbes Shape Human History

Throughout most of human history, we were unaware of the microbial world. Microorganisms have shaped human culture since our earliest civilizations. Yeasts and bacteria have made foods such as bread and cheese, as well as alcoholic beverages (**Fig. 1.9A**; also discussed in Chapter 16). "Rock-eating" bacteria known as lithotrophs leached copper and other metals from ores exposed by mining, enabling ancient human miners to obtain these metals. The lithotrophic oxidation of minerals for energy generates strong acid, which accelerates breakdown of the ore. Today, about 20% of the world's copper, as well as some uranium and zinc, are produced by bacterial leaching. Unfortunately, microbial acidification also consumes the stone of ancient monuments (**Fig. 1.9B**), a process intensified by airborne acidic pollution. Management of microbial corrosion is an important field of applied microbiology.

As humans became aware of microbes, our relationship with the microbial world changed in important ways (**Table 1.2**, pages 14–15). Early microscopists in the seventeenth and eighteenth centuries formulated key concepts of microbial existence, including their means of reproduction and death. In the nineteenth century, the "golden age" of microbiology, key principles of disease pathology and microbial ecology were established that scientists still use today. This period laid the foundation for modern science, in which genetics and molecular biology provide powerful tools for scientists to manipulate microorganisms for medicine and industry.

Microbial Disease Devastates Human Populations

Throughout history, microbial diseases such as tuberculosis and leprosy have profoundly affected human demographics and cultural practices (**Fig. 1.10**). The bubonic plague, which wiped out a third of Europe's population in the fourteenth century, was caused by *Yersinia pestis*, a bacterium spread by rat fleas. Ironically, the plague-induced population decline enabled the social

transformation that led to the Renaissance, a period of unprecedented cultural advancement. In the nineteenth century, the bacterium *Mycobacterium tuberculosis* stalked overcrowded cities, and tuberculosis became so common that the pallid appearance of tubercular patients became a symbol of tragic youth in European literature. Today, societies throughout the world have been profoundly shaped by the epidemic of acquired immunodeficiency syndrome (AIDS), caused by the human immunodeficiency virus (HIV).

Historians traditionally emphasize the role of warfare in shaping human destiny, the brilliance of leaders or the advantage of new technology in determining which civilizations rise or fall. Yet the fate of human societies has often been determined by microbes. For example, much of the native population of North America was exterminated by smallpox unwittingly introduced by European invaders. Throughout history, more soldiers have died of microbial infections than of wounds in battle. The significance of disease in warfare was first recognized by the British nurse and statistician Florence Nightingale (1820–1910) (**Fig. 1.11**).

Better known as the founder of professional nursing, Nightingale also founded the science of medical statistics. She used methods invented by French statisticians to demonstrate the high mortality rate due to disease among British soldiers during the Crimean War. Nightingale's statistics convinced the British government to improve army living conditions and to upgrade the standards of army hospitals. In modern epidemiology, statistical analysis continues to serve as a crucial tool in determining the causes of disease.

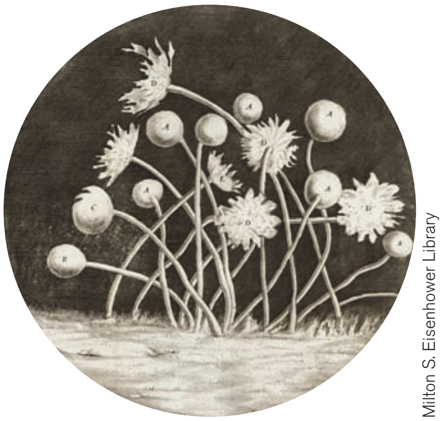
Microscopes Reveal the Microbial World

The seventeenth century was a time of growing inquiry and excitement about the "natural magic" of science and patterns of our world, such as the laws of gravitation and motion formulated by Isaac Newton (1642–1727). Robert Boyle (1627–1691) performed the first controlled experiments on the chemical conversion of matter. Physicians attempted new treatments for disease involving the application of "stone and minerals" (that is, the application of chemicals), what today we would call chemotherapy. Minds were open to at least consider the astounding possibility that our surroundings, indeed our very bodies, were inhabited by tiny living beings.

Robert Hooke observes the microscopic world. The first microscopist to publish a systematic study of the world as seen under a microscope was Robert Hooke (1635–1703). As Curator of Experiments to the Royal Society of London, Hooke built the first compound microscope—a magnifying instrument containing two or more lenses that multiply their magnification in series. With his microscope, Hooke observed biological materials such as nematode "vinegar eels," mites, and mold filaments, illustrations of which he published in *Micrographia* (1665), the first publication that illustrated objects observed under a microscope (**Fig. 1.12**).

Hooke was the first to observe distinct units of living material, which he called "cells." Hooke first named the units cells because the shape of hollow cell walls in a slice of cork reminded him of the shape of monks' cells in a monastery. But his crude lenses achieved at best 30-fold power (30×), so he never observed single-celled organisms.

Antoni van Leeuwenhoek observes bacteria with a single lens. Hooke's *Micrographia* inspired other microscopists, including Antoni van Leeuwenhoek (1632–1723), who became the first individual to observe single-celled microbes (**Fig. 1.13A**). As a young man, Leeuwenhoek lived in the Dutch city of Delft, where he worked as a cloth draper, a profession that introduced him to magnifying glasses. (The magnifying glasses were used to inspect the quality of the cloth, enabling the worker to count the number of threads.) Later in life, he took up the hobby of grinding ever stronger lenses to see into the world of the unseen.



Milton S. Eisenhower Library

Figure 1.12 Hooke's *Micrographia*. An illustration of mold sporangia, drawn by Hooke in 1665, from his observations of objects using a compound microscope.

Leeuwenhoek ground lenses stronger than Hooke's, which he used to build single-lens magnifiers, complete with sample holder and focus adjustment (**Fig. 1.13B**). First he observed insects, including lice and fleas, then the relatively large single cells of protists and algae, then ultimately bacteria. One day he applied his microscope to observe matter extracted from between his teeth. He wrote, "to my great surprise [I] perceived that the aforesaid matter contained very many small living Animals, which moved themselves very extravagantly."

Over the rest of his life, Leeuwenhoek recorded page after page on the movement of microbes, reporting their size and shape so accurately that in many cases we can determine the species he observed (**Fig. 1.13C**).

Table 1.2 **Microbes and human history.**

Date	Microbial discovery	Discoverer(s)
	Microbes impact human culture without detection	
10,000 BC	Food and drink are produced by microbial fermentation.	Egyptians, Chinese, and others
1,500 BC	Tuberculosis, polio, leprosy, and smallpox are evident in mummies and tomb art.	Egyptians
50 BC	Copper is recovered from mine water acidified by sulfur-oxidizing bacteria.	Roman metal workers under Julius Caesar
1546 AD	Syphilis and other diseases are observed to be contagious.	Girolamo Fracastoro (Padua)
	Early microscopy and the origin of microbes	
1676	Microbes are observed under a microscope.	Antoni van Leeuwenhoek (Netherlands)
1688	Spontaneous generation is disproved for maggots.	Francesco Redi (Italian)
1717	Smallpox is prevented by inoculation of pox material, a rudimentary form of immunization.	Turkish women taught Lady Montagu, who brought the practice to England
1765	Microbe growth in organic material is prevented by boiling in a sealed flask.	Lazzaro Spallanzani (Padua)
1798	Cowpox vaccination prevents smallpox.	Edward Jenner (England)
1835	Fungus causes disease in silkworms (first pathogen to be demonstrated in animals).	Agostino Bassi de Lodi (Italy)
1847	Chlorine as antiseptic wash for doctor's hands decreases pathogens.	Ignaz Semmelweis (Hungary)
1881	Bacterial spores survive boiling, but are killed by cyclic boiling and cooling.	John Tyndall (Ireland)
	"Golden age" of microbiology: principles and methods established	
1855	Statistical correlation is shown between sanitation and mortality (Crimean War).	Florence Nightingale (England)
1857	Microbial fermentation produces lactic acid or alcohol.	Louis Pasteur (France)
1864	Microbes fail to appear spontaneously, even in the presence of oxygen.	Louis Pasteur (France)
1866	Microbes are defined as a class distinct from animals and plants.	Ernst Haeckel (Germany)
1867	Antisepsis during surgery prevents patient death.	Robert Lister (England)
1877	Bacteria are a causative agent in developing anthrax.	Robert Koch (Germany)
1881	The first artificial vaccine is developed (against anthrax).	Louis Pasteur (France)
1882	First pure culture of colonies on solid medium, *Mycobacterium tuberculosis*.	Robert Koch (Germany)
1884	Koch's postulates are published, based on anthrax and tuberculosis.	Robert Koch (Germany)
1884	Gram stain devised to distinguish bacteria from human cells.	Hans Christian Gram (Netherlands)
1886	Intestinal bacteria include *Escherichia coli*, the future model organism.	Theodor Escherich (Austria)
1889	Bacteria oxidize iron and sulfur (lithotrophy).	Sergei Winogradsky (Russia)
1889	Bacteria isolated from root nodules are proposed to fix nitrogen.	Martinus Beijerinck (Netherlands)
1899	The concept of a virus is proposed to explain tobacco mosaic disease.	Martinus Beijerinck (Netherlands)
	Cell biology, biochemistry, and genetics	
1908	Antibiotic chemicals are synthesized and identified (chemotherapy).	Paul Ehrlich (USA)
1911	Cancer in chickens can be caused by a virus.	Peyton Rous (USA)
1917	Bacteriophages are recognized as viruses that infect bacteria.	Frederick Twort (England) and Felix D'Herelle (France)
1924	The ultracentrifuge is invented and used to measure the size of proteins.	Theodor Svedberg (Sweden)
1928	*Streptococcus pneumoniae* bacteria are transformed by a genetic material from dead cells.	Frederick Griffith (England)
1929	Penicillin, the first widely successful antibiotic, is made by a fungus. The molecule is isolated in 1941.	Alexander Fleming (Scotland), Howard Florey (Australia), and Ernst Chain (Germany)
1933–1945	The transmission electron microscope is invented and used to observe cells.	Ernst Ruska and Max Knoll, inventors (Germany); first cells observed by Albert Claude (Belgium), Christian de Duve (Belgium), and George Palade (USA)
1937	The tricarboxylic acid cycle is discovered.	Hans Krebs (England)
1938	The microbial "kingdom" is subdivided into eukaryotes and prokaryotes (Monera).	Herbert Copeland (USA)
1938	*Bacillus thuringiensis* spray is produced as the first bacterial insecticide.	Insecticide manufacturers (France)
1941	One gene encodes one enzyme in *Neurospora*.	George Beadle and Edward Tatum (USA)
1941	Poliovirus is grown in human tissue culture.	John Enders, Thomas Weller, and Frederick Robbins (USA)
1944	The genetic material responsible for transformation of *S. pneumoniae* is DNA.	Oswald Avery, Colin Macleod, and Maclyn McCarty (USA)
1945	Bacteriophage replication mechanism is elucidated.	Salvador Luria (Italy) and Max Delbrück (Germany), working in the USA
1946	Bacteria transfer DNA by conjugation.	Edward Tatum and Joshua Lederberg (USA)
1946–1956	X-ray diffraction crystal structures are obtained for the first complex biological molecules, penicillin and vitamin B_{12}.	Dorothy Hodgkin, J. D. Bernal, and coworkers (England)
1950	Anaerobic culture technique is devised to study anaerobes of the bovine rumen.	Robert Hungate (USA)
1950	Bacteria can carry latent bacteriophages (lysogeny).	André Lwoff (France)
1951	Transposable elements are discovered in maize and later shown in bacteria, where they play key roles in evolution.	Barbara McClintock (USA)
1952	DNA is injected into a cell by a bacteriophage.	Martha Chase and Alfred Hershey (USA)

Table 1.2 Microbes and human history (*continued*)

Date	Microbial discovery	Discoverer(s)
	Molecular biology and recombinant DNA	
1953	The overall structure of DNA is a double helix, based on X-ray diffraction analysis.	Rosalind Franklin and Maurice Wilkins (England)
1953	Double-helical DNA consists of antiparallel chains connected by the hydrogen bonding of AT and GC base pairs.	James Watson (USA) and Francis Crick (England)
1959	Expression of the messenger RNA for the *E. coli lac* operon is regulated by a repressor protein.	Arthur Pardee (England) and François Jacob and Jacques Monod (France)
1960	Radioimmunoassay for detection of biomolecules is developed.	Rosalyn Yalow and Solomon Bernson (USA)
1961	The chemiosmotic hypothesis, which states that biochemical energy is stored in a transmembrane proton gradient, is proposed and tested.	Peter Mitchell and Jennifer Moyle (England)
1966	The genetic code by which DNA information specifies protein sequence is deciphered.	Marshall Nirenberg, H. Gobind Khorana, and others (USA)
1967	Bacteria can grow at temperatures above 80° in hot springs at Yellowstone National Park.	Thomas Brock (USA)
1968	Serial endosymbiosis is proposed to explain the evolution of mitochondria and chloroplasts.	Lynn Margulis (USA)
1969	Retroviruses contain reverse transcriptase, which copies RNA to make DNA.	Howard Temin, David Baltimore, Renato Dulbecco (USA)
1972	Inner and outer membranes of gram-negative bacteria (*Salmonella*) are separated by ultracentrifugation.	Mary Osborn (USA)
1973	A recombinant DNA molecule is created in vitro (in a test tube).	Stanley Cohen, Annie Chang, Robert Helling, and Herbert Boyer (USA)
1974	The bacterial flagellum is driven by a rotary motor.	Howard Berg, Michael Silverman, and Melvin Simon (USA)
1975	mRNA-rRNA base pairing initiates protein synthesis.	Joan Steitz and Karen Jakes (USA) and Lynn Dalgarno and John Shine (Australia)
1975	The dangers of recombinant DNA are assessed at the Asilomar Conference.	Paul Berg, Maxine Singer, and colleagues (USA)
1975	Monoclonal antibodies are produced indefinitely in tissue culture by hybridomas, antibody-producing cells fused to cancer cells.	George Kohler and Cesar Milstein (USA)
1977	A DNA-sequencing method is invented and used to sequence the first genome of a virus.	Fred Sanger, Walter Gilbert, and Allan Maxam (USA)
1977	Archaea are a third domain of life, the others being eukaryotes and bacteria.	Carl Woese (USA)
1978	The first protein catalog is compiled for *E. coli* based on 2D gels.	Fred Neidhart, Peter O'Farrell, and colleagues (USA)
1978	Biofilms are a major form of existence of microbes.	William Costerton and others (Canada)
1979	Smallpox is declared eliminated, the culmination of worldwide efforts of immunology, molecular biology, and public health.	The World Health Organization
	Genomics, structural biology, and molecular ecology	
1981	Invention of the polymerase chain reaction (PCR) makes available large quantities of DNA.	Kary Mullis (USA)
1981–1986	Self-splicing RNA is discovered in the protist *Tetrahymena*, evidence that life could have originated as an "RNA world."	Thomas Cech and Sidney Altman (USA)
1982	Archaea are discovered with optimal growth above 100°C.	Karl Stetter (Germany)
1982	Viable but nonculturable bacteria contribute to ecology and pathology.	Rita Colwell, Norman Pace, and others (USA)
1982	Prions, infectious agents consisting solely of protein, are characterized.	Stanley Prusiner (USA)
1983	Human immunodeficiency virus (HIV) is implicated in the development of AIDS.	Luc Montagnier and colleagues (France)
1983	Genes are introduced into plants by using *Agrobacterium tumefaciens* plasmid vectors.	Eugene Nester, Mary-Dell Chilton, and colleagues at the Monsanto Company (USA)
1984	Acid-resistant *Helicobacter pylori* are discovered in the stomach, where they lead to gastritis.	Barry Marshall and Robin Warren (Australia)
1987–2004	*Geobacter* bacteria that can generate electricity are discovered, and their genomes are sequenced.	Derek Lovley and colleagues (USA)
1988	Earth's smallest and most abundant photosynthesizer is *Prochlorococcus*.	Sallie Chisholm and colleagues (USA)
1993	Giant bacterium (*Epulopiscium*) is identified, large enough to see.	Esther Angert and Norman Pace (USA)
1995	The first genome is sequenced for a cellular organism, *Haemophilus influenzae*.	Craig Venter, Hamilton Smith, Claire Fraser, and others (USA)
2001	The ribosome structure is obtained at near-atomic level by X-ray diffraction.	Marat Yusupov, Harry Noller, and colleagues (USA)
2008	Over 1,000 genome sequences of bacteria and archaea are publicly available.	National Center for Biotechnology Information (USA)

He performed experiments, comparing, for example, the appearance of "small animals" from his teeth before and after drinking hot coffee. The disappearance of microbes from his teeth after drinking a hot beverage suggested that heat killed microbes—a profoundly important principle for the study and control of microbes ever since.

Ironically, Leeuwenhoek is believed to have died of a disease contracted from sheep whose bacteria he observed. Historians have often wondered why it took so many centuries for Leeuwenhoek and his successors to determine the link between microbes and disease. Although observers such as Agostino Bassi de Lodi noted isolated cases of microbes associated with pathology (see Table 1.2), the very ubiquity of microbes—most of them actually harmless—may have obscured their more deadly roles. Also, it was hard to distinguish between microbes and the single-celled components of the human body, such as blood cells and sperm. It was not until the nineteenth century that human tissues could be distinguished from microbial cells by the application of differential chemical stains (discussed in Chapter 2).

THOUGHT QUESTION 1.3 Why do you think it took so long for humans to connect microbes with infectious disease?

Spontaneous Generation: Do Microbes Have Parents?

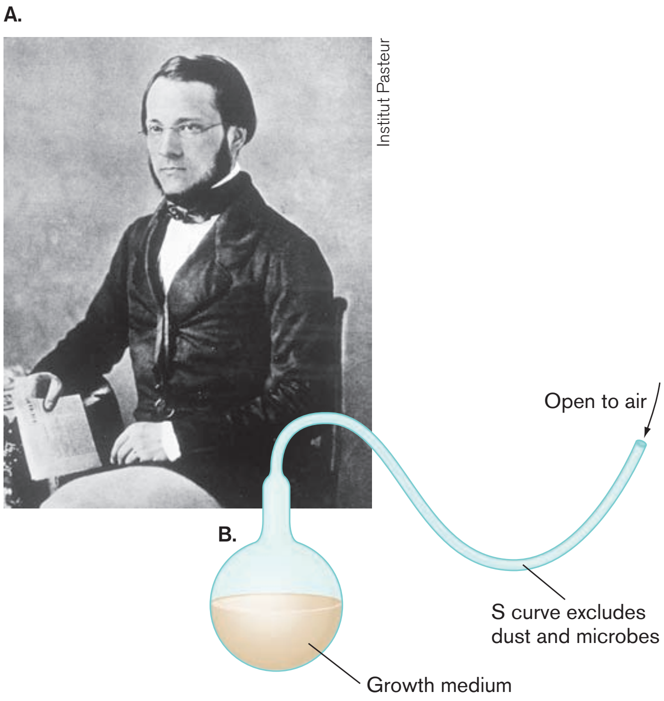
The observation of microscopic organisms led priests and philosophers to wonder where they came from. In the eighteenth century, scientists and church leaders intensely debated the question of **spontaneous generation**, the theory that living creatures such as maggots could arise spontaneously, without parental organisms. Chemists of the day tended to support spontaneous generation, as it appeared similar to the changes in matter that could occur upon mixture of chemicals. Christian church leaders, however, supported the biblical view that all organisms have "parents" going back to the first week of creation.

The Italian priest Francesco Redi (1626–1697) showed that maggots in decaying meat were the offspring of flies. Meat kept in a sealed container, excluding flies, did not produce maggots. Thus, Redi's experiment argued against spontaneous generation for macroscopic organisms. The meat still putrefied, however, producing microbes that seemed to arise "without parents."

To disprove spontaneous generation of microbes, another Italian priest, Lazzaro Spallanzani (1729–1799), showed that a sealed flask of meat broth sterilized by boiling failed to grow microbes. Spallanzani also noticed that microbes often appeared in pairs. Were these two parental microbes coupling to produce offspring, or did one microbe become two? By long and tenacious observation, Spallanzani watched a single microbe grow in size until it split in two. Thus, he demonstrated cell fission, the process by which cells arise by the splitting of preexisting cells.

Even Spallanzani's experiments, however, did not put the matter to rest. Proponents of spontaneous generation argued that the microbes in the priest's flask lacked access to oxygen and therefore could not grow. The pursuit of this question was left to future microbiologists, including the famous French microbiologist Louis Pasteur (1822–1895) (**Fig. 1.14A**). In addressing spontaneous generation and related questions, Pasteur and his contemporaries laid the foundations for modern microbiology.

Louis Pasteur reveals the biochemical basis of microbial growth. Pasteur began his scientific career as a chemist and wrote his doctoral thesis on the struc-



Institut Pasteur

Figure 1.14 Louis Pasteur, founder of medical microbiology and immunology. **A.** Pasteur's contributions to the science of microbiology and immunology earned him lasting fame. **B.** Swan-necked flask. Pasteur showed that in such a flask, after boiling, the contents remain free of microbial growth, despite access to air.

ture of organic crystals. He discovered the fundamental chemical property of chirality, the fact that some organic molecules exist in two forms that differ only by mirror symmetry. In other words, the two structures are mirror images of one another, like the right and left hands. Pasteur found that when microbes were cultured on a nutrient substance containing both mirror forms, only one mirror form was consumed. He concluded that the metabolic preference for one mirror form was a fundamental property of life. Subsequent research has confirmed that most biological molecules, such as DNA and proteins, occur in only one of their mirror forms.

As a chemist, Pasteur was asked to help with a widespread problem encountered by French manufacturers of wine and beer. The production of alcoholic beverages is now known to occur by **fermentation**, a process by which microbes gain energy by converting sugars into alcohol. In the time of Pasteur, however, the conversion of grapes or grain to alcohol was believed to be a spontaneous chemical process. No one could explain why some fermentation mixtures produced vinegar (acetic acid) instead of alcohol. Pasteur discovered that fermentation is actually caused by living yeast, a single-celled fungus. In the absence of oxygen, yeast produces alcohol as a terminal waste product. But when the yeast culture is contaminated with bacteria, the bacteria outgrow the yeast and produce acetic acid instead of alcohol. (Fermentative metabolism is discussed further in Chapter 13.)

Pasteur's work on fermentation led him to test a key claim made by proponents of spontaneous generation. The proponents claimed that Spallanzani's failure to find spontaneous appearance of microbes was due to lack of oxygen. From his studies of yeast fermentation, Pasteur knew that some microbial species do not require oxygen for growth. So he devised an unsealed flask with a long, bent "swan neck" that admitted air but kept the boiled contents free of microbes (**Fig. 1.14B**). The famous swan-necked flasks remained free of microbial growth for many years; but when a flask was tilted to enable contact of broth with microbe-containing dust, growth occurred immediately. Thus, Pasteur disproved that lack of oxygen was the reason for failure of spontaneous generation in Spallanzani's flasks.

But even Pasteur's work did not prove that microbial growth requires preexisting microbes. The Irish scientist John Tyndall (1820–1893) attempted the same experiment as Pasteur, but sometimes found the opposite result. Tyndall found that the broth sometimes gave rise to microbes, no matter how long it was sterilized by boiling. The microbes appear because some kinds of organic matter, particularly hay infusion, are contaminated with a heat-resistant form of bacteria called endospores (or spores). The spore form can only be eliminated by repeated cycles of boiling and resting, in which the spores germinate to the growing, vegetative form that is killed at 100°C.

It was later discovered that endospores could be killed by boiling under pressure, as in a pressure cooker, which generates higher temperatures than can be obtained at atmospheric pressure. The steam pressure device called the **autoclave** became a standard method for the sterilization of materials required for the controlled study of microbes. (Microbial control and antisepsis are discussed further in Chapter 5.)

While spontaneous generation has been discredited as a continual source of microbes, at some point in the past the first living organisms must have originated from nonliving materials. The origin of life is explored in **Special Topic 1.1**.

TO SUMMARIZE:

- **Microbes affected human civilization** for centuries before humans guessed at their existence through their contributions to our environment, food and drink production, and infectious diseases.
- **Robert Hooke and Antoni van Leeuwenhoek** were the first to record observations of microbes through simple microscopes.
- **Spontaneous generation** is the theory that microbes arise spontaneously, without parental organisms. **Lazzaro Spallanzani** showed that microbes arise from preexisting microbes and demonstrated that heat sterilization can prevent microbial growth.
- **Louis Pasteur** discovered the microbial basis of fermentation. He also showed that providing oxygen does not enable spontaneous generation.
- **John Tyndall** showed that repeated cycles of heat were necessary to eliminate spores formed by certain kinds of bacteria.
- **Florence Nightingale** quantified statistically the impact of infectious disease on human populations.

1.3 Medical Microbiology

Over the centuries, thoughtful observers, such as Fracastoro and Agostino Bassi (see Table 1.2), noted a connection between microbes and disease. Ultimately, researchers developed the **germ theory of disease**, the theory that many diseases are caused by microbes.

The first to establish a scientific basis for determining that a specific microbe causes a specific disease was

Special Topic 1.1 How Did Life Originate?

If all life on Earth shares descent from a microbial ancestor, how did the first microbe arise? The earliest fossil evidence of cells in the geological record appears in sedimentary rock that formed as early as 3.8 billion years ago. Although the nature of the earliest reported fossils remains controversial, it is generally accepted that "microfossils" from over 2 billion years ago were formed by living cells. Moreover, the living cells that formed these microfossils looked remarkably similar to bacterial cells today, forming chains of simple rods or spheres (**Fig. 1**).

The exact composition of the first environment for life is controversial. The components of the first living cells may have formed from spontaneous reactions sparked by ultraviolet absorption or electrical discharge. American chemists Stanley Miller (1930–) and Harold C. Urey (1893–1981) argued that the environment of early Earth contained mainly **reduced** compounds—compounds that have a strong tendency to donate electrons, such as ferrous iron, methane, and ammonia. More recent evidence has modified this view, but it is agreed that the strong electron acceptor oxygen gas (O_2) was absent until the first photosynthetic microbes produced it. Today, all our cells are composed of highly reduced molecules that are readily oxidized by O_2. This seemingly hazardous composition may reflect our cellular origin in the chemically reduced environment of early Earth.

In 1953, Miller attempted to simulate the highly reduced conditions of early Earth to test whether ultraviolet absorption or electrical discharge could cause reactions producing the fundamental components of life (**Fig. 2A**). Miller boiled a solution of water containing hydrogen gas, methane, and ammonia and applied an electrical discharge (comparable to a lightning strike). Astonishingly, the reaction produced a number of amino acids, including glycine, alanine, and aspartic acid. A similar experiment in 1961 by Spanish-American researcher Juan Oró (1923–2004) (**Fig. 2B**) combined hydrogen cyanide and ammonia under electrical discharge to obtain adenine, a fundamental component of DNA and of the energy carrier adenosine triphosphate (ATP).

How could early cells have survived the heat and chemically toxic environment of early Earth? Clues may be found in the survival of archaea that thrive under habitat conditions we consider extreme, such as solutions of boiling sulfuric acid. The specially adapted structures of such microbes may resemble those of the earliest life-forms.

Figure 2 Simulating early Earth's chemistry. **A.** Stanley Miller with the apparatus of his early Earth simulation experiment. **B.** Biochemist Juan Oró demonstrated formation of adenine and other biochemicals from reaction conditions found in comets.

Research since Miller's day has generated as many questions as answers concerning the origin of life. For example:

- Were the reduced forms of early carbon and nitrogen, such as methane (CH_4) and ammonia (NH_4), supplemented by oxidized forms such as CO_2, spewed out by volcanoes? If oxidized carbon and nitrogen were available, different kinds of early-life chemistry may have occurred.
- How did the origin of informational molecules, such as RNA and DNA, coincide with the origin of metabolism? One possibility is that early metabolism was catalyzed by molecules of RNA instead of protein. RNA molecules capable of catalysis, called ribozymes, were discovered in 1982 by Thomas Cech and Sidney Altman, who earned the Nobel Prize in Chemistry in 1989 (**Fig. 3**). The discovery of ribozymes and thousands of small functional RNAs expressed by genomes led to the theory that early organisms were composed primarily of RNA—the so-called "RNA world."
- Geochemical evidence suggests that cells may have originated on Earth as early as 3.8 billion years ago, when Earth was just barely cool enough to allow the existence of cells. How could cells have formed so quickly? Could the first cells in fact have come from somewhere else?

Most of the molecules that spontaneously formed in Miller's experiments are also found in meteorites and comets. This observation led Oró to propose that the first chemicals of life could have come from outer space, perhaps carried by comets. But could life itself have an extraterrestrial origin? This controversial concept was proposed by British physicists Fred Hoyle (1915–2001) and Chandra Wickramasinghe. Hoyle and Wickramasinghe argued that features of the infrared spectroscopy of interstellar matter might be explained by the existence of microbes in outer space—microbes that could be brought to Earth by comets or meteors. Alternatively, some scientists propose that the first microbes originated on Mars. Because Mars orbits farther out from the sun than Earth, its surface would have cooled before Earth did; therefore, life might have formed on Mars and traveled to Earth on a meteorite. But the "Mars first" explanation says nothing about how life would have arisen on Mars.

Current evidence for the origin and evolution of microbes is discussed in Chapter 17.

The RNA catalyzes cleavage of itself.

the German physician Robert Koch (1843–1910) (**Fig. 1.15**). As a college student, Koch conducted biochemical experiments on his own digestive system. Koch's curiosity about the natural world led him to develop principles and techniques crucial to modern microbial investigation, including the pure-culture technique and the famous Koch's postulates for identifying the causative agent of a disease. He applied his methods to numerous lethal diseases around the world, including anthrax and tuberculosis in Europe, malaria in Africa and the East Indies, and bubonic plague in India.

Growth of Microbes in Pure Culture

Unlike Pasteur, who was a university professor, Koch took up a medical practice in a small Polish-German town. To make space in his home for a laboratory to study anthrax and other deadly diseases, his wife curtained off part of his patients' examining room.

Anthrax interested Koch because its epidemics in sheep and cattle caused economic hardship among local farmers. Today, anthrax is no longer a major problem for agriculture, as its transmission is prevented by effective environmental controls and vaccination. It has, however, gained notoriety as a bioterror agent because anthrax bacteria can survive for long periods in the dormant, desiccated form of an endospore. In 2001, anthrax spores sent through the mail contaminated post offices throughout the northeastern United States, as well as an office building of the United States Senate, causing several deaths (**Fig. 1.16**).

To investigate whether anthrax was a transmissible disease, Koch used blood from an anthrax-infected carcass to inoculate a rabbit. When the rabbit died, he used the rabbit's blood to inoculate a second rabbit, which then died in turn. The blood of the unfortunate animal had turned black with long, rod-shaped bacilli. Upon introduction of these bacilli into healthy animals, the ani-

Figure 1.16 Disinfecting the Hart Senate Office Building, Fall 2001. The building became contaminated with anthrax spores sent through the U.S. mail.

mals became ill with anthrax. Thus, Koch demonstrated an important principle of epidemiology—the **chain of infection**, or transmission of a disease. In retrospect, his choice of anthrax was fortunate, for the microbes generate disease very quickly, multiply in the blood to an extraordinary concentration, and remain infective outside the body for long periods.

Koch and his colleagues then applied their experimental logic and culture methods to a more challenging disease: tuberculosis. In Koch's day, tuberculosis caused one-seventh of reported deaths in Europe; today, tuberculosis bacteria continue to infect millions of people worldwide. Koch's approach to anthrax, however, was less applicable to tuberculosis, a disease that develops slowly after many years of dormancy. Furthermore, the causative bacteria, *Mycobacterium tuberculosis*, are small and difficult to distinguish from human tissue or from different bacteria of similar appearance associated with the human body. How could Koch prove that a particular bacterium caused a particular disease?

What was needed was to isolate a **pure culture** of microorganisms, a culture grown from a single "parental" cell. This had been done by previous researchers using the laborious process of serial dilution of suspended bacteria until a culture tube contained only a single cell. Alternatively, inoculation of a solid surface such as a sliced potato could produce isolated **colonies**, distinct populations of bacteria, each grown from a single cell. For *M. tuberculosis*, Koch inoculated serum, which then formed a solid gel after heating. Later, he refined the solid-substrate technique by adding gelatin to a defined liquid medium, which could then be chilled to form a solid medium in a glass dish. A covered version called the **petri dish** (also called a petri plate) was invented by a colleague, Richard J. Petri (1852–1921). The petri dish consists of a round dish with vertical walls covered by an inverted dish of slightly larger diameter. Today, the petri dish, generally made of disposable plastic, remains an indispensable part of the microbiological laboratory.

Another improvement in solid-substrate culture was the replacement of gelatin with materials that remain solid at higher temperatures, such as the gelling agent **agar** (a polymer of the sugar galactose). The use of agar was recommended by Angelina Hesse (1850–1934), a microscopist and illustrator, to her husband, Walther Hesse (1846–1911), a young medical colleague of Koch's (**Fig. 1.17**). Agar comes from red algae (seaweed) which is used by East Indian birds to build nests; it is the main ingredient in the delicacy "bird's nest soup." Dutch colonists used agar to make jellies and preserves, and a Dutch colonist from Java introduced it to Angelina Hesse. The Hesses used agar to develop the first effective growth medium for tuberculosis bacteria. (Pure culture is discussed further in Chapter 4.)

Note that some kinds of microbes cannot be grown in pure culture without other organisms. For example, viruses can be cultured only in the presence of their host cells. The discovery of viruses is explored in **Special Topic 1.2**.

Koch's Postulates Link a Pathogen with a Disease

For his successful determination of the bacterium responsible for tuberculosis, *M. tuberculosis*, Koch was awarded the Nobel Prize in Physiology or Medicine in 1905. Koch formulated his famous set of criteria for establishing a causative link between an infectious agent and a disease (**Fig. 1.18**). These four criteria are known as **Koch's postulates**:

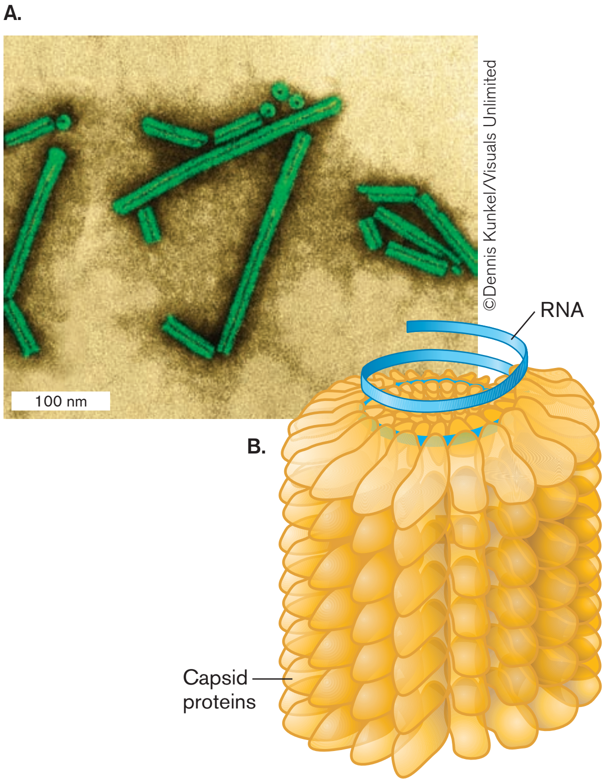
1. The microbe is found in all cases of the disease, but is absent from healthy individuals.
2. The microbe is isolated from the diseased host and grown in pure culture.
3. When the microbe is introduced into a healthy, susceptible host (or animal model), the same disease occurs.
4. The same strain of microbe is obtained from the newly diseased host. When cultured, the strain shows the same characteristics as before.

Special Topic 1.2 The Discovery of Viruses

The discovery of ever smaller and more elusive microorganisms continues to this day. From the nineteenth century on, researchers were puzzled to find contagious diseases whose agent of transmission could pass through a filter of a pore size that blocked known microbial cells—0.1 μm. One of these researchers was the Dutch plant microbiologist Martinus Beijerinck (1851–1931), who studied tobacco mosaic disease, a condition in which the leaves become mottled and the crop yield is decreased or destroyed altogether. Beijerinck concluded that because the agent of disease passed through a filter that retained bacteria, it could not be a bacterial cell.

The filterable agent was ultimately purified by the American scientist Wendell Stanley (1904–1971), who processed 4,000 kilograms (kg) of infected tobacco leaves and crystallized the infective particle. What he had crystallized was the tobacco mosaic virus, the causative agent of tobacco mosaic disease. The crystallization of a virus particle earned Stanley the 1946 Nobel Prize in Chemistry. The fact that an entity capable of biological reproduction could be inert enough to be crystallized amazed scientists and ultimately led to a new, more mechanical view of living organisms.

The individual particle of tobacco mosaic virus consists of a helical tube of protein subunits containing its genetic material coiled within (**Fig. 1**). Stanley thought that the virus was a catalytic protein, but colleagues later determined that it contained RNA as its genetic material. The structure of the coiled RNA was solved through X-ray diffraction crystallography by the British scientist Rosalind Franklin (1920–1958). We now know that all kinds of animals, plants, and microbial cells can be infected by viruses.



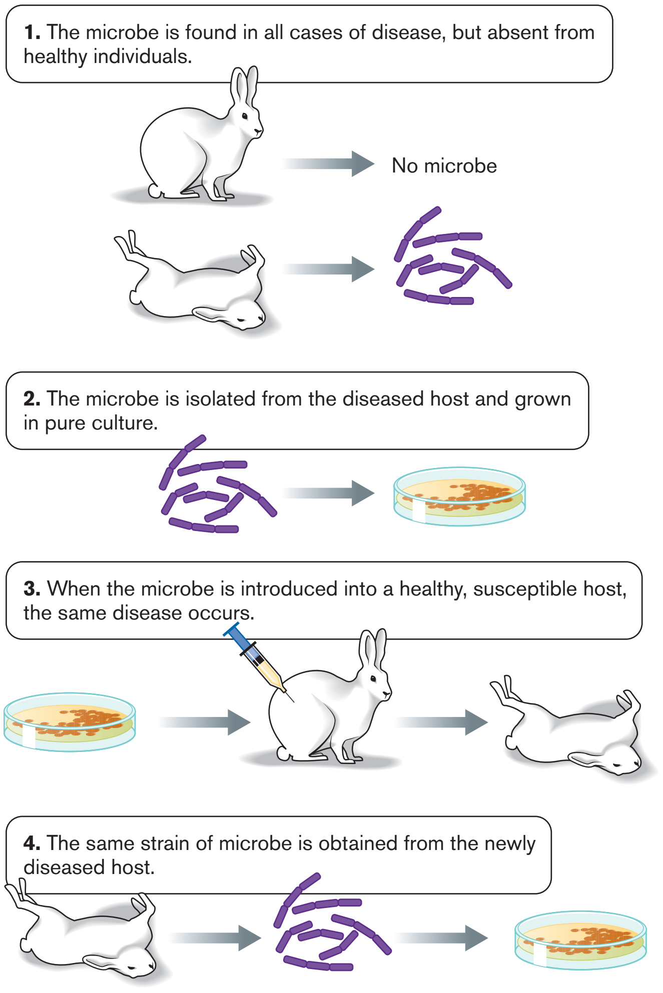
©Dennis Kunkel/Visuals Unlimited

Figure 1 Tobacco mosaic virus (TMV). A. Particles of tobacco mosaic virus (colorized transmission EM). **B.** In TMV, a protein capsid surrounds an RNA chromosome.

Toward the end of the twentieth century, even smaller infective particles were discovered consisting of a single molecule of RNA (viroids) or of protein (prions). Prions are suspected as a factor in the development of Alzheimer's disease. (The infectious processes of viruses, viroids, and prions are discussed in Chapters 6, 11, and 26.)

Koch's postulates continue to be used to determine whether a given strain of microbe causes a disease. Modern examples include Lyme disease, a tick-borne infection that has become widespread in New England and the Mid-Atlantic states, and hantaviral pneumonia, an emerging disease particularly prevalent among Native Americans in the Southwest. Nevertheless, the postulates remain only a guide; individual diseases and pathogens may confound one or more of the criteria. For example, tuberculosis bacteria are now known to cause symptoms in only 10% of the people infected. If Koch had been able to detect these silent bacilli, they would not have fulfilled his first criterion. In the case of AIDS, the concentration of HIV virus is so low that initially no virus could be detected in patients with fully active symptoms. It took the invention of the polymerase chain reaction (PCR), a method of producing any number of copies of DNA or RNA sequences, to detect the presence of HIV.

Another difficulty with AIDS and many other human diseases is the absence of an animal host that exhibits the same disease. In the case of AIDS, even the chimpanzees, our closest relatives, are not susceptible, although they exhibit a similar disease from a related pathogen, simian immunodeficiency virus (SIV). Experimentation on humans is prohibited, although in rare instances researchers have voluntarily exposed themselves to a proposed pathogen. For example, Australian researcher Barry Marshall ingested *Helicobacter pylori* to convince



1. The microbe is found in all cases of disease, but absent from healthy individuals.
No microbe
2. The microbe is isolated from the diseased host and grown in pure culture.
3. When the microbe is introduced into a healthy, susceptible host, the same disease occurs.
4. The same strain of microbe is obtained from the newly diseased host.

Figure 1.18 **Koch's postulates defining the causative agent of a disease.**

skeptical colleagues that this organism could colonize the extremely acidic stomach. *H. pylori* turned out to be the causative agent of gastritis and stomach ulcers, conditions that had long been thought to be caused by stress rather than infection. For the discovery of *H. pylori*, Marshall and colleague Robin Warren won the 2005 Nobel Prize in Physiology or Medicine.

THOUGHT QUESTION 1.4 How could you use Koch's postulates to demonstrate the causative agent of influenza? What problems would you need to overcome that were not encountered with anthrax?

Immunization Prevents Disease

Identifying the cause of a disease is, of course, only the first step to developing an effective therapy and preventing further transmission. Early microbiologists achieved some remarkable insights on how to control pathogens (see Table 1.2).

The first clue as to how to protect an individual from a deadly disease came from the dreaded smallpox. In the eighteenth century, smallpox infected a large fraction of the European population, killing or disfiguring many people. In Turkey, however, the incidence of smallpox was decreased by the practice of deliberately inoculating children with material from smallpox pustules, which contained naturally attenuated virus. Inoculated children usually developed a mild case of the disease and were protected from smallpox thereafter. The practice of smallpox inoculation was introduced from Turkey to Europe in 1717 by Lady Mary Montagu, a smallpox survivor (**Fig. 1.19A**). Stationed in Turkey with her husband, the British ambassador, Lady Montagu learned that many elderly women there had perfected the art of inoculation: "The old woman comes with a nut-shell full of the matter of the best sort of small-pox, and asks what vein you please to have opened." Lady Montagu arranged for the procedure on her own son, then brought the practice back to England where it became widespread.

Preventive inoculation with smallpox was dangerous, however, as some infected individuals still contracted serious disease and were contagious. Thus, doctors continued to seek a better method of prevention. In England, milkmaids claimed that they were protected from smallpox after they contracted cowpox, a related but much milder disease. This claim was confirmed by English physician Edward Jenner (1749–1823), who deliberately infected patients with matter from cowpox lesions (**Fig. 1.19B**). The practice of cowpox inoculation was called **vaccination**, after the Latin word *vacca* for "cow." To this day, cowpox, or vaccinia virus, remains the basis of the modern smallpox vaccine.

Pasteur was aware of vaccination as he studied the course of various diseases in experimental animals. In the spring of 1879, he was studying fowl cholera, a transmissible disease of chickens with a high death rate. He had isolated and cultured the bacteria responsible, but left his work during the summer for a long vacation. No refrigeration was available to preserve cultures, and when he returned to work, the aged bacteria failed to cause disease in his chickens. Pasteur then obtained fresh bacteria from an outbreak of disease elsewhere, as well as some new chickens. But the fresh bacteria also failed to make the original chickens sick (those who had been exposed to the aged bacteria). All of the new chickens, exposed only to the fresh bacteria, contracted the disease. Grasping the clue from his mistake, Pasteur had the insight to recognize that an attenuated (or "weakened") strain of microbe, altered somehow to eliminate its potency to cause disease, could still confer immunity to the virulent disease-causing form.

Pasteur was the first to recognize the significance of attenuation and extend the principle to other pathogens. We now know that the molecular components of pathogens generate **immunity**, the resistance to a specific disease, by stimulating the **immune system**, an organism's exceedingly complex cellular mechanisms of defense (see Chapter 23). Understanding the immune system awaited the techniques of molecular biology a century later, but nineteenth-century physicians developed several effective examples of **immunization**, the stimulation of an immune response by deliberate inoculation with an attenuated pathogen.

The way to attenuate a strain varies greatly among pathogens. Heat treatment or aging for various periods often turned out to be the most effective approach. In retrospect, the original success of prophylactic smallpox inoculation was probably due to natural attenuation during the time between acquisition of smallpox matter from a diseased individual and inoculation of the healthy patient. A far more elaborate treatment was required for the most famous disease for which Pasteur devised a vaccine: rabies.

The rabid dog loomed large in folklore, and the disease was dreaded for its particularly horrible and inevitable course of death. Pasteur's vaccine for rabies required a highly complex series of heat treatments and repeated inoculations. Its success led to his instant fame (**Fig. 1.20**). Grateful survivors of rabies founded the Pasteur Institute for medical research, one of the world's greatest medical research institutions, whose scientists in the twentieth century discovered the virus HIV, responsible for AIDS.

Antiseptics and Antibiotics Control Pathogens

Before the work of Koch and Pasteur, many patients died of infections transmitted unwittingly by their own doctors. In 1847, Hungarian physician Ignaz Semmelweis (1818–1865) noticed that the death rate of women in childbirth due to puerperal fever was much higher in his own hospital than in a birthing center run by midwives. He guessed that the doctors in his hospital were transmitting pathogens from cadavers that they had dissected. So he ordered the doctors to wash their hands

in chlorine, an **antiseptic** agent (a chemical that kills microbes). The mortality rate fell; but this revelation displeased other doctors, who refused to accept Semmelweis's findings.

In 1865, the British surgeon Joseph Lister (1827–1912) noted that half his amputee patients died of sepsis. Lister knew from Pasteur that microbial contamination might be the cause. So he began experiments to develop the use of antiseptic agents, most successfully carbolic acid, to treat wounds and surgical instruments. After initial resistance, Lister's work, with the support of Pasteur and Koch, drew widespread recognition. In the twentieth century, surgeons developed fully **aseptic** environments for surgery; that is, environments completely free of microbes.

Antibiotics. The problem with most antiseptic chemicals that killed microbes was that if taken internally, they also tended to kill the patients. Researchers sought a "magic bullet," an **antibiotic** molecule that killed microbes alone, leaving their host unharmed.

An important step in the search for antibiotics was the realization that microbes themselves produce antibiotic compounds with highly selective effects. This followed from the famous accidental discovery of penicillin by the English medical researcher Alexander Fleming (1881–1955) (**Fig. 1.21A**). In 1929, Fleming was culturing *Staphylococcus*, which infects wounds. He found that one of his plates of *Staphylococcus* was contaminated with a mold, *Penicillium notatum*, which he noticed was surrounded by a clear region, free of *Staphylococcus* colonies (**Fig. 1.21B**). Following up on this observation, Fleming showed that the mold produced a substance that killed bacteria. We now know this substance as penicillin.

In 1941, British biochemists Howard Florey (1898–1968) and Ernst Chain (1906–1979) purified the antibiotic molecule, which we now know inhibits formation of the bacterial cell wall. Penicillin saved the lives of many Allied troops during World War II, the first war in which an antibiotic became available to soldiers.

The second half of the twentieth century saw the discovery of many new and powerful antibiotics. Most of the new antibiotics, however, were produced by obscure strains of bacteria and fungi from dwindling ecosystems—a circumstance that focused attention on wilderness preservation worldwide. Furthermore, the widespread and often indiscriminate use of antibiotics has selected for pathogens that are antibiotic resistant. As a result, antibiotics have lost their effectiveness against certain strains of major pathogens. For example, multiple-drug-resistant *Mycobacterium tuberculosis* is now a serious threat to public health.

Fortunately, biotechnology provides new approaches to antibiotic development, including genetic engineering of microbial producers and artificial design of antimicrobial chemicals. This industry has become ever more critical because the indiscriminate use of antibiotics has led to a "molecular arms race" in which our only hope is to succeed faster than the pathogens develop resistance. (Microbial biosynthesis of antibiotics is discussed in Chapter 15, and the medical use of antibiotics is discussed in Chapter 27.)

THOUGHT QUESTION 1.5 Why do you think some pathogens generate immunity readily, whereas others evade the immune system?

THOUGHT QUESTION 1.6 How do you think microbes protect themselves from the antibiotics they produce?

TO SUMMARIZE:

- **Robert Koch** devised techniques of pure culture to study a single species of microbe in isolation. A key technique is culture on solid medium using agar, as developed by Angelina and Walther Hesse, in a double-dish container devised by Richard Petri.
- **Koch's postulates** provide a set of criteria to establish a causative link between an infectious agent and a disease.
- **Edward Jenner** established the practice of vaccination, inoculation of cowpox to prevent smallpox. Jenner's discovery was based on earlier observations by Lady Mary Montagu and others that a mild case of smallpox could prevent future cases.
- **Louis Pasteur** developed the first vaccines based on attenuated strains, such as the rabies vaccine.
- **Ignaz Semmelweis** and **Joseph Lister** showed that antiseptics could prevent transmission of pathogens from doctor to patient.
- **Alexander Fleming** discovered that the *Penicillium* mold generated a substance that kills bacteria. **Howard Florey** and **Ernst Chain** purified the substance, penicillin, the first commercial antibiotic to save human lives.

1.4 Microbial Ecology

Koch's growth of microbes in pure culture was a major advance in technology, enabling the systematic study of microbial physiology and biochemistry. In hindsight, this discovery eclipsed the equally important study of microbial ecology. Microbes are responsible for cycling the many minerals essential for all life. Yet barely 0.1% of all microbial species can be cultured in the laboratory—and the remainder make up the majority of Earth's entire biosphere. Only the outer skin of Earth supports complex multicellular organisms. The depths of Earth's crust, to at least 2 miles down, as well as the atmosphere 10 miles out into the stratosphere, remain the domain of microbes. So, to a first approximation, Earth's ecology *is* microbial ecology.

Microbes Support Natural Ecosystems

The first microbiologists to culture microbes in the laboratory selected the kinds of nutrients that feed humans, such as beef broth or potatoes. Some of Koch's contemporaries, however, suspected that other kinds of microbes living in soil or wetlands existed on more exotic fare. Soil samples were known to oxidize hydrogen gas, and this activity was eliminated by treatment with heat or acid, suggesting microbial origin. Ammonia in sewage was oxidized to nitrate, and this process was eliminated by antibacterial treatment. These findings suggested the existence of microbes that "ate" hydrogen gas or ammonia instead of beef or potatoes, but no one could isolate these microbes in culture.

Among the first to study microbes in natural habitats was the Russian scientist Sergei Winogradsky (1856–1953). Winogradsky waded through marshes to discover microbes with metabolism quite alien from human digestion. For example, Winogradsky discovered that species of the bacterium *Beggiatoa* oxidize hydrogen sulfide (H_2S) to sulfuric acid (H_2SO_4). *Beggiatoa* fixes carbon dioxide into biomass without consuming any organic food. Organisms that feed solely on inorganic minerals are known as **chemolithotrophs**, or **lithotrophs**, discussed further in Chapters 4 and 14.

The lithotrophs studied by Winogradsky could not be grown on Koch's plate media containing agar or gelatin. The bacteria that Winogradsky isolated could grow only on inorganic minerals; in fact, some species are actually poisoned by organic food. For example, nitrifiers convert ammonia to nitrate, forming a crucial part of the nitrogen cycle in natural ecosystems. Winogradsky cultured nitrifiers on a totally inorganic solution containing ammonia and silica gel, which supported no other kind of organism. This experiment was an early example of **enrichment culture**, the use of selective growth media that support certain classes of microbial metabolism while excluding others.

Instead of isolating pure colonies, Winogradsky built a model wetland ecosystem containing regions of enrichment for microbes of diverse metabolism. This model is called the **Winogradsky column** (**Fig. 1.22**). The model consists of a glass tube containing mud mixed with shredded newsprint (an organic carbon source) and calcium salts of sulfate and carbonate. After exposure to light for several weeks, several zones of color develop, full of mineral-metabolizing bacteria. At the top, cyanobacteria conduct **photosynthesis**, using light energy to split water and produce molecular oxygen. Below, purple sulfur bacteria use photosynthesis to split hydrogen sulfide, producing sulfur. At the bottom, sulfate reducers produce hydrogen sulfide and precipitate iron.

The gradient from oxygen-rich conditions at the surface to highly reduced conditions below generates a voltage potential, like a battery cell. We now know that the entire Earth's surface acts as a battery—for humans, a potential source of renewable energy.

Geochemical Cycling Depends on Bacteria

Winogradsky and later microbial ecologists showed that bacteria perform unique roles in **geochemical cycling**, the global interconversion of inorganic and organic forms of nitrogen, sulfur, phosphorus, and other minerals. Without these essential conversions (nutrient cycles), no plants or animals could live. Bacteria and archaea *fix nitrogen* (N_2) by reducing it to ammonia (NH_3), the form of nitrogen assimilated by plants. This process is called **nitrogen fixation** (**Fig. 1.23**). Other bacterial species oxidize NH_4^+ in several stages back to nitrogen gas.

Within plant cells, certain bacteria fix nitrogen as **endsymbionts**, organisms living symbiotically inside a larger organism. Endosymbiotic bacteria known as rhizobia induce the roots of legumes to form special nodules to facilitate bacterial nitrogen fixation. Rhizobial endosymbiosis was first observed by the Dutch plant microbiologist Martinus Beijerinck (1851–1931).

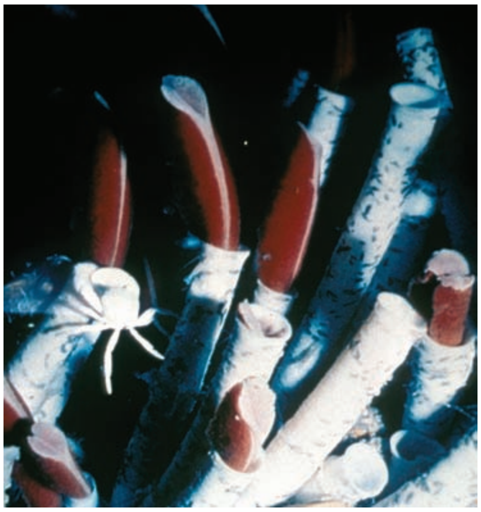
Figure 1.23 **The global nitrogen cycle.** All life depends on these oxidative and reductive conversions of nitrogen—most of which are performed only by microbes.

Special Topic 1.3 Microbial Endosymbionts of Animals

Numerous kinds of endosymbiosis have been found in which microbes make essential nutritional contributions to host animals. Ruminant animals, such as cattle, as well as insects such as termites, require digestive bacteria to break down cellulose and other plant polymers. Even humans obtain about 10% of their nutrition from colonic bacteria. A remarkable form of endosymbiosis is seen in marine animal communities such as those inhabiting thermal vents in the ocean floor, where superheated water emerges carrying reduced minerals, such as hydrogen sulfide (**Fig. 1**). Near these thermal vents, sulfide-oxidizing bacteria nourish giant worms and clams. The worms have evolved so as to lose their digestive tracts altogether, while their body fluids carry the hydrogen sulfide (highly toxic to most animals) needed for the bacteria to metabolize.

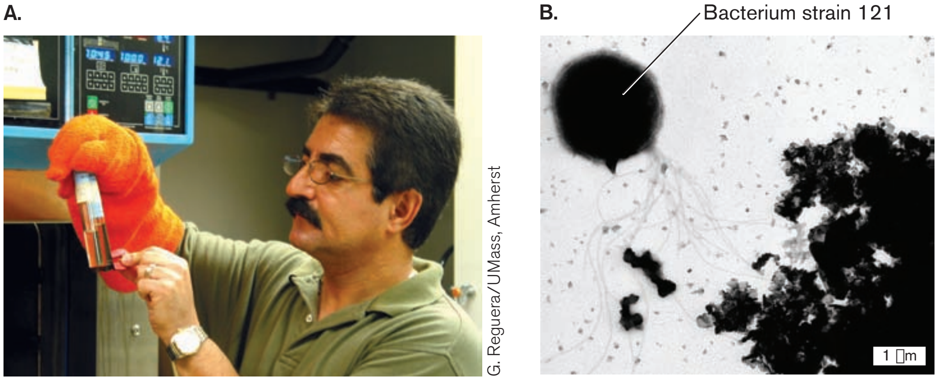
Many invertebrates, such as hydras and corals, harbor endosymbiotic phototrophs that provide products of photosynthesis in return for protection and nutrients. Other kinds of endosymbiosis involve more than nutrition. In the light organs of fish and squid, luminescent bacteria such as *Vibrio fischeri* respond to host signals, causing light emission. Certain sponges maintain endosymbiotic bacteria that produce antibiotics, preventing infection by pathogens. Similarly, some bacteria that normally inhabit the human skin are believed to protect us from infection. Microbial endosymbiosis has even inspired fictional creations, such as the "breathmicrobes" of Joan Slonczewski's novel *A Door into Ocean*, which acquire oxygen for human hosts swimming underwater. (Microbial endosymbiosis is discussed further in Section 21.2.)



Fritz Heide/WHOI

Figure 1 Tube worms in a thermal vent ecosystem. Tube worms do not feed themselves but depend on sulfide-oxidizing symbionts for nutrition.

Microbes with unusual properties, such as the ability to digest toxic wastes, have valuable applications in industry and bioremediation. For this reason, microbial ecology is a priority for funding by the National Science Foundation (NSF). The NSF program Life in Extreme Environments supports research aimed at documenting microbes from environments with extreme heat, salinity, acidity, or other factors. One such microbe is a species of *Geobacter* that reduces rust (iron oxide, Fe_2O_3) to the magnetic mineral magnetite (Fe_3O_4) while growing at 121°C, a temperature high enough to kill all other known organisms (**Fig. 1.24**).



G. Reguera/UMass, Amherst

Kazem Kashefi/UMass, Amherst

Figure 1.24 An extreme thermophile reduces iron oxide to magnetite. A. Microbiologist Kazem Kashefi (Michigan State University) pulls a live culture of *Geobacter* out of an autoclave generally used to kill all living organisms at 121°C (250°F). The magnet shows that strain 121 is converting nonmagnetic iron oxide (rust; Fe_2O_3) to the magnetic mineral magnetite, Fe_3O_4. **B.** Strain 121 is a round bacterium with a tuft of rotary flagella (transmission electron micrograph). The black material at right is iron oxide, which feeds the bacteria. *Source*: Part B reprinted with permission from Kashefi, et al. 2003. *Science* 301(5635):934. ©2005 AAAS.

TO SUMMARIZE:

- **Sergei Winogradsky** first developed a system of enrichment culture, the Winogradsky column, to grow microbes from natural environments.
- **Chemolithotrophs (or lithotrophs)** metabolize inorganic minerals, such as ammonia, instead of the organic nutrients used by the microbes isolated by Koch.
- **Geochemical cycling** depends on bacteria and archaea that cycle nitrogen, phosphorus, and other minerals throughout the biosphere.
- **Endosymbionts** are microbes that live within multicellular organisms and provide essential functions for their hosts, such as nitrogen fixation for legume plants.
- **Martinus Beijerinck** first demonstrated that nitrogen-fixing rhizobia grow as endosymbionts within leguminous plants.

1.5 The Microbial Family Tree

The bewildering diversity of microbial life-forms presented nineteenth-century microbiologists with a seemingly impossible task of classification. So little was known about life under the lens that natural scientists despaired of ever learning how to distinguish microbial species. The famous classifier of species, Swedish botanist Carl von Linné (Carolus Linnaeus, 1707–1778), called the microbial world "chaos."

Microbes Are a Challenge to Classify

Two challenges faced would-be taxonomists with respect to microbes. The first was that the resolution of the light microscope allows little more than visualizing the outward shape of microbial cells, and vastly different kinds of microbes look more or less alike (visualization of cells and molecules is discussed in Chapter 2). This challenge was overcome as advances in biochemistry and microscopy made it possible to distinguish microbes based on their metabolism and cell ultrastructure and ultimately on their DNA sequence.

The second challenge was that microbes do not readily fit the classic definition of a species—that is, a group of organisms that interbreed. Unlike multicellular eukaryotes, microbes generally reproduce asexually, with only occasional sexual exchange. When they do exchange genes, they may do so with distantly related species (discussed in Chapter 9). Nevertheless, microbiologists devise working definitions of microbial species that enable us to usefully describe populations while being flexible enough to accommodate continual revision and change. The most useful definitions are based on genetic similarity. For example, two distinct species generally share no more than 95% similarity of DNA sequence.

NOTE: The actual names of microbial species are often changed to reflect new understanding of genetic relationships. For example, the causative agent of bubonic plague has formerly been called *Bacterium pestis* (1896), *Bacillus pestis* (1900), and *Pasteurella pestis* (1923), but is now called *Yersinia pestis* (1944). The older names, however, still appear in the literature, a point to remember during research. Current and historical nomenclature is compiled at the List of Prokaryotic Names with Standing in Nomenclature.

www | List of Prokaryotic Names with Standing in Nomenclature

Microbes Include Eukaryotes and Prokaryotes

In the nineteenth century, taxonomists had no access to DNA information. As they tried to incorporate microbes into the tree of life, they faced a conceptual dilemma in that microbes could not be categorized as either animals or plants, which since ancient times were considered the two "kingdoms" or major categories of life. Taxonomists attempted to apply these categories to microbes—for example, by including algae and fungi with plants. But German naturalist Ernst Haeckel (1834–1919) recognized that microbes differed from both plants and animals in fundamental aspects of their lifestyle, cellular structure, and biochemistry. Haeckel proposed that microscopic organisms constituted a third kind of life—neither animal nor plant—which he called *Monera*.

In the twentieth century, biochemical studies revealed profound distinctions even within the microbial category. In particular, microbes such as protists and algae contain a nucleus bounded by a nuclear membrane, whereas bacteria do not. Herbert Copeland (1902–1968) proposed a system of classification that divided *Monera* into two groups: the eukaryotic protists (protozoa and algae) and the prokaryotic bacteria. Copeland's four-kingdom classification (plants, animals, eukaryotic protists, and prokaryotic bacteria) was later modified by Robert Whittaker (1924–1980) to include fungi as a fifth kingdom of eukaryotic microbes. Whittaker's system thus generated five kingdoms: bacteria, protists, fungi, and the multicellular plants and animals.

Eukaryotes Evolved through Endosymbiosis

The five-kingdom system was modified dramatically by Lynn Margulis, at the University of Massachusetts (**Fig. 1.25**). Margulis tried to explain how it is that eukaryotic cells contain mitochondria and chloroplasts, membranous organelles that possess their own chromosomes. She proposed that eukaryotes evolved by merging with bacteria to form composite cells by intracellular endosymbiosis, in which one cell internalizes another that grows within it. The endosymbiosis may ultimately generate a single organism whose formerly independent members are now incapable of independent existence.

Margulis proposed that early in the history of life, respiring bacteria similar to *E. coli* were engulfed by pre-eukaryotic cells, where they evolved into mitochondria, the eukaryote's respiratory organelle. Similarly, she proposed that a phototroph related to cyanobacteria was taken up by a eukaryote, giving rise to the chloroplasts of phototrophic algae and plants.

The endosymbiosis theory was highly controversial because it implied a **polyphyletic**, or multiple, ancestry of living species, inconsistent with the long-held assumption that species evolve only by divergence from a common ancestor (**monophyletic**). Ultimately, DNA sequence analysis produced compelling evidence of the bacterial origin of mitochondria and chloroplasts. Both these classes of organelles contain circular molecules of DNA, whose sequences show unmistakable homology (similarity) to those of modern bacteria. DNA sequences and other evidence established the common ancestry between mitochondria and respiring bacteria and between chloroplasts and cyanobacteria.

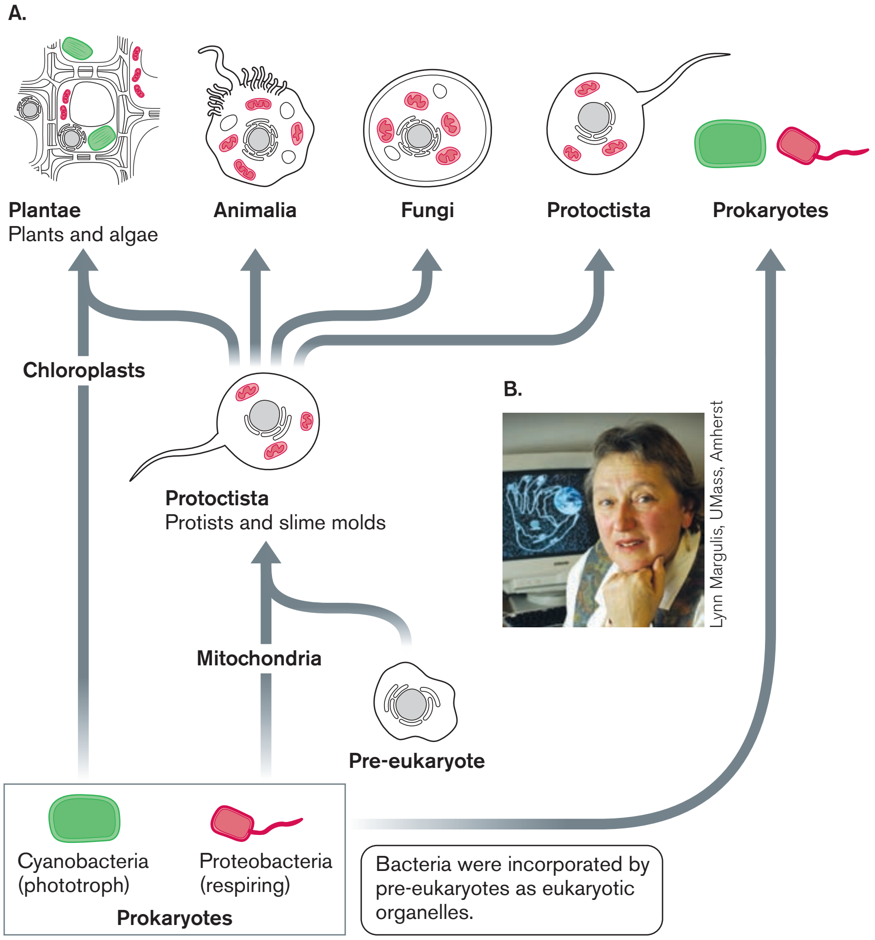


Figure 1.25 **Lynn Margulis and the serial endosymbiosis theory. A.** Five-kingdom scheme, modified by the endosymbiosis theory. **B.** Lynn Margulis (University of Massachusetts, Amherst) proposed that organelles evolve through endosymbiosis.

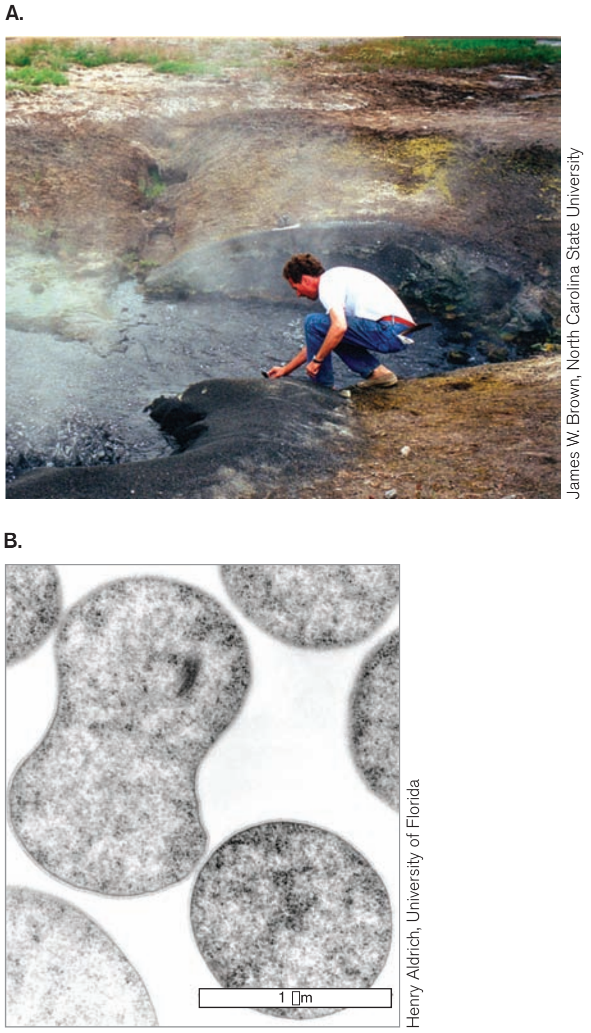
Archaea Differ from Bacteria and Eukaryotes

Gene sequence analysis led to another startling advance in our understanding of the evolution of cells. In 1977, Carl Woese, at the University of Illinois, was studying a group of recently discovered prokaryotes that live in seemingly hostile environments, such as the boiling sulfur springs of Yellowstone, or that exhibit unusual kinds of metabolism, such as production of methane (methanogenesis). Woese used the sequence of the gene for 16S ribosomal RNA (16S rRNA) as a "molecular clock," a gene whose sequence differences can be used to measure the time since the divergence of two species (discussed in Chapter 17). The divergence of rRNA genes showed that the newly discovered prokaryotes were a distinct form of life, archaea (**Fig. 1.26**). The archaea resemble bacteria in their relatively simple cell structure, in their lack of a nucleus, and in their ability to grow in a wide range of environments. Many archaea, however, grow in environments more extreme than any bacterium, such as 110°C at high pressure. The genetic sequences of archaea differ as much from those of bacteria as from those of eukaryotes; in fact, their gene expression machinery is more similar to that of eukaryotes.

Woese's discovery replaced the classification scheme of five kingdoms with three equally distinct groups, now called the three domains: *Bacteria*, *Archaea*, and *Eukarya* (**Fig. 1.27**). In the three-domain model, the bacterial ancestor of mitochondria derives from ancient proteobacteria (shaded pink), whereas chloroplasts derive from ancient cyanobacteria (shaded green). The three-domain classification is largely supported by the sequences of microbial genomes, although some horizontal transfer of genes occurs both within and between the domains (discussed in Chapter 17).

THOUGHT QUESTION 1.8 What arguments support the classification of *Archaea* as a third domain of life? What arguments support the classification of archaea and bacteria together, as prokaryotes, distinct from eukaryotes?



James W. Brown, North Carolina State University

Henry Aldrich, University of Florida

Figure 1.26 Archaea, newly discovered life-forms. **A.** Finding archaea in the hot spring Obsidian Pool, at Yellowstone. **B.** *Pyrococcus furiosus*, an organism that lives at temperatures above 100°C (transmission electron micrograph).

TO SUMMARIZE:

- **Classifying microbes** was a challenge historically because of the difficulties in observing distinguishing characteristics of different categories.
- **Ernst Haeckel** recognized that microbes constitute a form of life distinct from animals and plants.
- **Herbert Copeland and Robert Whittaker** classified prokaryotes as a form of microbial life distinct from eukaryotic microbes such as protists.

Figure 1.27 Carl Woese and the three domains of life. **A.** Carl Woese (University of Illinois at Urbana-Champaign) proposed that archaea constitute a third domain of life. **B.** Three domains, a monophyletic tree, based on 16S rRNA sequences. The length of each branch approximates the time of divergence from the last common ancestor. For an up-to-date tree that synthesizes both approaches, see Chapter 17.

- **Lynn Margulis** proposed that eukaryotic organelles such as mitochondria and chloroplasts evolved by endosymbiosis from prokaryotic cells engulfed by proto-eukaryotes.
- **Carl Woese** discovered a domain of prokaryotes, *Archaea*, whose genetic sequences diverge equally from those of bacteria and those of eukaryotes. Many, though not all, archaea grow in extreme environments.

1.6 Cell Biology and the DNA Revolution

During the twentieth century, amid world wars and societal transformations, the field of microbiology exploded with new knowledge (see Table 1.2). More than 99% of what we know about microbes today was discovered since 1900 by scientists too numerous to cite in this book. Advances in biochemistry and microscopy revealed the fundamental structure and function of cell membranes and proteins. The revelation of the structures of DNA and RNA led to the discovery of the genetic programs of model bacteria such as *E. coli* and the bacteriophage lambda. Beyond microbiology, these advances produced the technology of "recombinant DNA," or genetic engineering, the creation of molecules that combine DNA sequences from unrelated species. These microbial tools offered unprecedented applications to human medicine and industry.

Cell Membranes and Macromolecules

In 1900, the study of cell structure was still limited by the resolution of the light microscope and by the absence of tools that could take apart cells to isolate their components. Both these limitations were overcome by the invention of powerful instruments. Just as society was being transformed by machines ranging from jet airplanes to vacuum cleaners, the study of microbiology was also being transformed by machines. Two instruments had exceptional impact: The **electron microscope** revealed the internal structure of cells (Chapter 2), and the **ultracentrifuge** enabled isolation of subcellular parts (Chapter 3).

The electron microscope. In the 1920s, at the Technical College in Berlin, student Ernst Ruska (1906–1988) was invited to develop an instrument for focusing rays of electrons. Ruska recalled as a child how his father's microscope could magnify fascinating specimens of plants and animals, but that its resolution was limited by the wavelength of light. He was eager to devise lenses that could focus beams of electrons, with wavelengths far smaller than that of light, to reveal living details never seen before. Ultimately, Ruska built lenses to focus electrons using specially designed electromagnets. Magnetic lenses were used to complete the first electron microscope in 1933 (**Fig. 1.28**). Early transmission electron microscopes achieved about tenfold greater magnification than the light microscope, revealing details such as the ridged shell of a diatom. Further development steadily increased magnification, to as high as a millionfold.

For the first time, cells were seen to be composed of a cytoplasm containing macromolecules and bounded by a phospholipid membrane. By the 1960s, thin sections revealed the entire inner architecture of eukaryotic cells, including intracellular membranes, ribosomes, and organelles such as mitochondria and chloroplasts. Within the smaller cells of bacteria, the DNA-containing nucleoid was revealed, as well as specialized structures, such as photosynthetic organelles called chlorosomes (**Fig. 1.29**).

Subcellular structures, however, raised many questions about cell function that visualization alone could not answer. Biochemists showed how cell function involved numerous chemical transformations mediated by enzymes. A milestone in the study of metabolism was the elucidation by German biochemist Hans Krebs (1900–1981) of the tricarboxylic acid cycle (TCA, or Krebs cycle), by which the products of sugar diges-

tion are converted to carbon dioxide. The tricarboxylic acid cycle provides energy for many bacteria and for the mitochondria of eukaryotes. But even Krebs understood little of how metabolism is organized within a cell; he and his contemporaries considered the cell a "bag of enzymes." The full significance of cell structure required experiments on isolated parts of cells.

The ultracentrifuge. Whole cells could be separated from the fluid in which they were suspended by centrifugation, the spinning of samples in a rotor so as to subject the cells to centrifugal forces of a few thousand times that of gravity. Some biochemists proposed that even greater centrifugal forces could separate cell components, even macromolecules such as proteins. The Swedish chemist Theodor Svedberg (1884–1971), at the University of Uppsala, set out to build such a machine: the ultracentrifuge.

Svedberg studied the properties of macromolecules such as proteins and polysaccharides. A major challenge was to measure the size of such particles. Svedberg calculated that particle size could be determined based on the rate of the movement of particles in a tube, the subjected to forces of hundreds of thousands times that of gravity. So he designed and built rotors spinning at ever greater rates, rates so high that they required a vacuum to avoid burning up like a space reentry vehicle. Such an advanced centrifuge, used to separate components of cells, is called an ultracentrifuge.

Experiments based on electron microscopy and ultracentrifugation revealed how membranes govern energy transduction within bacteria and within organelles such as mitochondria and chloroplasts. In the 1960s, English biochemists Peter Mitchell (1920–1992) and Jennifer Moyle (1921–) proposed and tested a revolutionary idea called the **chemiosmotic hypothesis**. The chemiosmotic hypothesis states that the redox reactions of the electron transport system store energy in the form of a gradient of protons (hydrogen ions) across a membrane, such as the bacterial cell membrane or the inner membrane of mitochondria. The energy stored in the proton gradient in turn drives the synthesis of ATP.

The chemiosmotic hypothesis earned Mitchell the Nobel Prize in Chemistry in 1978. Nevertheless, the theory took many years to win acceptance by biologists committed to the "bag of enzymes" model of the cell. Ultimately the role of ion gradients across membranes was recognized as fundamental to all living cells. (Ion gradients in membranes are discussed further in Chapters 3 and 4, and their role in energy transduction is presented in Chapter 14.)

Microbial Genetics Leads the DNA Revolution

As the form and function of living cells emerged in the early twentieth century, a largely separate line of research revealed patterns of heredity of cell traits. In eukaryotes, the Mendelian rules of inheritance were rediscovered and connected to the behavior of subcellular structures called chromosomes. Frederick Griffith (1877–1941) showed in 1928 that some unknown substance out of dead bacteria could carry genetic information into living cells, transforming harmless bacteria into a strain capable of killing mice, a process called **transformation**. Some kind of "genetic material" must be inherited to direct the expression of inherited traits, but no one knew what that material was or how its information was expressed.

Then in 1944, Oswald Avery (1877–1955) and colleagues showed that the genetic material responsible for transformation is deoxyribonucleic acid, or DNA. An obscure acidic polymer, DNA was previously thought too uniform in structure to carry information; its precise structure was unknown. As World War II raged among nations, among scientists an epic struggle began: the quest for the structure of DNA.

The discovery of the double helix. The tool of choice for macromolecular structure was X-ray crystallography, a method developed by British physicists in the early 1900s. The field of X-ray analysis included an unusual number of women, including Dorothy Hodgkin (1910–1994), who won a Nobel Prize for the structures of penicillin and vitamin B_{12}. In 1953, crystallographer Rosalind Franklin (1920–1958) joined a laboratory at King's College to study the structure of DNA (**Fig. 1.30A**). As a woman and as a

Figure 1.30 **The DNA double helix.** **A.** Rosalind Franklin discovered that DNA forms a double helix. **B.** X-ray diffraction pattern of DNA, obtained by Rosalind Franklin. **C.** James Watson and Francis Crick discovered the complementary pairing between bases of DNA and the antiparallel form of the double helix.

Jew who supported relief work in Palestine, Franklin felt socially isolated at the male-dominated Protestant university. Nevertheless, the exceptional quality of her X-ray micrographs impressed her colleagues. The X-shaped pattern in her micrograph (**Fig. 1.30B**) showed for the first time that the standard B-form DNA was a double helix. Without Franklin's knowledge, her colleague Maurice Wilkins showed her data to a competitor, James Watson (1928–). The pattern led Watson and Francis Crick (1916–2004) to guess that the four bases of the DNA "alphabet" were paired in the interior of Franklin's double helix (**Fig. 1.30C**). They published their model in the journal *Nature*, while denying that they used Franklin's data.

The discovery of the double helix earned Watson, Crick, and Wilkins the 1962 Nobel Prize in Physiology or Medicine. Franklin died of ovarian cancer before the Nobel Prize was awarded. Before her death, however, she turned her efforts to the structure of ribonucleic acid (RNA). She determined the form of the RNA chromosome within tobacco mosaic virus, the first viral RNA to be characterized.

The structure of DNA base pairs led to development of techniques for **DNA sequencing**, the reading of the sequence of DNA base pairs. **Figure 1.31** shows an example of DNA sequence data, where each color represents one of the four bases and each peak represents a DNA fragment terminating in that particular base. The order of fragment lengths yields the sequence of bases in one strand. Reading the sequence enabled microbiologists to determine the beginning and endpoint of genes and ultimately entire genomes.

The DNA revolution began with bacteria. What amazed the world about DNA was that such a simple substance, composed of only four types of subunit, is the genetic material that determines all the different organisms on Earth. The promise of this insight was first fulfilled in bacteria and bacteriophages, whose small genomes and short generation times made key experiments possible. Furthermore, naturally occurring mechanisms of gene exchange in bacteria and viruses provided scientists with the key tools for transferring genes, including those of animals and plants. Consider these examples:

- **Restriction endonucleases led to recombinant DNA.** Bacteria make **restriction endonucleases**, enzymes that cut DNA at positions determined by specific short base sequences. In nature, restriction

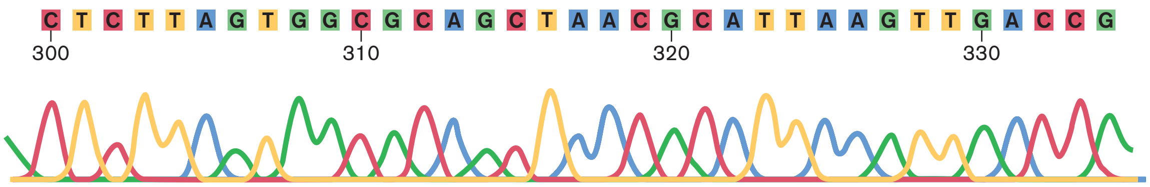

Figure 1.31 **A DNA sequence fluorogram.** Sequence obtained by an undergraduate at Kenyon College using an ABI sequencer, from genomic DNA of a microbe isolated from a discarded beverage container. Each colored trace represents the intensity of fluorescence of one of the four bases terminating a chain of DNA.

endonucleases protect bacteria from the foreign DNA of viruses. In the test tube, purified restriction endonucleases were used to "cut and paste" DNA from two unrelated organisms, generating **recombinant DNA**. The construction of artificially recombinant DNA, by "gene cloning," ultimately made it possible to transfer genes between the genomes of virtually all types of organisms, using processes derived from natural phenomena of bacterial transformation.

- **A thermophilic DNA polymerase was used for polymerase chain reaction (PCR) amplification of DNA.** While molecular biologists forged ahead in the laboratory, microbial ecologists discovered new species of bacteria and archaea in increasingly extreme habitats. A hot spring in Yellowstone National Park yielded the bacterium *Thermus aquaticus*, whose DNA polymerase could survive many rounds of cycling to near-boiling temperature. The Taq polymerase formed the basis of a multibillion-dollar industry of PCR amplification of DNA, with applications ranging from genome sequencing to forensic identification.
- **Gene regulation discovered in bacteria provided models for animals and plants.** The information carried by DNA was shown to be expressed by transcription to RNA and then translation of RNA to make proteins. Most of the key discoveries of gene expression were made in bacteria and bacteriophages. The regulation of expression of a bacterial gene was first demonstrated for the *lac* operon, a set of contiguous genes in *E. coli*. Transcription of the *lac* operon was shown to be regulated by a repressor protein binding to DNA. DNA-binding proteins were subsequently demonstrated in all classes of living organisms.

Public response. As early as the 1970s, when the DNA revolution was largely limited to bacteria, its implications drew public concern. The use of recombinant DNA to make hybrid organisms—organisms combining DNA from more than one species—seemed "unnatural," although we now know that interspecies gene transfer occurs ubiquitously in nature. Furthermore, recombinant DNA technology raised the specter of placing deadly genes that produce toxins such as botulin into innocuous human flora such as *E. coli*.

The unknown consequences of recombinant DNA so concerned molecular biologists that they held a conference to assess the dangers and restrict experimentation on recombinant DNA. The conference, led by Paul Berg and Maxine Singer at Asilomar in 1975, was possibly the first time in history that a group of scientists organized and agreed to regulate and restrict their own field.

Figure 1.32 **"Protein Jive Sutra."** At Stanford University, in 1971, rock dancers represented the process of protein synthesis in the ribosome. The depiction was immortalized in a film produced by chemist Kent Wilson and directed by Gabriel Weiss, with an introduction by Nobel laureate Paul Berg.

On the positive side, the emerging world of molecular biology drew excitement from students at a time of new ideas and social change. In 1971, the newly discovered process of protein translation by the bacterial ribosome inspired a classic cult film, *Protein Synthesis: An Epic on the Cellular Level*, directed by Gabriel Weiss and choreographed by Jackie Bennington, America's 1969 Junior Miss (**Fig. 1.32**). Introduced by Nobel laureate Paul Berg, the film depicts dancers on the Stanford University football field forming the shape of the ribosome while "messenger RNA" and "transfer RNAs" meet to assemble a "protein." The dancers sway to "Protein Jive Sutra," performed by a Haight-Ashbury-inspired rock band. Their excitement echoed that of scientists exploring the extraordinary potential of microbial discovery.

THOUGHT QUESTION 1.9 Do you think engineered strains of bacteria should be patentable? What about sequenced genes or genomes?

Microbial Discoveries Transform Medicine and Industry

Twentieth-century microbiology transformed the practice of medicine and generated entire new industries of biotechnology and bioremediation. Following the discovery of penicillin, Americans poured millions of dollars of private and public funds into medical research. The March of Dimes campaign for private donations to prevent polio

Table 1.3 Fields of research in microbiology.

Field	Subject of study
Experimental microbiology	Fundamental questions about microbial form and function, genetics, and ecology
Medical microbiology	The mechanism, diagnosis, and treatment of microbial disease
Epidemiology	Distribution and causes of disease in humans, animals, and plants
Immunology	The immune system and other host defenses against infectious disease
Food and industrial microbiology	Microbial and industrial food products, food contamination, and bioremediation
Environmental microbiology	Microbial diversity and microbial processes in natural and artificial environments
Forensic microbiology	Analysis of microbial strains as evidence in criminal investigations
Astrobiology	The origin of life in the universe and the possibility of life outside Earth

led to the successful development of a vaccine that has nearly eliminated the disease. With the end of World War II, research on microbes and other aspects of biology drew increasing financial support from U.S. government agencies, such as the National Institutes of Health and the National Science Foundation, as well as from governments of other countries, particularly the European nations and Japan. Further support has come from private foundations, such as the Pasteur Institute, the Wellcome Trust, and the Howard Hughes Medical Institute.

Research in microbiology finds applications in diverse fields (**Table 1.3**), all of which recruit microbiologists (**Fig. 1.33**). Cloned genes in bacteria produce valuable therapeutic proteins, such as insulin for diabetics. Recombinant viruses make safer vaccines. Bacteria and viral recombinant genomes are used to construct transgenic animals and plants. In environmental science, newly discovered microbes provide new ways to bioremediate wastes and control insect pests. On a global level, the management of our planet's biosphere, with the challenges of pollution and global warming, increasingly depends on our understanding of microbial ecology.

Figure 1.33 **Microbiologists at work.** Students at Kenyon College conduct research on bacterial gene expression.

TO SUMMARIZE:

- **Genetics of bacteria, bacteriophages, and fungi** in the early twentieth century revealed fundamental insights about gene transmission that apply to all organisms.
- **Structure and function of the genetic material, DNA** was revealed by a series of experiments in the twentieth century.
- **Molecular microbiology generated key advances**, such as the use of restriction enzymes, the cloning of the first recombinant molecules, and the invention of DNA-sequencing technology.
- **Genome sequence determination and bioinformatic analysis** became the tools that shape the study of biology in the twenty-first century.
- **Microbial discoveries transformed medicine and industry.** Biotechnology enables the production of new kinds of pharmaceuticals and industrial products.

Concluding Thoughts

The advances in microbial science raise important questions for society. Who shall bear the growing costs of sophisticated research on microbial pathogens? Should genetically modified bacteria be released into the environment for agriculture to increase crop yield? Should deadly viruses be engineered as vectors for gene therapy?

This book explores the current explosion of knowledge about microbial cells, genetics, and ecology. We introduce the applications of microbial science to human affairs, from medical microbiology to environmental science. Most importantly, we discuss research methods—how scientists make the discoveries that will shape tomorrow's view of microbiology. In the rest of Part 1, Chapter 2 presents the visualization tools that make possible our increasingly detailed view of the structures of cells (Chapter 3) and viruses (Chapter 6). Chapters 4 and 5 introduce microbial nutrition and growth in diverse habitats, including new information derived from the sequencing of microbial genomes. Throughout, we invite readers to share with us the excitement of discovery in microbiology.

CHAPTER REVIEW

Review Questions

1. Explain the apparent contradictions in defining microbiology as the study of microscopic organisms or the study of single-celled organisms.
2. What is the genome of an organism? How do genomes of viruses differ from those of cellular microbes?
3. Under what conditions might microbial life have originated? What evidence supports current views of microbial origin?
4. List the ways in which microbes have affected human life throughout history.
5. Summarize the key experiments and insights that shaped the controversy over spontaneous generation. What key questions were raised, and how were they answered?
6. Explain how microbes are cultured on liquid and solid media. Compare and contrast the culture methods of Koch and Winogradsky. How did their different approaches to microbial culture address different questions in microbiology?
7. Explain how a series of observations of disease transmission led to development of immunization to prevent disease.
8. Summarize key historical developments in our view of microbial taxonomy. What attributes of microbes have made them challenging to classify?
9. Explain how various discoveries in "natural" bacterial genetics were used to develop recombinant DNA technology.

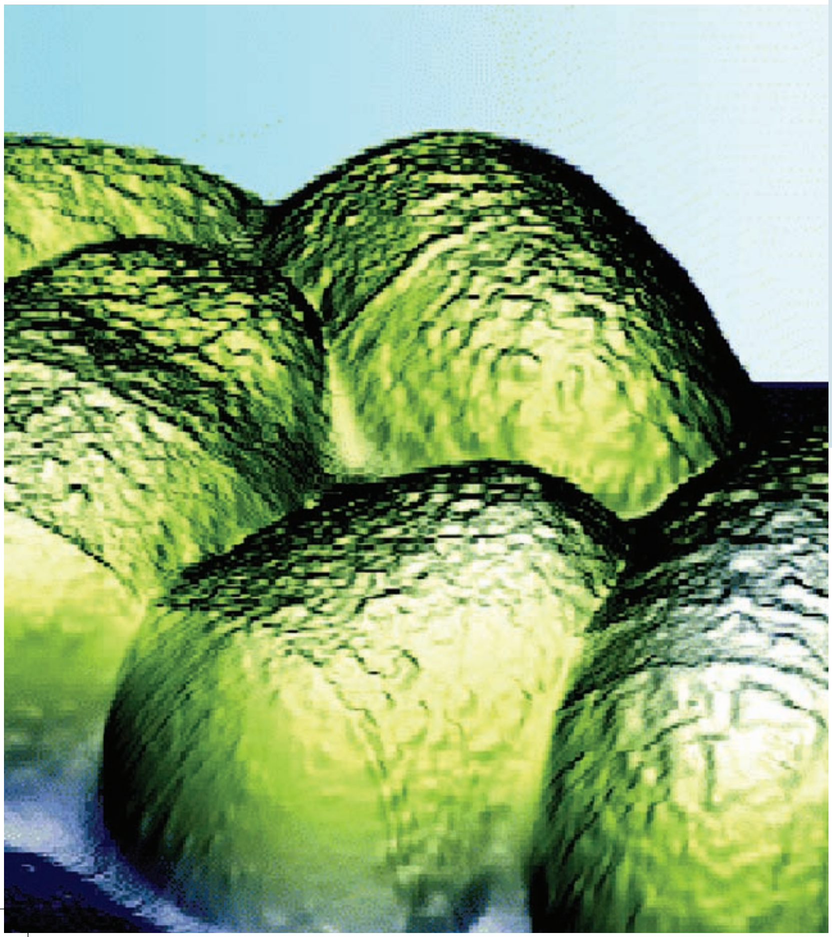
Chapter 2

Observing the Microbial Cell

2.1 Observing Microbes
2.2 Optics and Properties of Light
2.3 Bright-Field Microscopy
2.4 Dark-Field, Phase-Contrast, and Interference Microscopy
2.5 Fluorescence Microscopy
2.6 Electron Microscopy
2.7 Visualizing Molecules

Microscopy reveals the vast realm of bacteria and protists invisible to the unaided eye. The microbial world spans a wide range of size—over several orders of magnitude. For different size ranges, we use different instruments, from the simple bright-field microscope to the electron microscope. The microscope enables us to count the number of microbes in the human bloodstream or in dilute natural environments such as the ocean. It shows how microbes swim and respond to signals such as a new food source.

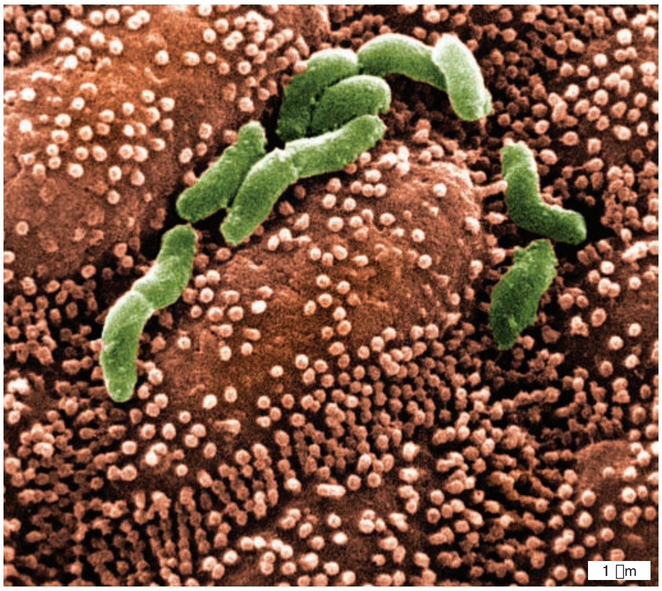
Advanced forms of microscopy reveal microbes in remarkable detail. Fluorescence microscopy shows how microbial cells develop and reproduce. Electron microscopy explores the cell's interior, showing how all the parts of the cell fit together. The electron microscope is used to build models of viruses, and to probe the subcellular structures of membranes, ribosomes, and flagellar motors. Scanning probe microscopy images live microbes with an unprecedented degree of realism.



Atomic-force microscopic image (AFM) of *Corynebacterium glutamicum* cells, showing the contours of their formidable S-layer. Each cell is 1.0–1.5 µm in length, and about 0.7 µm in diameter. *C. glutamicum* is a major industrial producer of amino acids and vitamins. *Source:* Nicole Hansmeier, et al. 2006. *Microbiology* 152:923–935. Photo from Hansmeier, et al. 2006. *SGM Microbiology* No. 4.

When the microscope of Antoni van Leeuwenhoek (1632–1723) first revealed the tiny life-forms on his teeth, scientists in England refused to believe it until their own instruments showed the same. Van Leeuwenhoek's superior lenses were key to his success. Since the time of van Leeuwenhoek, microscopists have devised ever more powerful instruments to search for microbes in unexpected habitats.

An example of such a habitat is the human stomach, long believed too acidic to harbor life. In the 1980s, however, Australian scientist Barry Marshall reported finding a new species of bacterium in the stomach. The bacteria, *Helicobacter pylori*, proved difficult to isolate and culture, and for over a decade, medical researchers refused to believe Marshall's report. Ultimately, electron microscopy (EM) confirmed the existence of *H. pylori* in the stomach and helped document its role in gastritis and stomach ulcers. The scanning electron micrograph in **Figure 2.1** shows *H. pylori* colonizing the gastric crypt cells. *H. pylori* bacteria are comma-shaped rods with a polar tuft of flagella. The contours of cells and flagella are well resolved by the scanning beam of electrons, an achievement far beyond that possible with a light microscope.



Veronika Burmeister/Visuals Unlimited

Figure 2.1 ***Helicobacter pylori* within the crypt cells of the stomach lining.** Microscopy demonstrated the presence of *H. pylori*, the causes of stomach ulcers, growing on the lining of the human stomach, a location previously believed too acidic to permit microbial growth. Scanning electron micrograph, colorized to indicate bacteria (green).

Today, various kinds of microscopes are used in many settings, from hospitals and veterinary clinics to industrial plants and wastewater treatment facilities. This chapter covers two areas:

- **Light microscopy.** The theory and practice of light microscopy are essential for every student and professional observing microorganisms.
- **Advanced tools for research.** Fluorescence microscopy, electron microscopy, and X-ray diffraction crystallography probe ever farther the frontiers of the unseen.

2.1 Observing Microbes

Most microbes are too small to be seen; that is, they are microscopic, requiring the use of a **microscope** to be seen. But why can't we see microbes without magnification? The answer is surprisingly complex. In fact, our definition of "microscopic" is based not on inherent properties of the organism under study, but on the properties of our eyes. What is "microscopic" actually lies in the eye of the beholder.

Resolution of Objects by Our Eyes

The size at which objects become visible depends on the resolution of the observer's eye. **Resolution** is the smallest distance by which two objects can be separated and still be distinguished. In the eyes of humans and other animals, resolution is achieved by focusing an image on a retina packed with light-absorbing photoreceptor cells (**Fig. 2.2**). A group of photoreceptors with their linked neurons forms one unit of detection, comparable to a pixel on a computer screen. The distance between two retinal "pixels" limits resolution.

The resolution of the human retina (that is, the length of the smallest object most human eyes can see) is about 150 μm, or one-seventh of a millimeter. In the retinas of eagles, photoreceptors are more closely packed, so an eagle can resolve objects eight times as small or eight times as far away as a human can; hence, the phrase "eagle-eyed" means sharp-sighted. On the other hand, insect compound eyes have one-hundredth the resolution of human eyes because their receptor cells are farther apart than ours. If a science-fictional giant ameba had eyes with a retinal resolution of 2 meters (m), it would perceive humans as we do microbes.

NOTE: In this book, we use standard metric units for size:

1 millimeter (mm) = one thousandth of a meter
= $\mathbf{10^{-3}}$ **m**
1 micrometer (μm) = one thousandth of a millimeter
= $\mathbf{10^{-6}}$ **m**
1 nanometer (nm) = one thousandth of a micrometer
= $\mathbf{10^{-9}}$ **m**
1 picometer (pm) = one thousandth of a nanometer
= $\mathbf{10^{-12}}$ **m**

Some authors still use the traditional unit **angstrom (Å)**, which equals a tenth of a nanometer, or 10^{-10} m.

Figure 2.2 Defining the microscopic. We define what is visible and what is microscopic in terms of the human eye. Within the human eye, the lens focuses an image on the retina. Adjacent light receptors are sufficiently close to resolve the image of a human being, even at a distance where its apparent height shrinks to a millimeter.

Resolution Differs from Detection

Objects of sizes below the resolution limit may yet be *detected;* that is, we can observe their presence as a group. Thus, our eyes can detect a large population of microbes, such as a spot of mold on a piece of bread (about a million cells) or a cloudy tube of bacteria in liquid culture (a million cells per milliliter; **Fig. 2.3A**). **Detection**, the ability to determine the presence of an object, differs from resolution. When the unaided eye detects the presence of mold or bacteria, it cannot resolve individual cells. To resolve bacterial cells, such as those of the wetland phototroph *Rhodospirillum rubrum* (**Fig. 2.3B**), requires magnification. In microscopy, **magnification** means to increase the apparent size of an image so as to resolve smaller separations between objects and thus increase the information obtained by our eyes.

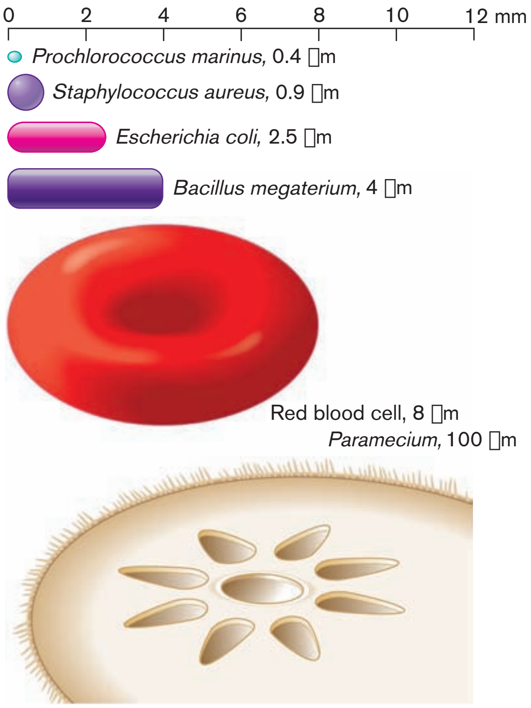
Figure 2.3 Detecting and resolving bacteria. A. A tube of bacterial culture, *Rhodospirillum rubrum*. Bacterial cells are detected, though not resolved. **B.** Bright-field image. Individual cells of *R. rubrum* are resolved.

Microbial Size and Shape

Different kinds of microbes differ in size, over a range of several orders of magnitude, or powers of ten (**Fig. 2.4**). Eukaryotic microbes are often sufficiently large (10–100 µm)



0
2
4
6
8

Bacillus megaterium, 4 µm
Red blood cell, 8 µm
Paramecium, 100 µm

Figure 2.4 Relative sizes of different cells. Microbial cells come in various sizes, most of which are below the threshold of resolution by the unaided human eye (150 µm). Note that most bacteria are much smaller than the human red blood corpuscle, a small eukaryotic cell.

that we can resolve their compartmentalized structure under a light microscope. Prokaryotes (bacteria and archaea) are generally smaller (0.4–10 μm); thus, their overall size can be seen, but their internal structures are too small to be resolved. Nevertheless, a few bacterial species, such as *Thiomargarita namibiensis*, are large enough to be seen without a microscope, while many unculturable marine eukaryotes are as small as the smallest bacteria. Thus, the actual size ranges of eukaryotic and prokaryotic microbes overlap substantially.

Many eukaryotes, such as protists and algae, can be resolved under low-power magnification to reveal internal and external structures such as the nucleus, vacuoles, and flagella (**Fig. 2.5**). Protists show complex shapes and appendages. For example, amebas from an aquatic ecosystem show large nuclei and pseudopods to engulf prey (**Fig. 2.5A**). Pseudopods can be seen to move through streaming of their cytoplasm. Another protist readily observed by light microscopy is *Giardia lamblia*, a water contaminant that causes outbreaks of intestinal illness in cities and day-care centers (**Fig. 2.5B**). In the *Giardia* cell, we observe two nuclei and multiple flagella. Eukaryotic flagella propel the cell by a whiplike action. Similarly, we can observe the complex internal patterns of chloroplasts in algae and the exceptional variety of crystalline forms in diatoms. For more on microbial eukaryotes, see Chapter 20.

Prokaryotic cell structures are generally simpler than those of eukaryotes (see Chapter 3). **Figure 2.6** shows representative members of several common cell types, as visualized by light microscopy or by scanning electron microscopy. Note that with light microscopy, the cell shape is barely discernable under the highest power. With scanning electron microscopy, the shapes appear clearer, but we still see no subcellular structures. Subcellular structures are best visualized with transmission electron microscopy and fluorescence microscopy (discussed below).

Certain shapes of bacteria are common to many taxonomic groups (**Fig. 2.6**). For example, both bacteria and archaea form similarly shaped **rods**, or **bacilli**, and **cocci** (spheres). Thus, rods and spherical shapes have evolved independently within different taxa. On the other hand, a unique bacterial shape is seen in the **spirochetes**, which cause diseases such as syphilis and Lyme disease. Spirochetes possess an elaborate spiral structure with internal axial filaments and flagella as well as an outer sheath (for more on spirochetes, see Section 18.7). Spiral axial filaments are found only within the spirochete group of closely related species.

LM, Magnification ×100 at 35 mm size. **B.** *Pseudomonas* sp., rod-shaped bacteria, are barely resolved. LM, Magnification ×1200. **C.** Internal structures of the bacterium *Escherichia coli* are revealed by transmission electron microscopy (TEM). Magnification ×32,000. **D.** Individual ribosomes are attached to the messenger RNA molecules that are translated to make peptides (TEM). Magnification ×150,000. **E.** A ribosome (diameter, 21 nm) cannot be observed directly but can be modeled using X-ray crystallography.

NOTE: The genus name *Bacillus* refers to a specific taxonomic group of bacteria, but the term *bacillus* (plural, bacilli) refers to any rod-shaped bacterium or archaeon.

Microscopy for Different Size Scales

To resolve microbes and microbial structures of different sizes requires different kinds of microscopes. **Figure 2.7** shows the different techniques used to resolve microbes and structures of various sizes. For example, a paramecium can be resolved under a light microscope, but an individual ribosome requires electron microscopy.

- **Light microscopy** resolves images of individual bacteria based on their absorption of light. The specimen is commonly viewed as a dark object against a light-filled field, or background; this is called **bright-field microscopy** (seen in **Figs. 2.7A, B**). Advanced techniques, based on special properties of light, include dark-field, phase-contrast, and fluorescence microscopy.
- **Electron microscopy (EM)** uses beams of electrons to resolve details several orders of magnitude smaller than those seen under light microscopy. In **scanning electron microscopy (SEM)**, the electron beam is scattered from the metal-coated surface of an object, generating an appearance of three-dimensional depth. In **transmission electron microscopy (TEM)** (**Figs. 2.7C, D**), the electron beam travels through the object, where the electrons are absorbed by an electron-dense metal stain.
- **Atomic force microscopy (AFM)** uses van der Waals forces between a probe and an object to map the three-dimensional topography of a cell.
- **X-ray crystallography** detects the interference pattern of X-rays entering the crystal lattice of a molecule. From the interference pattern, researchers build a computational model of the structure of the individual molecule, such as a protein or a nucleic acid, or even a molecular complex such as a ribosome (**Fig. 2.7E**).
- **Nuclear magnetic resonance (NMR)** imaging provides structural information based on the magnetic properties of atomic nuclei.

THOUGHT QUESTION 2.1 You have discovered a new kind of microbe, never observed before. What kind of questions about this microbe might be answered by light microscopy? What questions would be better addressed by electron microscopy?

TO SUMMARIZE:

- **Detection** is the ability to determine the presence of an object.
- **Resolution** is the smallest distance by which two objects can be separated and still be distinguished.
- **Magnification** means an increase in the apparent size of an image so as to resolve smaller separations between objects.
- **Eukaryotic microbes may be large enough to resolve subcellular structures** under a light microscope, although some eukaryotes are as small as bacteria.
- **Bacteria and archaea are usually too small for subcellular resolution.** Their shapes include characteristic forms, such as rods and cocci.
- **Different kinds of microscopy** are required to resolve cells and subcellular structures of different sizes.

2.2 Optics and Properties of Light

Light microscopy directly extends the lens system of our own eyes. Light is part of the spectrum of electromagnetic radiation (**Fig. 2.8**), a form of energy that is propagated as waves associated with electrical and magnetic fields. Regions of the electromagnetic spectrum are defined by wavelength, which for visible light is about 400–750 nm. Radiation of longer wavelengths includes infrared and radio waves, whereas shorter wavelengths include ultraviolet rays and X-rays.

Light Carries Information

All forms of electromagnetic radiation carry information from the objects with which they interact. The information carried by radiation can be used to detect objects; for example, radar (using radio waves) detects a speeding car. All electromagnetic radiation travels through a vacuum at the same speed (*c*), about 3×10^8 meters per second (m/s). The speed of light (*c*) is equal to the wavelength (λ) of the radiation multiplied by its frequency (ν), the number of wave cycles per unit time. Frequency is usually measured in hertz (Hz), reciprocal seconds:

$$c = \lambda\nu$$

Because *c* is constant, the longer the wavelength λ, the lower the frequency ν.

For electromagnetic radiation to resolve an object from neighboring objects or from its surrounding medium, certain conditions must exist:

400 nm

Figure 2.8 Electromagnetic energy. **A.** Electromagnetic radiation is composed of electrical and magnetic waves perpendicular to each other. **B.** The electromagnetic spectrum includes the visual range, used in light microscopy.

- **Contrast between the object and its surroundings.** **Contrast** is the difference in light and dark. If an object and its surroundings absorb or reflect radiation equally, then the object will be undetectable. Thus, it is hard to observe a cell of transparent cytoplasm floating in water because the aqueous cytoplasm and the extracellular water tend to transmit light similarly, producing little contrast.
- **Wavelength smaller than the object.** For an object to be resolved, the wavelength of the radiation must be equal to or smaller than the size of the object. If the wavelength of the radiation is larger than the object, then most of the wave's energy will simply pass through it, like an ocean wave passing around

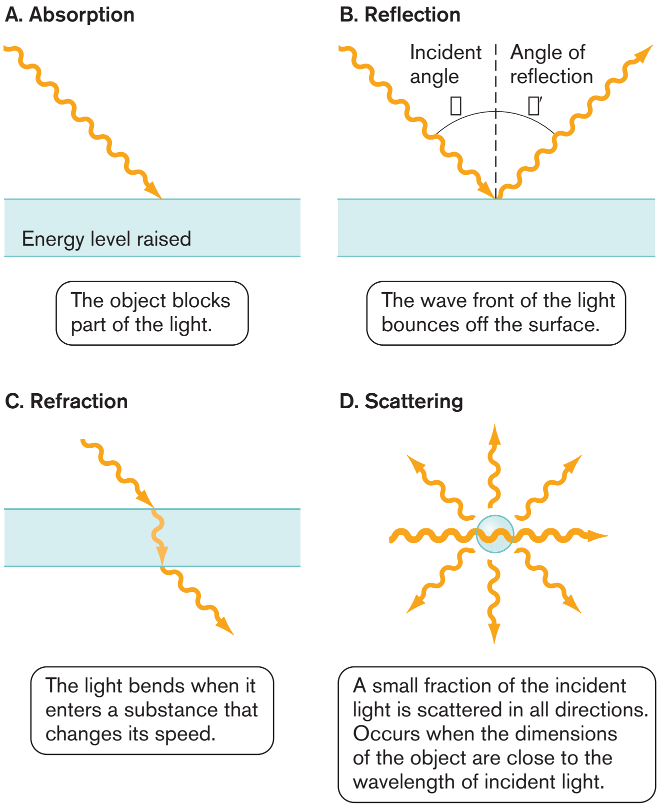
a dock post. Thus, radar, with a wavelength of 1–100 centimeters (cm), cannot resolve microbes, though it easily resolves cars and people.

- **A detector with sufficient resolution for the given wavelength.** The human eye has a retina with photoreceptors that absorb radiation within a narrow range of wavelengths, 400–750 nm (0.40–0.75 μm), which we define as “visible light.” But the distance between our retinal photoreceptors is 150 μm, about 500 times the wavelength of light. Thus, our eyes are unable to access all the information contained in the light that enters. In order for us to exploit the full information capacity of light, the light rays from point sources of light must be spread apart sufficiently to be resolved by our retinal photoreceptors. The spreading of the light rays results in magnification of the image.

Light Interacts with an Object

The physical behavior of light in some ways resembles a beam of particles and in other ways a waveform. The particles of light are called photons. Each photon has an associated wavelength that determines how the photon will interact with a given object. The combined properties of particle and wave enable light to interact with an object in several different ways: absorption, reflection, refraction, and scattering.

- **Absorption** means that the photon’s energy is acquired by the absorbing object (**Fig. 2.9A**). The energy is converted to a different form, usually heat (infrared radiation), a form of electromagnetic radiation of longer wavelength than light. When a microbial specimen absorbs light, it can be observed as a dark spot against a bright field, as in bright-field microscopy. Some molecules that absorb light of a specific wavelength reemit energy not as heat, but as light with a longer wavelength; this is called **fluorescence**. Fluorescence is also used in microscopy (discussed later).
- **Reflection** means that the wave front redirects from the surface of an object at an angle equal to its incident angle (**Fig. 2.9B**). Reflection of light waves is analogous to the reflection of water waves. Reflection from a silvered mirror or a glass surface is used in the optics of microscopy.
- **Refraction** is the bending of light as it enters a substance that slows its speed (**Fig. 2.9C**). Such a substance is said to be “refractive” and, by definition, has a higher **refractive index** than air. Refraction is the key property that enables a lens to magnify an image.
- **Scattering** occurs when a portion of the wave front is converted to a spherical wave originating from the object (**Fig. 2.9D**). If a large number of particles simultaneously scatter light, a haze is observed—for example, the haze of bacteria suspended in a culture tube. Special optical arrangements (such as **dark-field microscopy**, discussed later) can use scattered light to detect (but not resolve) microbial shapes smaller than the wavelength of light.



A. Absorption

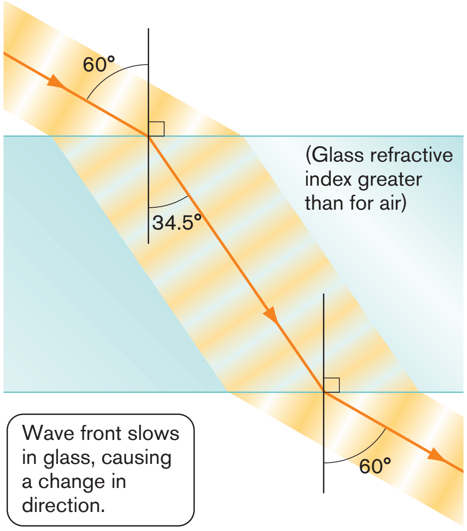
D. Scattering
A small fraction of the incident light is scattered in all directions. Occurs when the dimensions of the object are close to the wavelength of incident light.

Figure 2.9 Interaction of light with matter.

Refraction Enables Magnification

Magnification requires refraction of light through a medium of high refractive index, such as glass. As a wave front of light enters a refractive material, the region of the wave that first reaches the material is slowed, while the rest of the wave continues at its original speed until it also passes into the refractive material (**Fig. 2.10**). As the entire wave front continues through the refractive material, its path continues at an angle from its original direction. At the opposite face of the refractive material, the wave front resumes its original speed.

THOUGHT QUESTION 2.2 Explain what happens to the refracted light wave as it emerges from a piece of glass of even thickness. How does its new speed and direction compare with its original (incident) speed and direction?



60°
(Glass refractive index greater than for air)
34.5°
Wave front slows in glass, causing a change in direction.
60°

Light rays entering lens
Focus
A wider parabola has a more distant focal point.
Focus
A narrower parabola has a closer focal point.

Figure 2.11 The focus of a parabola. The wider the parabola, the more distant the focal point.

Refraction magnifies an image when light passes through a refractive material shaped so as to spread its rays, widening the wave front. The shape that accomplishes this widening is that of a parabola. Light rays entering a parabolic surface are focused; that is, they are each bent at an angle such that all rays meet at a certain point, called the focus of the parabola (**Fig. 2.11**).

In a lens, a parabolic surface focuses impinging light rays. Parallel light rays entering the lens emerge at angles so as to intersect each other at the **focal point**, equivalent to the focus of the parabola (**Fig. 2.12**). From the focal point, the light rays continue onward in an expanding wave front. This expansion magnifies the image carried by the wave. The distance from the lens to the focal point (called the focal distance) is determined by the degree of parabolic curvature of the lens and by the refractive index of its material.

In **Figure 2.12**, the object under observation is placed just outside the **focal plane**, a plane containing the focal point of the lens. All light rays from the object are bent by the lens, converging at the opposite focal point. At the focal point, the light rays continue through until they converge with nonparallel light rays refracted by the lens. The plane of convergence generates a reversed image of the object. The image is expanded, or magnified, by the spreading out of refracted rays. The distances between parts of the image are enlarged, enabling our eyes to resolve finer details.

WWW | FSU Tutorial on Magnification

THOUGHT QUESTION 2.3 Parabolic lenses are generally "biconvex," that is, curving outward on both sides. What would happen to parallel light rays that pass through a lens that is concave on both sides? Or a lens that is convex on one side and concave with equal curvature on the other?

Magnification and Resolution

The spreading of light rays does not necessarily increase resolution. For example, an image composed of dots does not gain detail when enlarged on a photocopier, nor does an image composed of pixels gain detail when enlarged on a computer screen. In these cases, resolution fails to increase because the individual details of the image expand in proportion to the expansion of the overall image. Magnification without increase in resolution is called **empty magnification**.

The resolution of detail in microscopy is limited by the degree to which details "expand" with magnification. This expansion of detail is limited by the interference of light rays converging at the focal point. In **interference**, two wave fronts interact by addition (amplitudes in phase) or subtraction (amplitudes out of phase) (**Fig. 2.13A**). The result of interference between two waves is a pattern of alternating zones of constructive and destructive interference (brightness and darkness) (**Fig. 2.13B**).

In theory, a perfect lens that focuses all the light from an object should have no interference as its rays

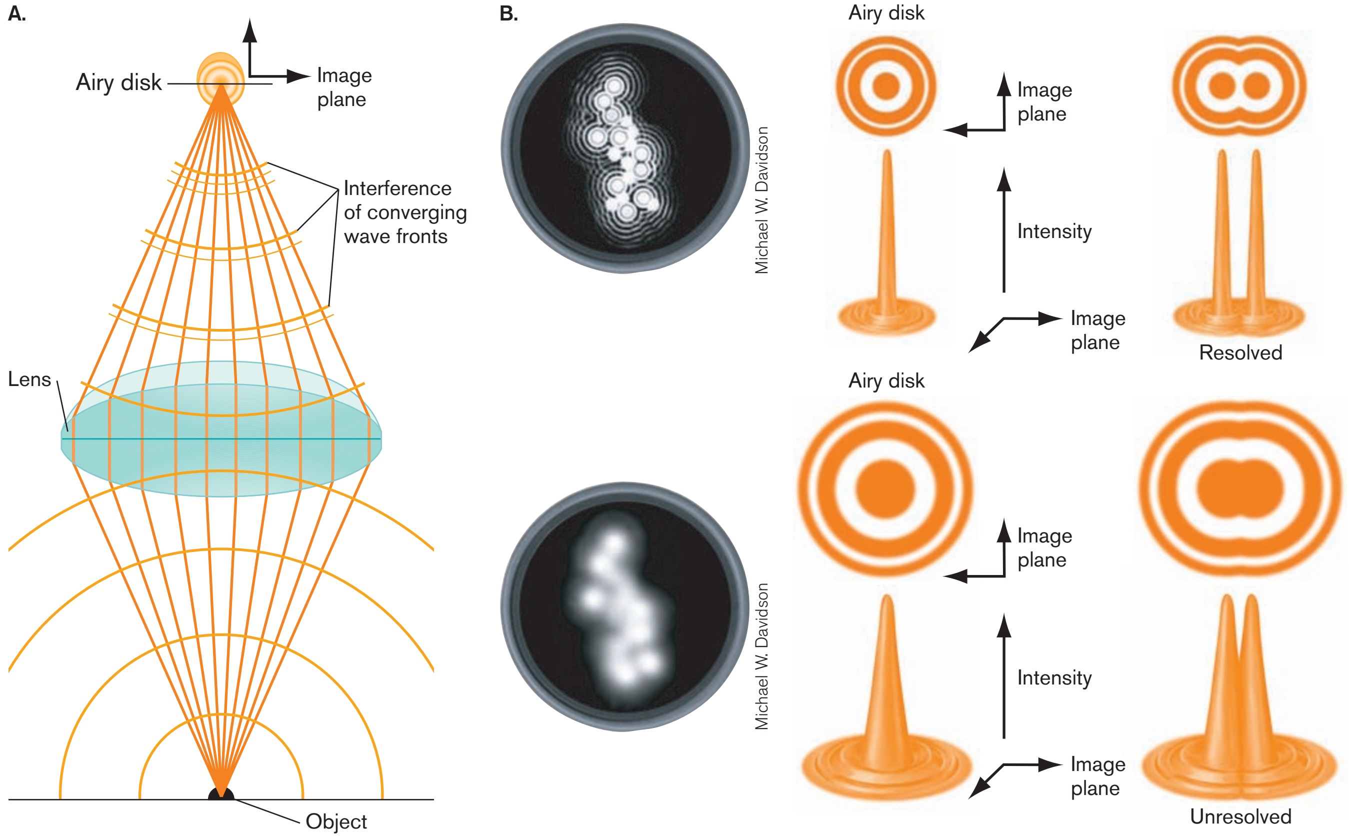
Intensity of interfering waves is proportional to peak height squared.

Figure 2.13 Constructive (additive) and destructive (subtractive) interference of light waves. A. In constructive interference, the peaks of the two wave trains rise together; their amplitudes are additive, creating a wave of greater amplitude. In destructive interference, the peaks of the waves are opposite one another, so their amplitudes cancel, creating a wave of lesser amplitude. **B.** Two wave fronts approaching at an angle generate an interference pattern in which intensity alternately increases and decreases.

converge toward the focal point. In fact, however, the outer edges of the lens introduce imperfection. The converging edges of the wave interfere with each other to create alternating regions of light and dark. At the focal point, the interference forms a central sphere of intensity surrounded by a series of concentric spheres of alternating light and dark (**Fig. 2.14A**). The viewing plane intersects the concentric spheres to form an **Airy disk**, a disk containing a bright central peak surrounded by rings of light and dark. The Airy disk was originally discovered by the astronomer George Airy (1801–1892), who showed that the stars viewed through a telescope could never appear as true point sources, but only as tiny disks of light surrounded by rings. The same principle applies to objects viewed under a microscope.

WWW | FSU Tutorial on Airy Disk



Michael W. Davidson

Michael W. Davidson

Figure 2.14 Interference of light waves at the focal point generates an Airy disk. A. The interference of converging spherical wave fronts creates a sphere with a central zone of maximum intensity, surrounded by alternating zones of bright and dark. A plane section through the sphere generates the Airy disk. **B.** The Airy peak and its surrounding rings.

The width of the Airy disk—and hence the limit to resolution of detail—depends on the wavelength of light and the quality of the lens. The shorter the wavelength, the narrower the Airy disk. In addition, the central peak of intensity is sharpest when the specimen is at the focal point, where the specimen is said to be in **focus**.

Suppose an object consists of a collection of point sources of light. Each point source generates an Airy disk of rings surrounding one central peak of intensity. The width of the central peak increases with distance away from the focal point. This width will define the resolution, or separation distance, between any two points of the object (**Fig. 2.14B**). Full resolution is achieved for two points when there is complete separation of the central peaks of the two Airy disks. This resolution distance determines the degree of detail that can be observed along the edge of an object.

TO SUMMARIZE:

- **Electromagnetic radiation** interacts with an object and acquires information we can use to detect the object.
- **Contrast** between object and background makes it possible to detect the object and resolve its component parts.
- **The wavelength of the radiation** must be equal to or smaller than the size of the object if we are to resolve its shape.
- **Absorption** means that the energy from light (or other electromagnetic radiation) is acquired by the object.
- **Reflection** means that the wave front bounces off the surface of a particle at an angle equal to its incident angle.
- **Refraction** is the bending of light as it enters a substance that slows its speed.
- **Scattering** occurs when a wave front interacts with an object of smaller dimension than the wavelength. Light scattering enables detection of objects whose detail cannot be resolved.

2.3 Bright-Field Microscopy

In bright-field microscopy, an object such as a bacterial cell is perceived as a dark silhouette blocking the passage of light. Details of the dark object are defined by the points of light surrounding its edge.

Increasing Resolution

The optics of a modern bright-field microscope are designed to maximize detail under magnification by a lens. In maximizing the resolution, the following factors need to be considered:

- **Wavelength.** The theoretical maximum magnification can be calculated as the resolution distance of our retina (0.15 mm, or 150,000 nm) divided by the average wavelength of light (550 nm, for green). This gives an approximately 300-fold magnification with increasing resolution. Additional optical factors can bring this magnification closer to 1,000×, although full resolution is rarely reached in practice. Any greater magnification expands only the width of the interference patterns; the image becomes larger but with no greater resolution (empty magnification).
- **Light and contrast.** For any given lens system, there is an optimal amount of light that yields the highest contrast between the dark specimen and the light background. High contrast is needed to achieve the maximum resolution at high magnification.
- **Lens quality.** All lenses possess inherent **aberrations** that detract from perfect parabolic curvature. Instead of trying to grind a "perfect" single lens, modern manufacturers construct microscopes with a series of lenses that multiply each other's magnification and correct for aberrations.

Let us first consider magnification of an image by a single lens. The principles described would hold for any lens. **Figure 2.15** shows an **objective lens**, a lens situated directly above an object or specimen that we wish to observe at high resolution. How can we maximize the resolution of details in the image?

An object at the focal point of a lens sits at the tip of an inverted light cone formed by rays of light from the lens converging at the object. The angle of the light cone is determined by the curvature and refractive index of the lens. The lens fills an aperture, or hole, for the passage of light; and for a given lens, the light cone is defined by an angle θ (theta) projecting from the midline, known as the **angle of aperture**. As θ increases and the horizontal width of the light cone (sin θ) increases, a wider cone of light passes through the specimen. The wider cone of light rays improves the precision of the image by lessening the proportion of edge interference between wave fronts, thereby narrowing the width of the Airy disk interference pattern. Another way to say this is that as sin θ increases, the resolvable distance decreases. Thus, the greater the angle of aperture of the lens, the better the resolution.

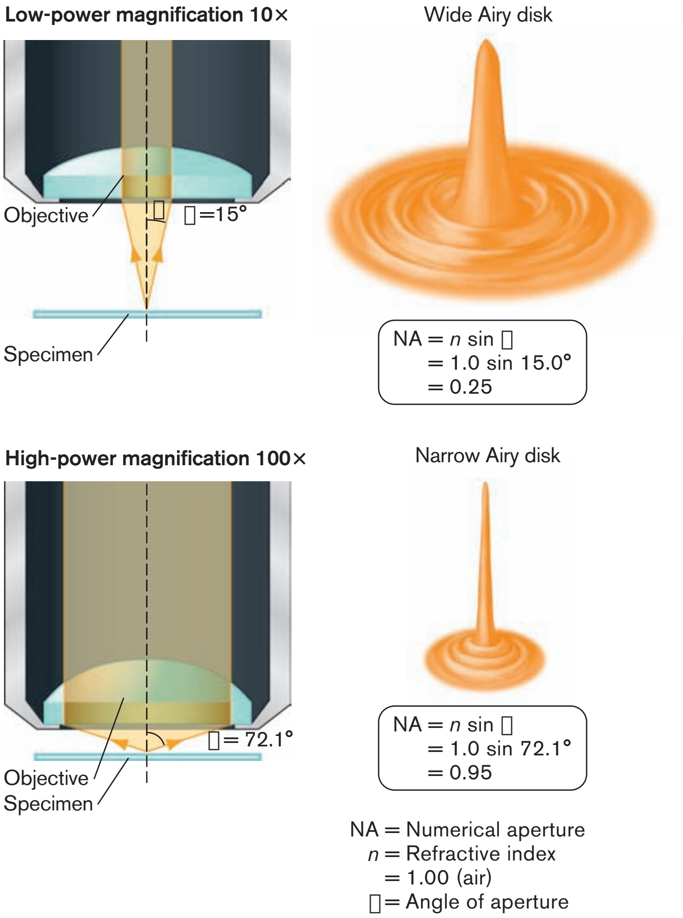


Figure 2.15 Resolution and numerical aperture. The resolution depends on numerical aperture (NA), which equals the refractive index (n) of the medium containing the light cone multiplied by the sine of the angle of the light cone (θ). Higher magnification occurs at higher NA.

THOUGHT QUESTION 2.4 In theory, what angle θ would produce the highest resolution? What practical problem would you have in designing a lens to generate this light cone?

Resolution also depends on the refractive index of the medium containing the light cone, which is usually air. The refractive index is the ratio of the speed of light in a vacuum to its speed in another medium. For air, the refractive index (n) is taken as 1, whereas lens material has a refractive index greater than 1. The lens bends the light spreading at an angle (θ). The product of the refractive index (n) of the medium times sin θ is the **numerical aperture** (NA):

$$\mathrm{NA} = n \sin \theta$$

In **Figure 2.15**, we see the calculation of NA for an objective lens of magnification 10×, and for a lens magnification

100×. As NA increases, the magnification power of the lens increases, although the increase is not linear. Note that as the lens strength increases and the light cone widens, the lens must come nearer the object. Defects in lens curvature become more of a problem, and focusing becomes more challenging. As □ becomes very wide, too much of the light from the object is lost owing to refraction at the glass-to-air interface. The greater the refractive index of the medium between the object and the objective lens, the more light can be collected and focused. For the highest-power objective lens, generally 100×, a zone of even refractive index is maintained by insertion of **immersion oil** with a refractive index comparable to that of glass (n = 1.5) (**Fig. 2.16**). Immersion oil minimizes loss of light rays at the widest angles and makes it possible to reach 100× magnification with minimal distortion.

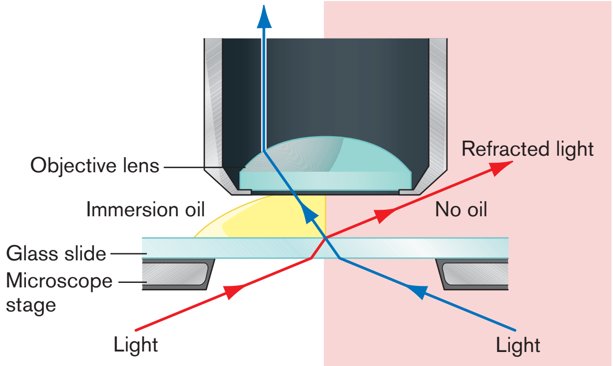

Figure 2.16 **Use of immersion oil in microscopy.** Immersion oil with a refractive index comparable to that of glass (n = 1.5) prevents light rays from bending away from the objective lens. Thus, more light is collected, NA increases, and resolution improves.

The Compound Microscope

The manufacture of higher-power lenses is difficult owing to decreasing tolerance for aberration. For this reason, we rarely observe through a single lens. Instead we use a **compound microscope**, a system of multiple lenses designed to correct or compensate for aberration. A typical arrangement of a compound microscope is shown in **Figure 2.17**. In this arrangement, the light source is placed at the bottom, shining upward through a series of lenses, including the condenser, objective, and ocular lenses.

The **condenser** consists of one or more lenses that focus parallel light rays from the light source onto a small area of the slide. The condensed light rays generate a narrower Airy interference pattern and thus improve the resolution of the objective lens.

Between the light source and the condenser sits a **diaphragm**, a device to vary the diameter of the light column. Lower-power lenses require operation at lower light levels because the excess light makes it impossible to observe the darkening effect of absorbance by the specimen (contrast). Higher-power lenses require more light and thus an open diaphragm.

The nosepiece of a compound microscope typically holds three or four objective lenses of different magnifying power, such as 4□, 10□, 40□, and 100□ (requiring immersion oil). These lenses are arranged so as to rotate in turn into the optical column. A high-quality instrument will have the lenses set at different heights from the slide so as to be **parfocal**. In a parfocal system, when an object is focused using one lens, it remains in focus, or nearly so, when another lens is rotated to replace the first.

NOTE: Objective lenses can be obtained in several different grades of quality, manufactured with different kinds of correction for aberrations. Lenses should feature at minimum the following corrections: "plan" correction for field curvature, to generate a field that appears flat, and "apochromat" correction for spherical and chromatic aberrations.

The image from the objective lens is amplified by a secondary focusing step through the **ocular lens**. The

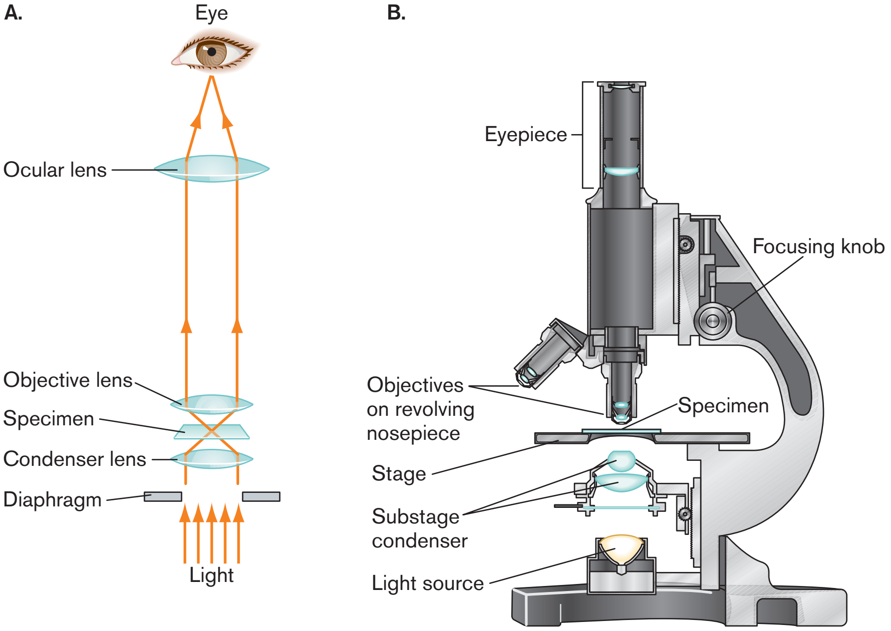

Figure 2.17 **The anatomy of a compound microscope.** **A.** Light path through a compound microscope. **B.** Cutaway view of a compound microscope.

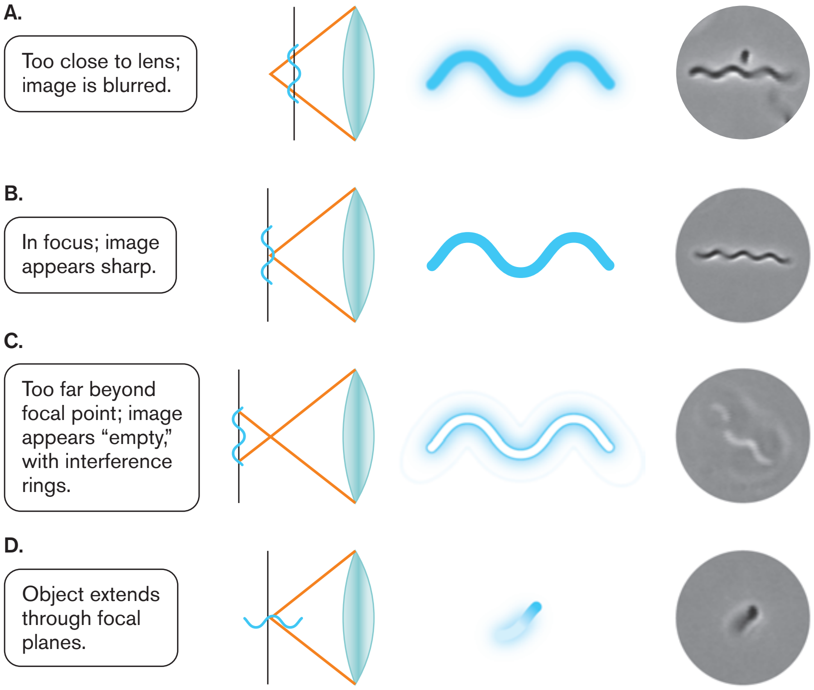
ocular lens sits directly beneath the observer's eye. In the process of magnification, each light ray traces a path toward a position opposite its point of origin, thus creating a mirror-reversed image. This reversal must be kept in mind when exploring a field of cells. Research-grade microscopes include a series of ocular and objective lenses.

The magnification factor of the ocular lens is multiplied by the magnification factor of the objective lens to generate the **total magnification** (power). For example, a 10× ocular times a 100× objective generates 1,000× total magnification.

Observing a specimen under a compound microscope requires several steps:

- **Position the specimen centrally in the optical column.** Only a small area of a slide can be visualized within the field of view of a given lens. The higher the magnification, the smaller the field of view will be seen.
- **Optimize the amount of light.** At lower power, too much light will wash out the light absorption of the specimen without contributing to magnification. At higher power, more light needs to be collected by the condenser. To optimize light, the condenser must be set at the correct vertical position to focus on the specimen, and the diaphragm must be adjusted to transmit the amount of light that produces the best contrast.
- **Focus the objective lens.** The focusing knob permits adjustment of the focal distance between the objective lens and the specimen on the slide so as to bring the specimen into the focal plane. Typically, we focus first using a low-power objective, which generates a greater **depth of field**—that is, a region along the optical column over which the object appears in reasonable focus. After focusing under low power, we can rotate a higher-power lens into view, then perform a smaller adjustment of focus.



A.
Too close to lens; image is blurred.
B.
In focus; image appears sharp.
C.
Too far beyond focal point; image appears "empty," with interference rings.
D.
Object extends through focal planes.

Steffen Klamt, U. Magdeburg

Figure 2.18 ***Rhodospirillum rubrum*** **observed at different levels of focus.** **A.** When a bacterium swims too close to the lens, its image blurs. **B.** When the bacterium lies within the focal plane, its image appears sharp. If the width of the cell crosses several focal planes, some parts appear sharp, whereas other parts appear blurred. **C.** When the bacterium lies too far from the lens, its image appears "empty" or "hollow," surrounded by rings of Airy-like interference. **D.** When the spirillum extends through the focal plane, different parts show different focal effects (in focus, too near, or too far).

Is the Object in Focus?

An object appears in focus (that is, is situated within the focal plane of the lens) when its edge appears sharp and distinct from the background. At higher power, however, recognition of the focal plane is a challenge because of Airy-like interference. The shape of the dark object is actually defined by the points of light surrounding its edge. The partial resolution of these points of light generates extra rings of light surrounding an object whose dimensions are close to the resolution limit.

In **Figure 2.18**, we see microscopic observation of *Rhodospirillum rubrum*, photosynthetic bacteria that contribute to wetland productivity. As cells of *R. rubrum* swim in and out of the focal plane, their appearance changes through optical effects. When a bacterium swims out of the focal plane too close to the lens, resolution declines and the image blurs (**Fig. 2.18A**). When the bacterium swims within the focal plane, its image appears sharp, with a bright line along its edge. A helical cell like *R. rubrum* shows well-focused segments alternating with hazier segments that are too close to the lens (**Fig. 2.18B**). When the cell swims too far past the focal plane, the bright interference lines collapse into the object's silhouette, which now appears bright or "hollow" (**Fig. 2.18C**). In fact, the bacterium is not hollow at all; only its image has changed.

When the cell extends across several focal planes, different portions appear out of focus (either too near or too far from the lens). In addition, when the end of a cell points toward the observer, light travels through the length of the cell before reaching the observer, so the cell absorbs more light and appears dark (see **Fig. 2.18D**). The observation and identification of motile bacteria swimming in and out of the focal plane present a challenge even to experienced microscopists. The higher the magnification, the narrower the depth of the focal plane; thus, when observing swimming organisms, there is a tradeoff between magnification and depth of field.

THOUGHT QUESTION 2.5 Under starvation conditions, bacteria such as *Bacillus thuringiensis*, the biological insecticide, repackage their cytoplasm into spores, leaving behind an empty cell wall. Suppose, under a microscope, you observe what appears to be a hollow cell. How can you tell if the cell is indeed hollow or if it is simply out of focus?

Fixation and Staining Improve Resolution and Contrast

The simplest way to observe microbes is to place them in a drop of water on a slide with a coverslip. This is called a **wet mount** preparation. The advantage of the wet mount is that the organism is viewed in as natural a state as possible, without artifacts resulting from chemical treatment; and live behavior such as swimming can be observed. The disadvantage is that most living cells are transparent and therefore show little contrast with the external medium. With limited contrast, the cells can barely be distinguished from background, and both detection and resolution are minimal.

The detection and resolution of cells under a microscope are enhanced by **fixation** and **staining**, procedures that usually kill the cell. Fixation is a process by which cells are made to adhere to a slide in a fixed position. Cells may be fixed with methanol or by heat treatment to denature cellular proteins, whose exposed side chains then adhere to the glass. A stain absorbs much of the incident light, usually over a wavelength range that results in a distinctive color. The use of chemical stains was developed in the nineteenth century, when German chemists used organic synthesis to invent new coloring agents for women's clothing. Clothing was made of natural fibers such as cotton or wool, so a substance that dyed clothing would be likely to react with biological specimens.

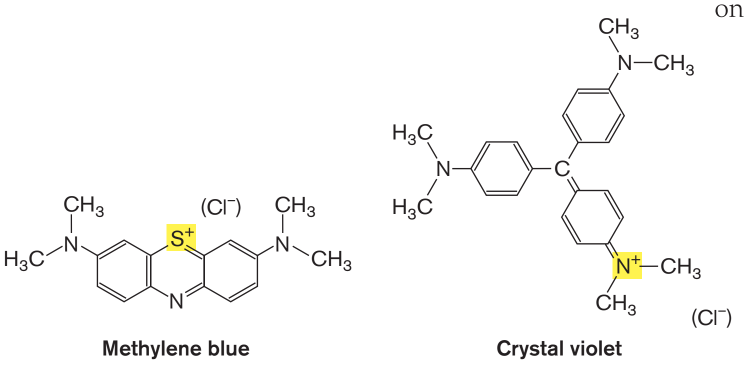


Figure 2.19 Chemical structure of stains. Methylene blue and crystal violet are cationic (positively charged) dyes. The positively charged groups react with the bacterial cell envelope, which carries mainly negative charge. Chloride (Cl) is the counter ion.

How do stains work? Most stain molecules contain conjugated double bonds or aromatic rings that absorb visible light (**Fig. 2.19**) and one or more positive charges that bind to negative charges on the bacterial cell envelope (discussed in Section 3.4). Different stains vary with respect to their strength of binding and the degree of binding to different parts of the cell.

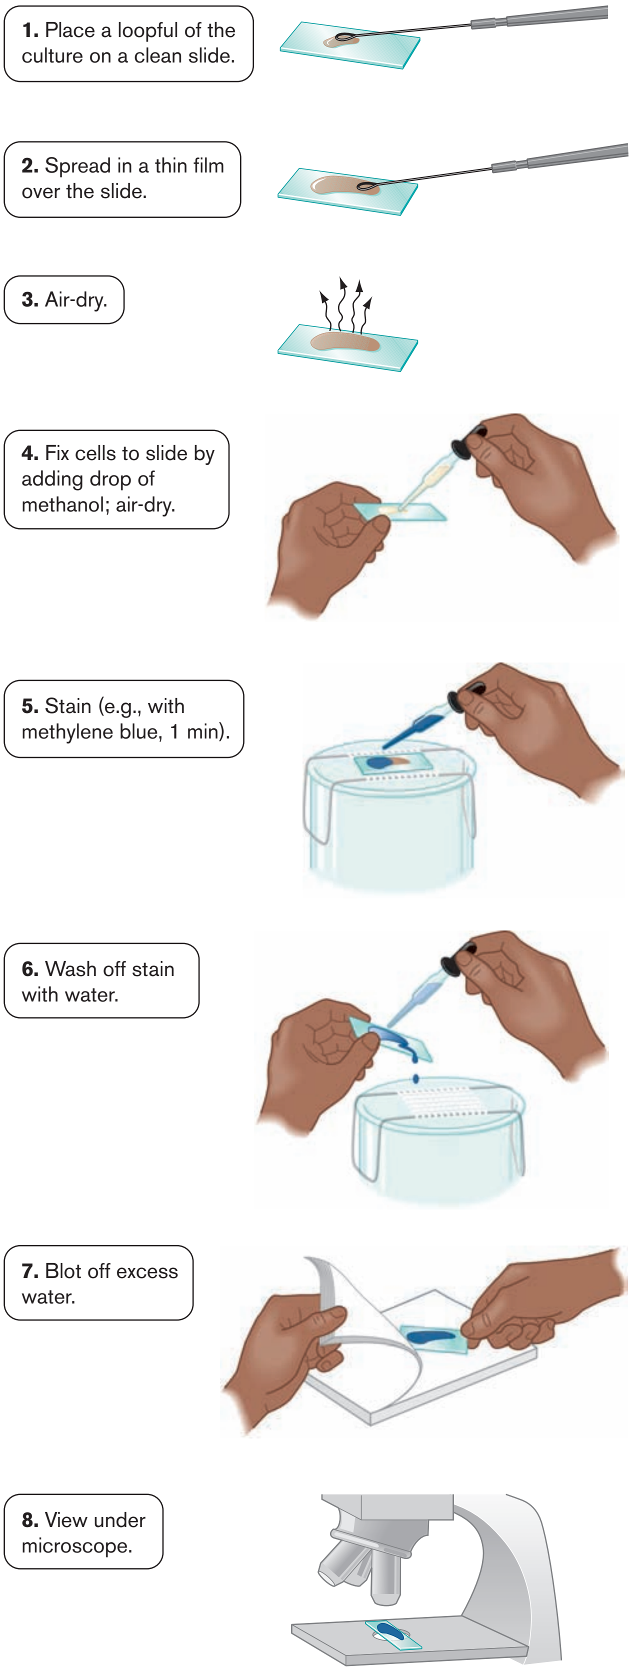
Different Kinds of Stains

A **simple stain** adds dark color specifically to cells, but not to the external medium or surrounding tissue (in the case of pathological samples). The most commonly used simple stain is methylene blue, originally used by Robert Koch to stain bacteria. A typical procedure for fixation and staining is shown in **Figure 2.20**. First, a drop of culture is fixed on a slide by treatment with methanol or by incubation on a slide warmer. Either treatment denatures cell proteins, exposing side chains that bind to the glass. The slide is then flooded with methylene blue solution. The positively charged molecule binds to the negatively charged cell envelope. After excess stain is washed off and the slide has been dried, it is observed under high-power magnification using immersion oil.

A **differential stain** stains one kind of cell but not another. The most famous differential stain is the **Gram stain**, devised in 1884 by the Dutch physician Hans Christian Gram (1853–1938). Gram first used the Gram stain to distinguish pneumococcus (*Streptococcus pneumoniae*) bacteria from human lung tissue. A similar use of the Gram stain is seen in **Figure 2.21A**, where *S. pneumoniae* bacteria appear dark purple against the pink background of human epithelial cells. Not all species of bacteria retain the Gram stain (**Fig. 2.21B**). Different bacterial species are classified gram-positive or gram-negative, depending on whether they retain the purple stain.

Gram Staining Separates Bacteria into Two Classes

In the Gram stain procedure (**Fig. 2.22**), a dye such as crystal violet binds to the bacteria; it also binds to the surface of human cells, but less strongly. After the excess stain is washed off, a **mordant**, or binding agent, is applied. The mordant used is iodine solution, which contains iodide ions (I^-). The iodide complexes with the positively charged crystal violet molecules trapped inside the cells. The crystal violet–iodide complex is now held more strongly within the cell wall. The thicker the cell wall, the more crystal violet–iodide molecules are held.



1. Place a loopful of the culture on a clean slide.

2. Spread in a thin film over the slide.

3. Air-dry.

4. Fix cells to slide by adding drop of methanol; air-dry.

5. Stain (e.g., with methylene blue, 1 min).

6. Wash off stain with water.

7. Blot off excess water.

8. View under microscope.

Figure 2.20 Procedure for simple staining with methylene blue.

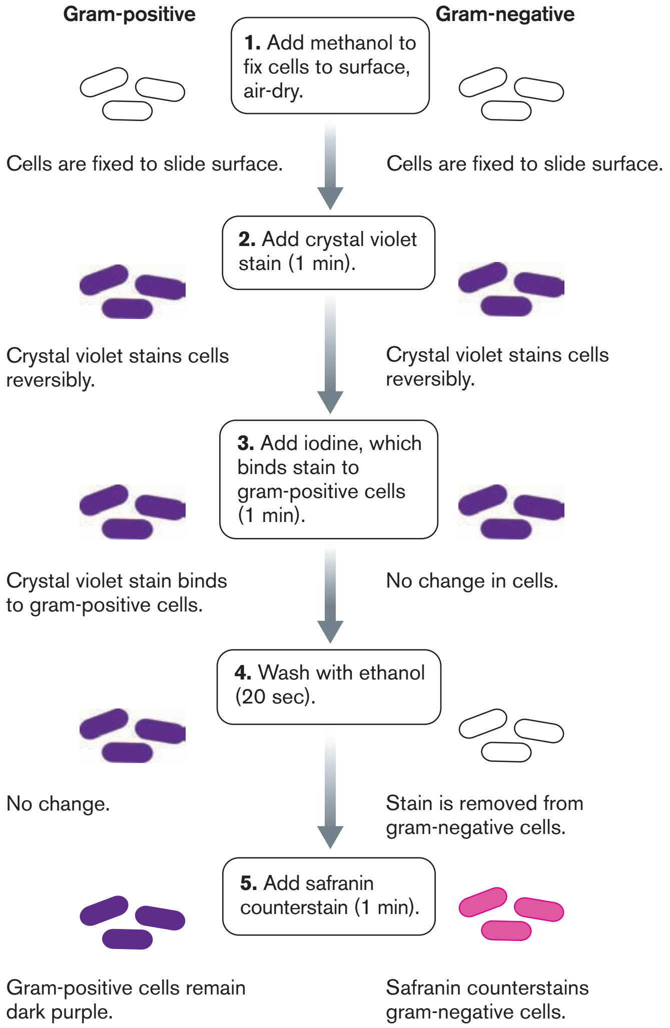
Figure 2.21 Gram staining of bacteria (a type of differential staining). A. Gram stain of a sputum specimen from a patient with pneumonia, containing gram-positive *Streptococcus pneumoniae* (purple cocci). Cell length, 0.5 to 1.0 µm. **B.** Gram stain of a gingival specimen containing both gram-positive and gram-negative bacteria (purple and pink rods). Cell length, 0.5 to 1.0 µm.



1. Add methanol to fix cells to surface, air-dry.

Cells are fixed to slide surface.

Cells are fixed to slide surface.

2. Add crystal violet stain (1 min).

Crystal violet stains cells reversibly.

Crystal violet stains cells reversibly.

3. Add iodine, which binds stain to gram-positive cells (1 min).

Crystal violet stain binds to gram-positive cells.

No change in cells.

4. Wash with ethanol (20 sec).

No change.

Stain is removed from gram-negative cells.

5. Add safranin counterstain (1 min).

Gram-positive cells remain dark purple.

Safranin counterstains gram-negative cells.

Figure 2.22 The Gram stain procedure. The Gram stain distinguishes between gram-positive cells, with thick cell walls, which retain the crystal violet stain, and gram-negative cells, with thinner cell walls, which lose the crystal violet stain but are counterstained by safranin.

Next, a decolorizer, ethanol, is added for a precise time interval (typically, 20 seconds). The decolorizer removes loosely bound crystal violet–iodide, but gram-positive cells retain the stain tightly. The **gram-positive** cells that retain the stain appear dark purple, while the **gram-negative** cells are colorless. The decolorizer step is critical because if it lasts too long, the gram-positive cells, too, will release their crystal violet stain.

In the final step, a **counterstain**, safranin, is applied. This process allows the visualization of gram-negative material, which is stained pale pink by the safranin.

The Gram stain procedure was originally devised to distinguish bacteria (gram-positive) from human cells (gram-negative). Microscopists soon discovered, however, that many important species, such as the intestinal bacterium *Escherichia coli* and the nitrogen-fixing symbiont *Rhizobium meliloti*, do not retain the Gram stain. It turns out that gram-negative species of bacteria possess a thinner and more porous cell wall than gram-positive species (**Fig. 2.23**). A gram-negative cell wall has only a single layer of peptidoglycan (sugar chains cross-linked by peptides), whereas a gram-positive cell has multiple layers. The multiple layers of peptidoglycan retain enough stain complex so that the cell appears purple.

Among bacteria, the Gram stain distinguishes two groups with distinctive cell wall structures: Proteobacteria, with a thin cell wall plus an outer membrane (gram-negative), and Firmicutes, with a multiple-layered cell wall but no outer membrane (gram-positive). The outer membrane of Proteobacteria (discussed in Chapter 3) often possesses important pathogenic factors, such as the lipopolysaccharide endotoxins that cause toxic shock. During the Gram stain procedure, however, the outer membrane is disrupted by the decolorizer, allowing most of the crystal violet–iodide complex to leak out.

Thus, the Gram stain emerged as a key tool for biochemical identification of species, and it remains essential in the clinical laboratory. Note, however, that still other groups of bacteria and archaea have different kinds of cell walls that may stain either positive or negative and are thus not distinguished by the Gram stain. Prokaryotic diversity and identification are discussed further in Chapters 18 and 19.

2. Iodide complexes with crystal violet.
3. Decolorizer releases loosely bound stain.

Figure 2.23 Mechanism of the Gram stain. In a gram-positive cell, the crystal violet–iodide complex is retained by multiple layers of peptidoglycan. In a gram-negative cell, the stain leaks out. If the decolorizer is applied for too long, the gram-positive cell will lose its stain as well.

Other Differential Stains

Other differential stains applied to various types of prokaryotes are illustrated in **Figure 2.24**. These include:

- **Acid-fast stain.** Carbolfuchsin specifically stains mycolic acids of *Mycobacterium tuberculosis* and *M. leprae*, the causative agents of tuberculosis and leprosy, respectively (**Fig. 2.24A**).
- **Spore stain.** When samples are boiled with malachite green, the stain binds specifically to the endospore coat (**Fig. 2.24B**). It detects spores of *Bacillus* species such as the insecticide *B. thuringiensis* and *B. anthracis*, the causative agent of anthrax, as well as spores of *Clostridium botulinum*, which produces botulin toxin.
- **Negative stain.** Some bacteria synthesize a capsule of extracellular polysaccharide filaments, which protects

Figure 2.24 **Differential stains.** **A.** *Mycobacterium tuberculosis*, acid-fast stain (stained cells are red, 1–2 □m long). LM □600. **B.** *Clostridium botulinum*, endospore stain (stained endospores are blue-green, 2 □m long). LM □400. **C.** *Gloeocapsa*, a colonial blue green alga, whose individual cells are encased in thick sheaths. Staining with India ink makes the sheaths clearly visible. Individual cell size, 3–5 □m.

the cell from predation or from engulfment by white blood cells (discussed in Section 3.4). The capsule is transparent and invisible in suspended cells. However, a suspension of opaque particles such as India ink can be added to darken the surrounding medium. The particles are excluded by the thick polysaccharide capsule, which thus appears clear against the dark background (**Fig. 2.24C**). This is an example of a **negative stain**.

- **Antibody stains.** Specialized stains utilize monoclonal antibodies to identify precise strains of bacteria or even specific molecular components of cells. The antibody (which binds a specific cell protein) is linked to a reactive enzyme for detection or to a fluorophore (fluorescent molecule) for fluorescence microscopy (see below).

TO SUMMARIZE:

- **In bright-field microscopy**, resolution depends on:
  - The wavelength of light, which limits resolution to about 200 nm.
  - The magnifying power of a lens, which depends on its numerical aperture ($n \sin$ □).
  - The position of the focal plane, the location where the specimen is "in focus" (that is, where the sharpest image is obtained).
- **A compound microscope** achieves magnification and resolution through a series of lenses: the condenser, objective, and ocular lenses.
- **A wet mount** specimen is the only way to observe living microbes.
- **Fixation and staining** of a specimen kills it but improves contrast and resolution.
- **Differential stains** distinguish between different kinds of bacteria with different structural features.
- **The Gram stain** differentiates between two major bacterial taxa, Proteobacteria (gram-negative) and Firmicutes (gram-positive). Other bacteria and archaea vary in their Gram stain appearance. Eukaryotes stain negative.

2.4 Dark-Field, Phase-Contrast, and Interference Microscopy

Advanced optical techniques enable us to visualize structures that are difficult or impossible to detect under a bright-field microscope, either because their size is below the limit of resolution of light or because their cytoplasm is transparent. These techniques take advantage of special properties of light waves, including scattering and interference patterns.

One application of dark-field illumination is the detection of pathogenic spirochetes, such as *Treponema pallidum*, the causative organism of syphilis. *T. pallidum* cells are so narrow (0.1 □m) that their shape cannot be fully resolved by light microscopy. Nevertheless, the spiral form of *T. pallidum* can be detected by dark-field microscopy (**Fig. 2.25**).

Dark-Field Observation Detects Unresolved Objects

Dark-field optics enables microbes to be visualized as halos of bright light against the darkness, just as stars are

Figure 2.25 **Dark-field observation of bacteria.** *Treponema pallidum* specimen from a patient with syphilis. Note the detection of dust particles. Dark-field LM, □1,100. Cell length about 10 □m; actual cell width, 0.2 □m.

observed against the night sky. A tiny object whose size is well below the wavelength of light, such as a virus particle, can be detected by light scattering. The wave front of scattered light is spherical, like a wave emitted by a point source (see **Fig. 2.9D**).

Light scattering. The scattered wave has a much smaller amplitude than that of the incident (incoming) wave. Therefore, with ordinary bright-field optics, scattered light is washed out. Detection of scattered light requires a modified condenser arrangement that excludes all light transmitted directly (**Fig. 2.26**). The condenser contains a "spider light stop," an opaque disk held by three "spider legs" across an open ring. The ring permits only a hollow cone of light to focus on the object. The incident hollow cone converges at the object, then generates an inverted hollow cone radiating outward.

The objective lens is positioned in the central region, where it completely misses the directly transmitted light. For this reason, the field appears dark. However, light scattered by the object radiates outward in a spherical wave. A sector of this spherical wave enters the objective lens and is detected as a halo of light.

An intriguing application of dark-field optics is the study of bacterial motility. Motility is important in bacterial diseases such as urethritis, in which the organism needs to swim up through the urethra. The bacterial swimming apparatus consists of helical filaments called **flagella**, which are rotated by a motor device imbedded in the bacterial cell wall (for flagellar structure, see Section 3.7). The "swimming strokes" of bacteria were first elucidated by Howard Berg (1934–) and Robert Macnab (1940–2003) using dark-field optics to view the helical flagella. The length of flagella is great enough to be resolved with light waves—but their width is not. Thus, dark-field optics is needed to detect and observe the helical flagella (**Fig. 2.27**). Note, however, that the bacterial cell itself appears "overexposed;" its shape is unresolved owing to the high light intensity.

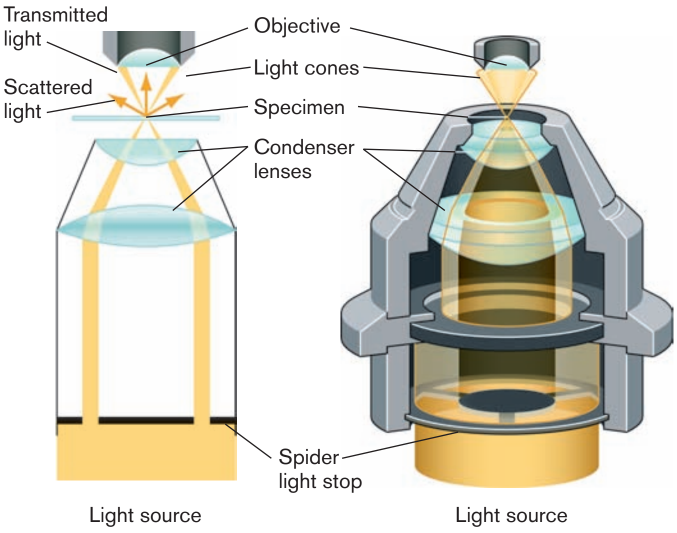

Figure 2.26 **A dark-field condenser system, with a spider light stop.** Below the condenser, the spider light stop excludes all but an annular ring of light from the light source. The annular ring converges as a hollow cone of light focused on the specimen. Objects in the specimen scatter light in all directions. The scattered light is collected by the objective lens, but the transmitted light shines outside the range of the objective; thus, in the absence of scattering objects, the field appears dark. Only light scattered by the specimen enters the objective lens.

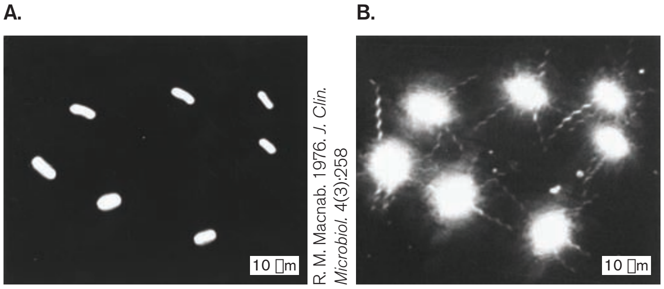

R. M. Macnab. 1976. *J. Clin. Microbiol.* 4(3):258

Figure 2.27 **Motile bacteria observed under dark-field microscopy.** **A.** Flagellated *E. coli* observed with low light, which limits scattering. Only cell bodies are detected, no flagella. **B.** The light intensity is increased. Flagella are detected, although their fine structure is not resolved because their width is below the threshold of resolution by light.

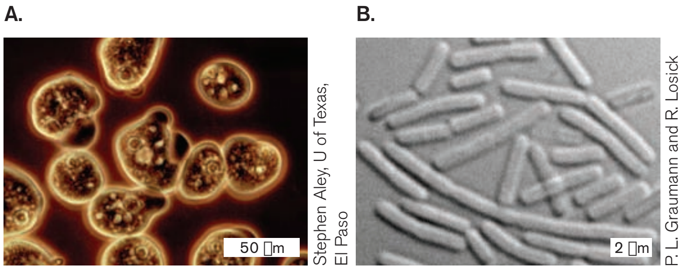
WWW | Videos of swimming bacteria

THOUGHT QUESTION 2.6 Some early observers claimed that the rotary motions observed in bacterial flagella could not be distinguished from whiplike patterns, comparable to the motion of eukaryotic flagella. Can you imagine an experiment to distinguish the two and prove that the flagella rotate? *Hint*: Bacterial flagella can get "stuck" to the microscope slide or coverslip.

Limitations of dark-field microscopy. A disadvantage of dark-field microscopy is that any tiny particle, including specks of dust, can scatter light and interfere with visualization of the specimen. Unless the medium is extremely clear, it can be difficult to distinguish microbes of interest from particulates. Other methods of contrast enhancement, such as phase contrast and fluorescence, avoid this difficulty.

Phase-Contrast Microscopy

Phase-contrast microscopy exploits differences in refractive index between the cytoplasm and the surrounding medium or between different organelles. This technique is particularly useful for eukaryotic cells, such as algae and protists, which contain many intracellular compartments. For example, **Figure 2.28A** shows an image of the protist *Entamoeba histolytica*, a human parasite, obtained by phase-contrast microscopy. In some cells, the nucleus is clearly visible.



Stephen Aley, U of Texas, El Paso

P. L. Graumann and R. Losick

Figure 2.28 Phase and interference effects in microscopy. **A.** Phase-contrast micrograph of the parasitic protist *Entamoeba histolytica*. **B.** Nomarski interference micrograph of *Bacillus subtilis*. Losick. 2001. *J Bacteriol.* 183(13): 4052–4060.

The optical system for phase contrast was invented in the 1930s by the Dutch microscopist Frits Zernike (1888–1966), for which he earned the Nobel Prize in Physics. In this system, slight differences in the refractive index of the various cell components are transformed into differences in the intensity of transmitted light. Zernike's scheme makes use of the fact that living cells have relatively high contrast owing to their high concentration of solutes. Given the size and refractive index of commonly observed cells, light is retarded by approximately one-quarter of a wavelength when it passes through the cell. In other words, after having passed through a cell, light exits the cell about one-quarter of a wavelength behind the phase of light transmitted directly through the medium.

The Zernike optical system is designed to retard the refracted light by an additional one-quarter of a wavelength, so that the light refracted through the cell is slowed by a total of half a wavelength compared with the light transmitted through the medium. When two waves are out of phase by half a wavelength, they produce destructive interference, canceling each other's amplitude (see Fig. 2.13). The result is a region of darkness in the image of the specimen.

As in dark-field microscopy, the light transmitted through the medium in phase-contrast microscopy needs to be separated from the light interacting with the object—in this case, light waves slowed by refraction. This separation is performed by a ring-shaped slit, called an "annular ring," similar in function to the spider light stop. The annular ring stops light from passing directly through the center of the lens system, where the specimen is located, and generates a hollow cone of light, which is focused through the specimen and generates an inverted cone above it (**Fig. 2.29**). Light passing through the specimen, however, is not only retarded; it is also refracted and thus bent into the central region within the inverted cone.

Both the refracted light from the specimen and the outer cone of transmitted light enter the phase plate. The phase plate consists of refractive material that is thinner in the region met by the outer (transmitted) light cone. The refracted light passing

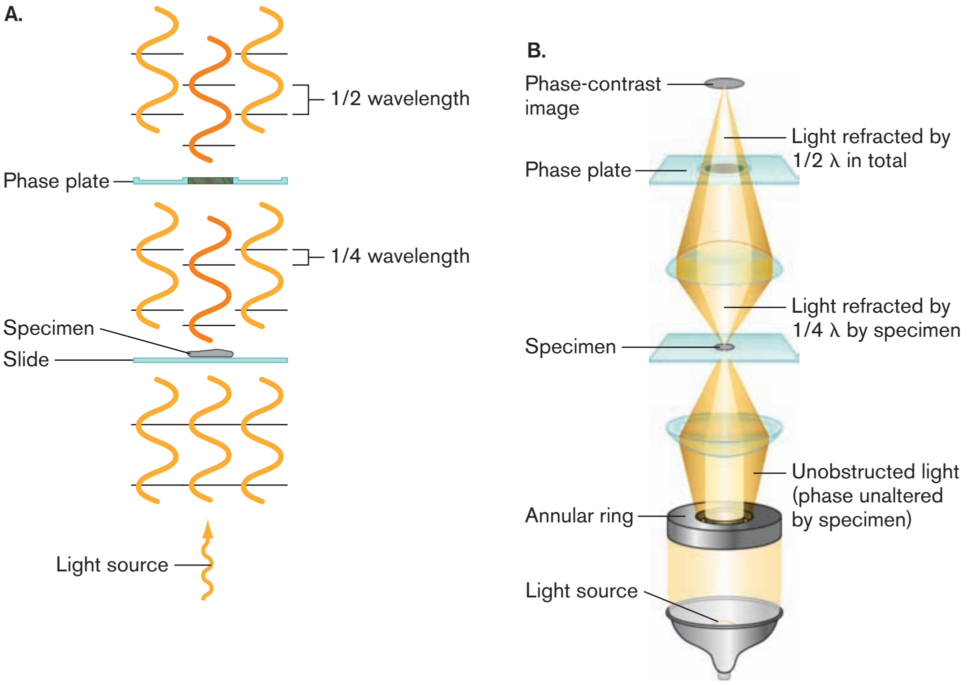


Figure 2.29 Phase-contrast optics. **A.** The specimen retards light by approximately one-quarter of a wavelength. The phase plate contains a central disk of refractive material that retards light from the specimen by another quarter wavelength, increasing the phase difference to half a wavelength. The light from the specimen and the transmitted light are now fully out of phase, and if they coincide, their waveforms cancel, making the specimen appear dark. **B.** In the phase-contrast microscope, the annular ring forms a hollow cone of light. As the light cone passes through the refractive material of the specimen, it is delayed by about one-quarter of a wavelength, and its path bends inward to the central region. This refracted light is surrounded by the hollow cone of unrefracted light. The light refracted by the specimen enters the lens through the dense central disk of the phase plate, which retards the wave by another quarter wavelength. When the transmitted and refracted light cones rejoin at the focal point, they are out of phase; their amplitudes cancel each other, and that region of the image appears dark against a bright background.

through the center of the phase plate is retarded by an additional one-quarter wavelength compared with the transmitted light passing through the thinner region on the outside. The overall difference approximates half a wavelength, so that the two waves are out of phase, thus canceling each other's amplitude. When the light from the inner and outer regions focuses at the ocular lens, the amplitudes of the wave trains cancel and produce a region of darkness. In this system, small differences in refractive index can produce dramatic differences in contrast between the offset phases of light.

WWW | FSU Phase contrast tutorial

Interference Microscopy

Other kinds of optical systems have been devised using light interference to enhance cytoplasmic contrast. **Interference microscopy** enhances contrast by superimposing the image of the specimen on a second beam of light that generates interference fringes. The interference pattern produces an illusion of shadowing across the specimen. For example, the shapes of the *Bacillus subtilis* cells illuminated by interference contrast (**Fig. 2.28B**) are more clearly defined than in conventional bright-field microscopy (for comparison see **Fig. 2.21**).

One optical system for producing interference contrast is based on the Wollaston-Nomarski prism. In this system, light is polarized to obtain waves oriented in one direction. The polarized light is then split by the prism into two separate beams, which are out of phase with each other. The two beams recombine to generate interference patterns whose edges are highly sensitive to slight differences in the refractive index of the specimen.

TO SUMMARIZE:

- **Dark-field microscopy** uses scattered light to detect objects too small to be resolved by light rays.
  Advantage: Extremely small microbes and thin extracellular structures can be detected.
  Limitation: The shape of objects is not resolved. Dust particles easily obscure the image of the specimen.
- **Phase-contrast microscopy** superimposes refracted light and transmitted light shifted out of phase so as to observe differences in refractive index as patterns of light and dark.
  Advantage: Live microbes with transparent cytoplasm, especially eukaryotes, can be observed with high contrast.
  Limitation: Phase contrast is less effective for smaller microbes and for organisms whose cytoplasm has a low refractive index.
- **Interference microscopy** superimposes interference bands on an image, accentuating small differences in refractive index.
  Advantage: The shape of cells can be defined most clearly.
  Limitations: Interference microscopy requires complex optical adjustment and is less effective for organisms with low refractive index.

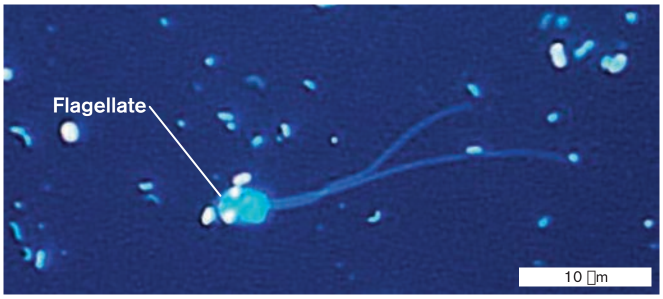
2.5 Fluorescence Microscopy

In fluorescence microscopy, incident light is absorbed by the specimen and reemitted at a lower energy, thus longer wavelength. Fluorescence microscopy offers a powerful way to detect microbes and subcellular structures while avoiding artifacts caused by dust and other nonspecific materials.

One use of fluorescence microscopy is to assess microbial populations in highly dilute natural environments (**Fig. 2.30**). This technique was used by the Oceanic Microbial Observatory at the Bermuda Biological Station for Research to conduct a long-term study assessing the effects on microbial populations of changing water chemistry due to climate changes such as global warming. Populations of microbes, including viruses, bacteria, and protists, are measured using DNA-specific fluorescence. The advantage of this fluorescence technique is that it detects only live organisms whose DNA is intact, distinguishing them from fine debris in natural environments.

Fluorescence Requires Excitation and Emission at Different Wavelengths

Fluorescence occurs when light of a specific wavelength (the **excitation wavelength**) is absorbed by an atom (or molecule) capable of promoting an electron to an orbital of higher energy (**Fig. 2.31**). Because this higher-energy electron state is unstable, the electron decays to an orbital with a slightly lower energy level through the loss of energy as heat. The electron then falls to its original level by emitting a photon of lower energy and longer wavelength, the **emission wavelength**. The emitted photon has a longer wavelength (less energy) because part of the electron's energy of absorption was lost as heat.



Craig A. Carlson, University of California, Santa Barbara

Figure 2.30 Cell counting using fluorescence microscopy. Bacterioplankton and flagellated protists from the surface waters of the Sargasso Sea near Bermuda are enumerated to investigate their contribution to the oceanic carbon cycle. Live organisms are detected by fluorescence using the DNA-specific fluorophore DAPI.

Figure 2.31 **Fluorescence.** Energy gained from UV absorption is released as heat and as a photon of longer wavelength in the visible region. **A.** Fluorescence on the molecular level. **B.** Comparison of absorption and emission spectra for a fluorophore.

The wavelengths of excitation and emission are determined by the **fluorophore**, the fluorescent molecule used to stain the specimen. For example, the slides for cell counting in the Bermuda study (see **Fig. 2.30**) used the DNA-specific stain 4′,6-diamidino-2-phenylindole (DAPI). The aromatic groups of DAPI associate exclusively with the base pairs of DNA. Another commonly used DNA-specific fluorophore is acridine orange (**Fig. 2.32**). These fluorophores provide an extremely sensitive means of detecting diverse microorganisms in the environment, including those whose dimensions are too small to be resolved.

The optical system for fluorescence microscopy utilizes filters to limit incident light to the wavelength of excitation and the emitted light to the wavelength of emission. The wavelengths of excitation and emission are determined by the specific fluorophore used.

Fluorophores Can Label Specific Parts of Cells

Fluorescence can be used to label specific parts of cells. The specificity of the fluorophore can be arranged in several ways:

- **Chemical affinity.** Certain fluorophores have chemical affinity for certain classes of biological molecules; for example, the fluorophore acridine specifically binds DNA.
- **Labeled antibodies.** Antibodies that specifically bind a cell component are chemically linked to a fluorophore molecule. The use of antibodies linked to fluorophores is known as immunofluorescence.
- **Gene fusion.** Genetic recombination can be used to create a hybrid gene expressing a protein that generates fluorescence, such as green fluorescent protein (GFP).
- **DNA hybridization.** A short sequence of DNA attached to a fluorophore will hybridize to a specific sequence in the genome, thus labeling one position in the chromosome or nucleoid.

Fluorophore labeling is used to dissect endospore formation in *Bacillus* species (**Fig. 2.33**). The cell envelope and DNA origin of replication are labeled by different fluorophores to track movements of DNA during sporulation. Richard Losick and colleagues applied this technique to show how the DNA origin moves toward one pole of the cell, followed by formation of a septum, a new portion of cell envelope, just behind the developing endospore.

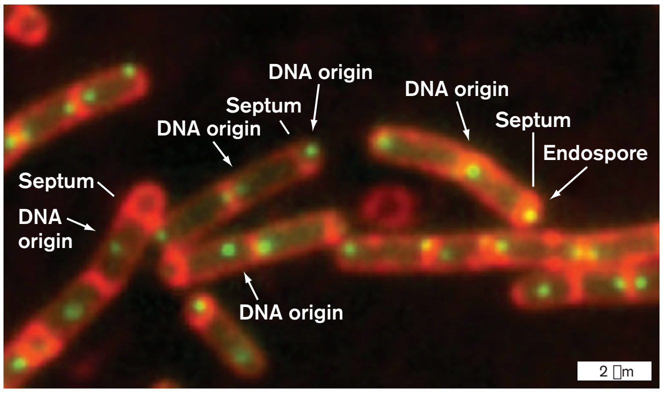
Figure 2.32 **Fluorescent molecules (fluorophores) commonly used in microscopy.** Because of the abundance of conjugated double bonds, these molecules have closely spaced molecular orbitals that give rise to fluorescence.



P. L. Graumann and R. Losick. 2001. *J. Bacteriol.* 183:4052

Figure 2.33 Fluorescence micrograph of *Bacillus subtilis* cells during sporulation. Red fluorescence arises from membrane stained with the dye FM-464. Green fluorescence arises from green fluorescent protein (GFP) bound to the DNA origin of replication. The yellow color occurs where green fluorescence overlaps red.

In the micrograph, the cell envelope is stained red by the fluorescent dye FM-464. The dye FM-464 specifically binds phospholipid membranes. The DNA origin of replication is stained by green fluorescent protein (GFP) fused to a protein that specifically binds the DNA origin of replication. The fluorescence micrographs were taken at two different wavelengths for both excitation and emission to record the two different fluorescent labels. The images were superimposed with two different colors marking envelope and DNA. The result shows how, in sporulation, DNA replication originates not at the midpoint of the cell, as in vegetative growth of most bacteria, but at the poles where the endospore forms.

THOUGHT QUESTION 2.7 What experiment could you devise to determine the actual order of events in DNA movement toward the pole during formation of an endospore?

THOUGHT QUESTION 2.8 Compare and contrast fluorescence microscopy with dark-field microscopy. What similar advantage do they provide, and how do they differ?

Fluorescence microscopy has been used to develop advanced optical systems that reconstruct three-dimensional models of cells. An example is confocal fluorescence microscopy (**Special Topic 2.1**).

TO SUMMARIZE:

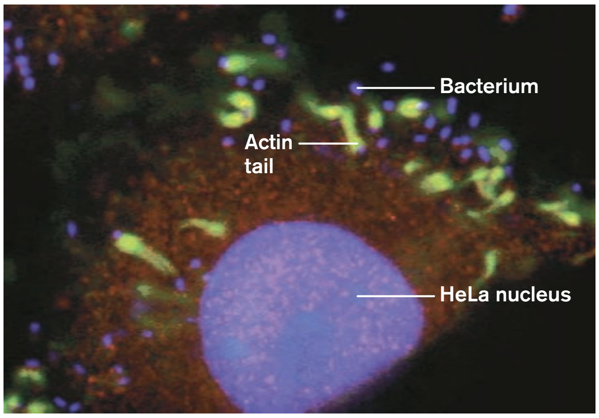
- **Fluorescence microscopy** involves detection of specific cells or cell parts based on fluorescence by a fluorophore.
- **Cell parts can be labeled** by a fluorophore attached to an antibody stain.

Special Topic 2.1 Confocal Fluorescence Microscopy

An advanced application of fluorescence is **laser scanning confocal microscopy**, in which both excitation light and emitted light are focused together. Confocal microscopy is used to produce images of cells at high resolution, with interference effects decreased by laser optics. The images can be "stacked" computationally to model a cell in three dimensions.

In **Figure 1**, we see a confocal image of human tissue culture cells infected by enteroinvasive *Escherichia coli*. The DNA of bacteria and of the nuclei of HeLa cells (an immortal cancer cell line) are stained blue with DAPI fluorophore. Invading bacteria cause the host to form actin "tails," which help the bacteria move. Tails are stained green by an actin-binding fluorophore, FITC.

In confocal microscopy, a laser beam is focused onto the specimen and scanned across it in two dimensions—that is, in two planes at right angles to each other (**Fig. 2**). The laser beam excites the fluorophore, causing it to emit light at a longer wavelength. The emitted light passes in reverse direction through the objective, where it encounters a dichroic mirror that allows light transmission at the excitation wavelength but reflects light at the wavelength of emission. The reflected emission rays are then focused and pass through a pinhole, which eliminates all unfocused light. A narrow focused beam, representing one "pixel" of image, enters the photomultiplier tube. Scanning across the specimen yields a two-dimensional pattern of pixels that forms an image.



Michael S. Donnenberg/University of Maryland

Figure 1 Human tissue culture cells infected by enteroinvasive *Escherichia coli*. DNA of bacteria and of HeLa nuclei are stained blue with DAPI fluorophore. Invading bacteria (blue-stained rods, 1–2 μm long) cause the host to form actin "tails," stained green with an actin-binding FITC fluorophore.

The scanning feature of confocal microscopy is also used to acquire data for high-throughput experiments in which a large number of chemical reactions are arranged in microscopic quantities in an array. An example of an array is a DNA microarray containing probes for all the genes of a genome. Short segments of DNA are arrayed on a microscope slide such that an entire genome of potential protein-encoding genes may be present on a single slide.

One use of arrays is to investigate the mode of action of a new antibiotic molecule by testing which of the microbe's genes are induced or repressed in response to the antibiotic. The DNA array is hybridized to fluorescence-labeled cDNA copies of messenger RNA from bacteria cultured with or without the antibiotic. The confocal laser then scans the slide to detect binding of the genes to cDNA molecules labeled with a fluorophore. This technique makes it possible to measure transcription of all known genes in the genome and reveal those whose expression varies during exposure to an antibiotic. The antibiotic-induced genes indicate the mode of action of the antibiotic within the cell and aid the design of better antibiotics. DNA microarrays are discussed further in Chapter 12.

Figure 2 **Confocal microscopy.** In confocal optics, the incident laser beam (blue) passes through a dichroic mirror and reaches the specimen, where its absorption leads to fluorescent emission at a longer wavelength. The fluorescent emission travels back to the dichroic mirror, where it is reflected toward the photomultiplier. Only the confocal rays (those emitted from the focal point) pass through the pinhole and reach the photomultiplier. The laser scans across the specimen, generating a pixilated image. The scanned images can be stacked through a series of focal planes to generate a three-dimensional model.

2.6 Electron Microscopy

All cells are built of macromolecular structures. The tool of choice for observing the shape of these macromolecular structures is **electron microscopy (EM)**. In electron microscopy, beams of electrons are focused to generate images of cell membranes, chromosomes, and ribosomes with a resolution a thousand times that of light microscopy. The modern electron microscope was developed in the 1950s and was popularly known as the centerpiece of any biological research program. In Michael Crichton's film, *The Andromeda Strain*, for example, an electron microscope is used to analyze a fictional pathogen from outer space.

The Electron Microscope Focuses Beams of Electrons

How does an electron microscope work? Electrons are ejected from a metal subjected to a voltage potential. The electrons travel in a straight line, like photons. Like photons, electrons interact with matter and carry information about their interaction. And like photons, electrons can exhibit the properties of waves. The wavelength associated with an electron is a 100,000 times smaller than that of a photon; for example, an electron accelerated over a voltage of 100 kilovolts (kV) has a wavelength of 0.0037 nm (0.037 Å) compared with 400–750 nm for visible light. The actual resolution of electrons in microscopy is limited, however, not by the wavelength, but by the aberrations of the lensing systems used to focus electrons. The magnetic lenses used to focus electrons never achieve the precision required to utilize the full potential resolution of the electron beam.

Electrons are focused by means of a magnetic field directed along the line of travel of the beam (**Fig. 2.34**). As a beam of electrons enters the field, it spirals around the magnetic field lines. The shape of the magnet can be designed to generate field lines that will focus the beam of electrons in a manner analogous to the focusing of photons by a refractive lens. The electron beam, however, forms a spiral because electrons travel around magnetic field lines. Because magnetic lenses generate aberrations, a series of corrective magnetic lenses is generally required to obtain a resolution of about 0.2 nm. This represents a resolution a thousand times greater than the 200-nm resolution of light microscopy.

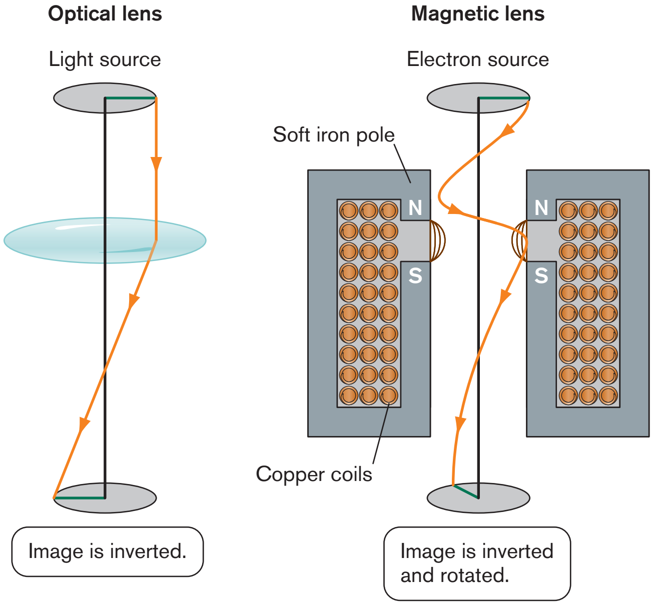

Figure 2.34 A magnetic lens. The beam of electrons spirals around the magnetic field lines. The U-shaped magnet acts as a lens, focusing the spiraling electrons much as a refractive lens focuses light rays.

THOUGHT QUESTION 2.9 An electron microscope can be focused at successive powers of magnification, as in a light microscope. At each level, the image rotates at an angle of several degrees. Based on the geometry of the electron beam, as shown in Figure 2.34, why do you think this rotation occurs?

Transmission EM and scanning EM. Two major types of electron microscopy are **transmission electron microscopy (TEM)** and **scanning electron microscopy (SEM)**. In TEM, electrons are transmitted through the specimen as in light microscopy to reveal internal structure. In SEM, the electron beams scan across the surface of the specimen and are reflected to reveal the contours of its three-dimensional surface.

The transmission electron microscope closely parallels the design of a bright-field microscope, including a source of electrons (instead of light), a magnetic condenser lens, a specimen, and an objective lens. A projection lens projects the image onto a fluorescent screen and the final images are obtained by a digital camera (charge-coupled device, CCD) (**Fig. 2.35**). The scanning microscope is arranged somewhat differently than the TEM in that a series of condenser lenses focuses the electron beam onto the surface of the specimen. Reflected electrons are then picked up by a detector (**Fig. 2.36**). In either case, the overall apparatus required for electron microscopy is complex, resembling the bridge of a *Star Trek* spaceship.

Electron Microscopy Requires Specialized Sample Preparation

Electron microscopy poses special problems for biological specimens. With the exception of cryo EM (discussed shortly), the entire optical column must be maintained under vacuum to prevent the electrons from colliding with the gas molecules in air. The requirement for a vacuum precludes the viewing of live specimens, which

The light source is replaced by an electron source consisting of a high-voltage current applied to a tungsten filament, which gives off electrons when heated. The electron beam is focused by a condenser magnet lens onto the specimen. The specimen image is then magnified by an objective magnetic lens. The projector lens, analogous to the ocular lens of a light microscope, focuses the image on the cathode-ray tube (CRT) screen. *Note*: Because of the greater problem of aberrations in focusing electrons, each magnetic lens shown (condenser, objective, projection) actually represents a series of lenses. **B.** Using an electron microscope.

Figure 2.36 Scanning electron microscopy. A. In the scanning electron microscope (SEM), the electron beam is scanned across a specimen coated in gold, which acts as a source of secondary electrons. The incident electron beam ejects secondary electrons toward a detector, generating an image of the surface of the specimen. **B.** Operating an SEM. **C.** Loading a specimen into the vacuum column.

in any case would be quickly destroyed by the electron beam. Moreover, the structure of most specimens lacks sufficient electron density (ability to block electrons) to provide contrast. Thus, the specimen usually requires an electron-dense stain using salts of heavy metals such as gold or uranium.

The specimen can be prepared in one of three ways:

- **Embedded in a polymer for thin sections.** A special knife called a microtome cuts slices through the specimen, each slice a fraction of a micrometer thick.

- **Sprayed onto a copper grid.** The electron beam penetrates straight through the entire object, as if it were transparent. This method is effective for virus particles and for isolated macromolecular complexes.
- **Flash-frozen (for cryo EM).** Samples frozen rapidly in refrigerant provide sufficient contrast for detection by a high-intensity electron beam, a recent innovation.

For sectioned samples or for samples sprayed onto a grid, the specimen is coated with a heavy metal salt such as uranyl acetate. The metal salt is deposited around the biological structures, acting as a negative stain. (For comparison, a negative stain used in light microscopy is the India ink stain, illustrated in Fig. 2.24C.)

Mesnage, et al. *J. Bacteriol.*

Figure 2.37 SEM and TEM images of gram-positive rod-shaped bacteria.

In **Figure 2.37**, we see examples of SEM and TEM images from gram-positive rod bacteria. The SEM in **Figure 2.37A** shows an exterior view of the capsules of *M. paratuberculosis*. The image provides far greater magnification of surface detail than does a bright-field view of rod bacteria. In **Figure 2.37B**, flagellar motors have been isolated or "unplugged" from a bacterial cell envelope and spread on a grid for TEM. The micrograph reveals details of the motor, including the axle and individual rings. The TEM of *B. anthracis* in **Figure 2.37C** shows a thin section through a bacillus, including cell wall, membranes, and glycoprotein filaments. The TEM is "transparent," summing electron density throughout the depth of the section.

THOUGHT QUESTION 2.10 What kind of research questions could you investigate using SEM? What questions would be answered using TEM?

An important limitation of traditional electron microscopy, whether TEM or SEM, is that in most cases it can only be applied to fixed, stained specimens. The fixatives and heavy-atom stains can introduce artifacts into the image, especially at finer details of resolution. In some cases, different preparation procedures have led to substantially different interpretations of subcellular structure.

The development of exceptionally high-strength electron beams now permits low-temperature **cryoelectron microscopy (cryo EM)**. In cryo EM, the specimen is flash-frozen, that is, suspended in water and frozen rapidly in a refrigerant of high heat capacity (ability to absorb heat). The rapid freezing avoids ice crystallization, leaving the water solvent in a glass-like amorphous phase. The specimen retains water content and thus closely resembles its viable form, although it is still ulti-

Figure 2.38 **Cryoelectron microscopy.** Cryoelectron tomography of *Spiroplasma melliferum*. The tomographic slice reveals ribosomes identified using molecular identification software, false-colored yellow.

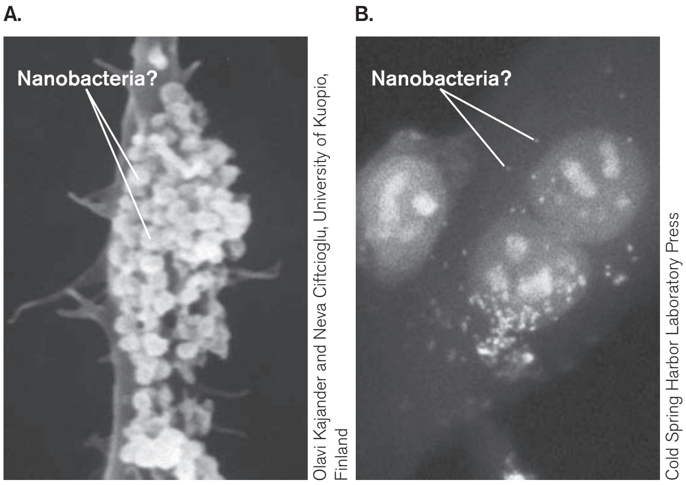
mately destroyed by electron bombardment. The sample does not require staining because the high-intensity electron beams can detect smaller signals than in earlier instruments. **Figure 2.38** shows a cryo EM of *Spiroplasma melifera*.

Another innovation in cryo EM is **tomography**, the acquisition of projected images from different angles of a transparent specimen. Tomography avoids the need to physically slice the sample for thin-section TEM. The images from EM tomography are combined digitally to visualize the entire object. An example is the tomographic image of the spiral bacterium *Spiroplasma melliferum*, in which individual ribosomes clearly appear (**Fig. 2.38**).

Cryo EM is also used to generate high-resolution models of virus particles and purified structures such as the ribosome (**Special Topic 2.2**). For these small particles, multiple images can be averaged together by computational analysis. The digitally combined images can achieve high resolution, nearly comparable to that of X-ray crystallography.

Microscopy Results Require Careful Interpretation

The images produced by high-level microscopy can be difficult to interpret. For example, an oval that appears hollow might be interpreted as a cell when in fact it represents a deposit of staining material. A microscopic structure that is interpreted incorrectly is termed an **artifact**. Avoiding artifacts is an important concern in microscopy.



Olavi Kajander and Neva Ciftcioglu, University of Kuopio, Finland

Cold Spring Harbor Laboratory Press

Figure 2.39 Artifacts of microscopy. A. Objects attached to the surface of a fibroblast were observed by SEM. The objects (200–300 nm in diameter) were identified as "nanobacteria," exceptionally small bacteria inhabiting human blood plasma, but they are now believed to be mineral deposits. **B.** Cultured human cells observed by immunofluorescence microscopy revealed small particles identified as nanobacteria. This observation, however, has not been reproduced by other researchers.

Sometimes, published interpretations generate controversy. For example, electron microscopy and immunofluorescence microscopy were used to test for contamination of cultured white blood cells that grew poorly (**Fig. 2.39**). The SEM images were interpreted to show the presence of tiny prokaryotic cells, 200–300 nm in diameter, attached to cultured fibroblast cells (**Fig. 2.39A**). These proposed cells were termed "nanobacteria." Unfortunately, other researchers were unable to confirm these results and suggested that the objects observed might actually be mineral deposits. Another technique, immunofluorescence microscopy, reportedly showed the invasion of cultured cells by nanobacteria (**Fig. 2.39B**). The technique required use of fluorescent-tagged antibodies against nanobacteria, but the actual specificity of the antibodies was unclear. The existence of small infective particles in the blood remains a question of interest to medical researchers.

THOUGHT QUESTION 2.11 What kind of experiments could prove or disprove the interpretations of the images of "nanobacteria" in blood plasma?

Emerging Methods of Microscopy

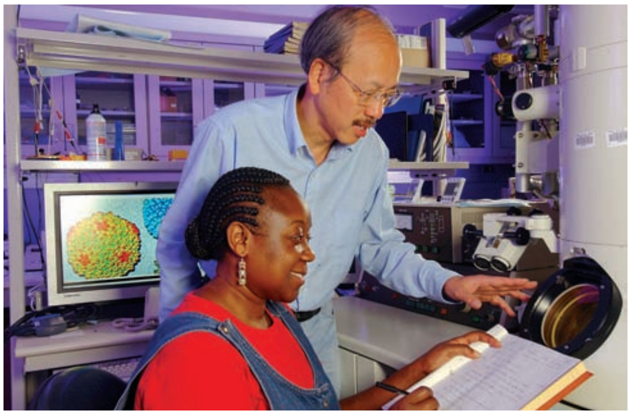
New methods of microscopy are emerging that enable nanoscale observation of cell surfaces, in some cases of living cells suspended in water. A general term for these methods is scanning probe microscopy (SPM). SPM methods differs from light and electron microscopy, in which the sample interacts with a beam of light or electrons. Instead, SPM methods measure a physical interaction, such as the "atomic force" between the sample and a sharp tip. **Atomic force microscopy (AFM)** measures the van der Waals forces between the electron shells of adjacent atoms of the cell surface and the sharp tip. AFM is particularly useful to study the surfaces of live bacteria.

In AFM, an instrument probes the surface of a sample with a sharp tip a couple of micrometers long and often less than 10 nm in diameter (**Fig. 2.40A**). The tip is located at the free end of a lever that is 100–200 μm long. The lever is deflected by van der Waals forces between the tip and the sample surface. Deflection of the lever is measured by a laser beam reflected off a cantilever attached to the tip as the sample scans across. The measured deflections allow a computer to map the topography of cells in liquid medium with a resolution below 1 nm.

In the example in **Figure 2.40B**, obtained by Mark Martin at Occidental College, AFM reveals the outline of

Special Topic 2.2 Three-Dimensional Electron Microscopy Solves the Structure of a Major Agricultural Virus

One of the world's most economically damaging agricultural pathogens is rice dwarf virus. Rice dwarf virus (RDV) is transmitted by leafhopper beetles in China and Southeast Asia, where it systemically infects rice, discoloring the leaves and stunting the plant, devastating the harvest. A retrovirus, RDV has a genome of double-stranded RNA enclosed within an icosahedral capsid of proteins, approximately 70 nm in diameter. Determining the molecular structure of the virus particle may enable us to design antiviral agents.



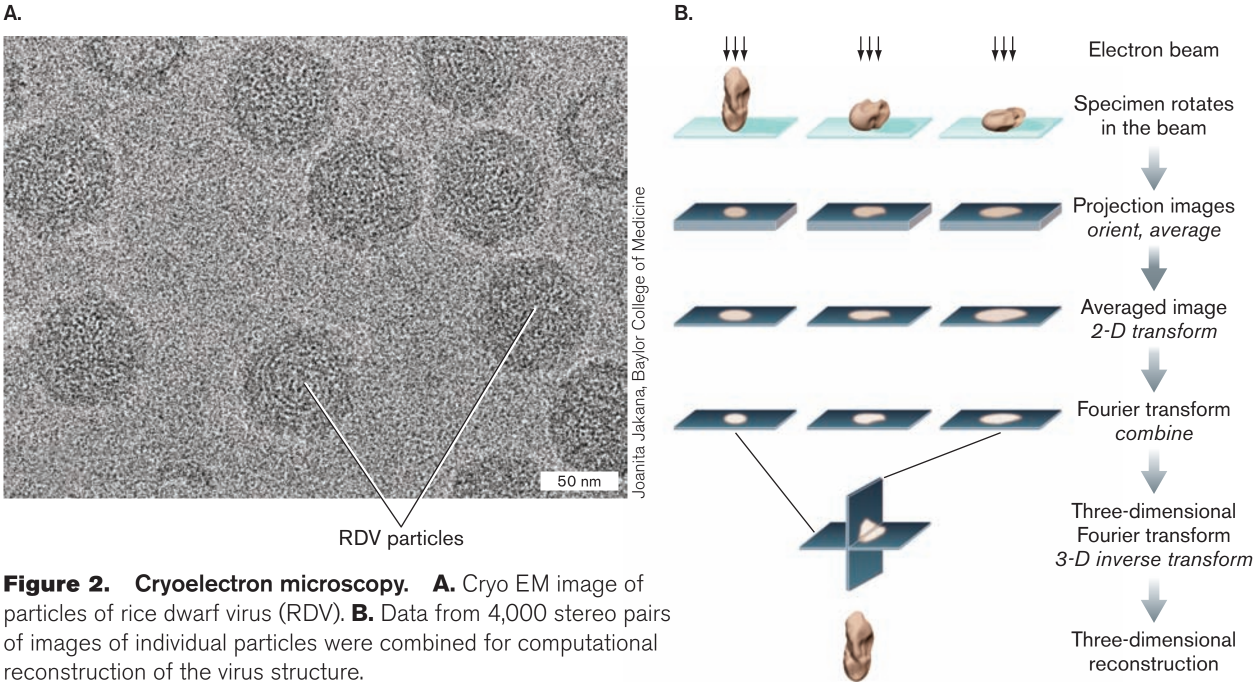
Wah Chiu, Baylor College of Medicine

Figure 1 Three-dimensional cryoelectron microscopy. Dr. Wah Chiu (standing), at Baylor University, succeeded in imaging the structure of rice dwarf virus using three-dimensional cryoelectron microscopy.

Wah Chiu (**Fig. 1**) and colleagues at the National Center for Macromolecular Imaging, at Baylor University, imaged the structure of RDV at high resolution using three-dimensional cryo EM tomography. Cryo EM is especially important for particles that cannot be crystallized for X-ray diffraction analysis, the most common means of molecular visualization. Because the frozen sample remains hydrated, the biological molecules retain the same conformation as in solution. The sample is imaged without heavy-metal stains, and thus higher resolution is obtained (see **Fig. 2B**). This technique avoids introducing stain artifacts but generates very low contrast. Repeated scans can be summed computationally to obtain an image at higher resolution.

In **Figure 2A**, a cryo EM image reveals the outline of the RDV particles. Each particle was imaged in stereo by rotating the specimen to receive the electron beam at different angles (**Fig. 2B**). In theory, a three-dimensional picture of the virus could be obtained from a stereo pair of images from one particle. In practice, however, one image pair reveals little information because the ratio of signal to noise is so low, so stereo pairs of images were combined from 4,000 individual RDV particles (see **Fig. 2B**). A visual model was generated by computation requiring the use of a supercomputer.

The computational model of RDV reveals in three dimensions the capsid, a protein shell that encloses the virus's RNA



Joanita Jakana, Baylor College of Medicine

chromosome (**Fig. 3A**). The model includes detailed representations of both the outer shell (P8 subunits) and inner shell (P3 subunits). The remarkable resolution of the RDV model provides enough detail to map the alpha helices of a P3 subunit (**Fig. 3B**), although it does not yet reach the atomic resolution of X-ray diffraction. This structure can be used to model molecular interactions for potential antiviral agents that would inactivate the capsid.

Figure 2.40 Atomic force microscopy enables visualization of untreated cells. A. The atomic force microscope (AFM) has a fine-pointed tip attached to a cantilever that moves over a sample. The tip interacts with the sample surface through atomic force. As the tip is pushed away, or pulled into a depression, the cantilever is deflected. The deflection is measured by a laser light beam focused onto the cantilever and reflected into a photodiode detector. **B.** *Escherichia coli* cells under attack by *Bdellovibrio bacteriovorus*, bacterial predators that invade the periplasmic space of *E. coli*. The untreated cells allow AFM observation of *B. bacteriovorus* cells, *E. coli* cells, pili, and flagella. Each *E. coli* cell is about 2 μm in length.

TO SUMMARIZE:

- **Electron microscopy** is based on the focusing of electron beams on an object stained with a heavy-metal salt that blocks electrons. Much higher resolution is obtained than for light microscopy.
- **Transmission electron microscopy (TEM)** involves electron beam penetration of a thin sample.
- **Scanning electron microscopy (SEM)** involves scanning of a three-dimensional surface with an electron beam.
- **Cryoelectron microscopy (cryo EM)** observes a sample flash-frozen in water solution. Multiple images may be combined digitally to achieve high resolution.
- **Atomic force microscopy**, an emerging alternative to EM, uses van der Waals force measurement to observe cells in water solution.

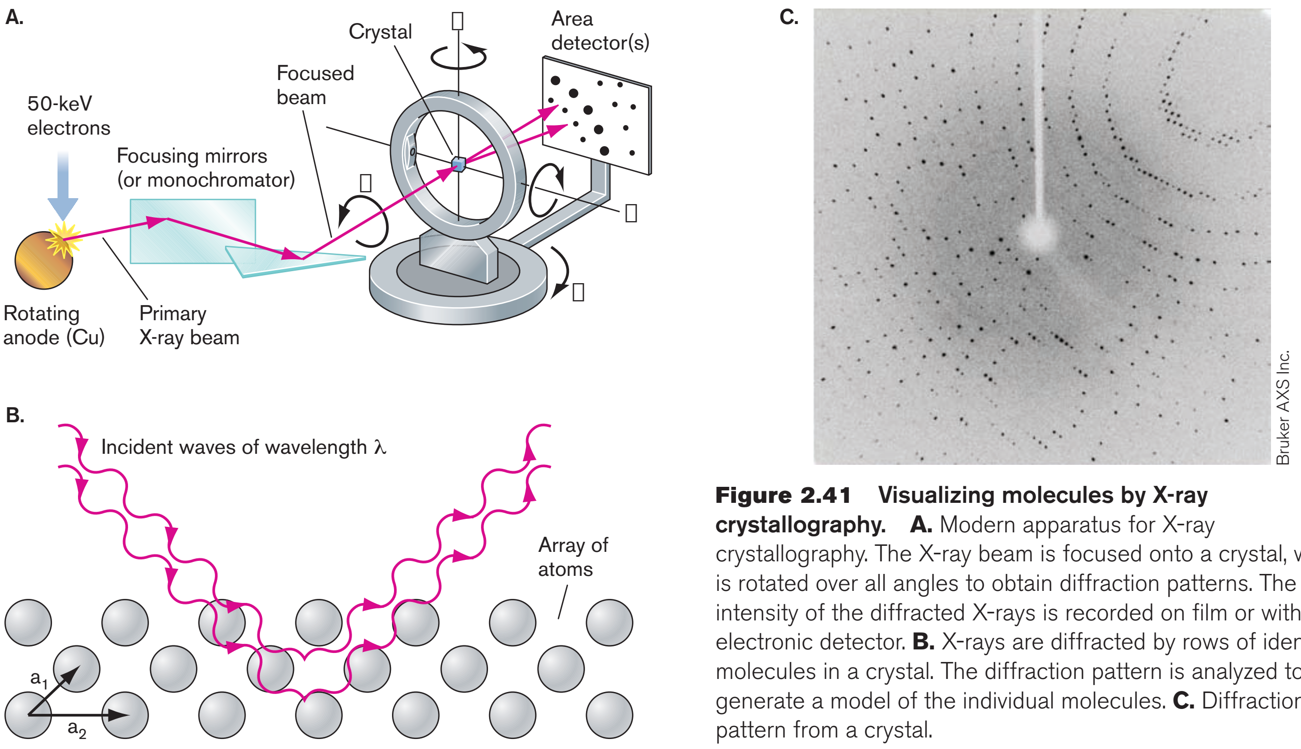
2.7 Visualizing Molecules

To understand the structure of cells, ultimately we need to isolate the cell's molecules to observe their individual structure and function. The major tool used at present for molecular visualization is **X-ray diffraction analysis**, or **X-ray crystallography**. In some cases, cryo EM modeling based on thousands of samples has also reached near atomic resolution. Another emerging alternative to X-ray diffraction for analysis of small molecules and proteins is **nuclear magnetic resonance (NMR)**. The advantage of NMR is that it presents a dynamic view of molecules in solution, including multiple conformation states.

Unlike microscopy, X-ray diffraction does not present a direct view of a sample, but generates computational models. Dramatic as the models are, they can only represent particular aspects of electron clouds and electron density that are fundamentally "unseeable." That is why molecular structures are represented in different ways that depend on the context—by electron density maps, as models defined by van der Waals radii, or as stick models, for example. Proteins are frequently presented in a cartoon form that shows alpha helix and beta sheet secondary structures.

X-Ray Diffraction Analysis

For substances that can be crystallized, X-ray diffraction makes it possible to fix the position of each individual atom in a molecule, because the wavelengths of X-rays are much shorter than the wavelengths of visible light and are of the same magnitude as the dimensions of atoms. X-ray diffraction, like phase microscopy, involves the principle of wave interference (see **Fig. 2.13**). The interference pattern is generated when a crystal containing many copies of an isolated molecule is bombarded by a beam of X-rays (**Fig. 2.41A**). The wave fronts associated with the X-rays are diffracted as they pass through the crystal, causing interference patterns. In the crystal, the diffraction pattern is generated by a symmetrical array of many sample molecules (**Fig. 2.41B**). The larger the number of copies of the molecule in the array, the narrower the interference pattern and the greater the reso-



Bruker AXS Inc.

Figure 2.41 Visualizing molecules by X-ray crystallography. A. Modern apparatus for X-ray crystallography. The X-ray beam is focused onto a crystal, which is rotated over all angles to obtain diffraction patterns. The intensity of the diffracted X-rays is recorded on film or with an electronic detector. **B.** X-rays are diffracted by rows of identical molecules in a crystal. The diffraction pattern is analyzed to generate a model of the individual molecules. **C.** Diffraction pattern from a crystal.

lution of atoms within the molecule. Diffraction patterns obtained from the passage of X-rays through a crystal (**Fig. 2.41C**) can be analyzed by computation to develop a precise structural model for the molecule, detailing the position of every atom in the structure.

The application of X-ray crystallography to complex biological molecules was pioneered by the Irish crystallographer John Bernal (1901–1971) (**Fig. 2.42A**). Bernal was particularly supportive of women students and colleagues, including Rosalind Franklin (1920–1958) who made important discoveries about DNA and RNA, and Nobel laureate Dorothy Crowfoot Hodgkin (1910–1994). Hodgkin won the 1964 Nobel Prize in Chemistry for solving the crystal structures of penicillin and vitamin B_{12} (**Fig. 2.42B**). She later solved one of the first protein structures, that of the hormone insulin.

Today, X-ray data undergo digital analysis to generate sophisticated molecular models, such as the one seen in **Figure 2.43** of anthrax lethal factor, a toxin produced by *B. anthracis* that kills the infected host cells. The model for anthrax lethal factor was encoded in a Protein Data Bank (PDB) text file that specifies coordinates for all atoms of the structure. The Protein Data Bank is a growing world database of solved X-ray structures, freely available on the Internet. Visualization software is used to present the structure as a "ribbon" of amino acid residues, color-coded for secondary structure. In **Figure 2.43**, the pink-colored coils represent alpha helix structures, whereas the blue arrows represent beta sheets (for a review of these secondary structures, see Appendix 1).

WWW Protein Data Bank: Research Collaboratory for Structural Bioinformatics Protein and Nucleic Acid Databases

John Bernal developed X-ray crystallography to solve the structure of complex biological molecules. **B.** Dorothy Hodgkin (1910–1994) was awarded the 1964 Nobel Prize in Chemistry for her work in X-ray crystallography. **C.** Vitamin B_{12}, whose structure was originally solved by Dorothy Hodgkin. The corrin ring structure (see Chapter 15) is built around an atom of cobalt (pink). Carbon atoms are gray; oxygen, red; nitrogen, blue; phosphorus, yellow. Hydrogen atoms are omitted for clarity.

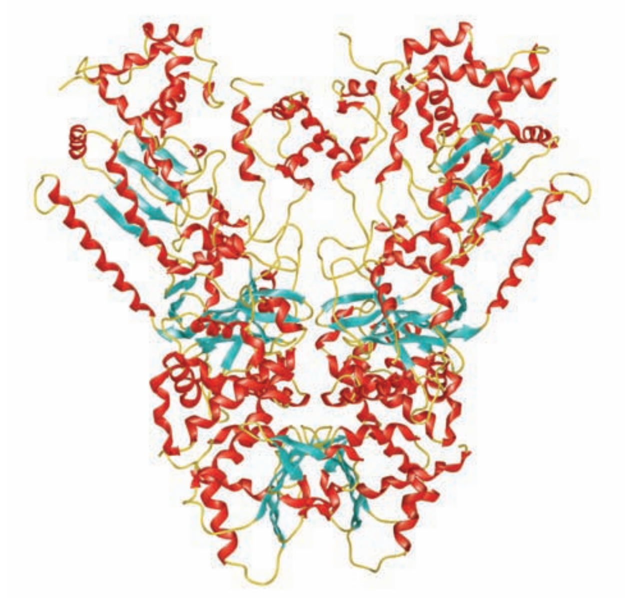

Figure 2.43 X-ray crystallography of a protein complex, anthrax lethal factor. The toxin consists of a butterfly-shaped dimer of two peptide chains. This cartoon model is based on X-ray crystallographic data, showing alpha helix (pink coils) and beta sheet (orange arrows). (PDB code: 1J7N)

A limitation of X-ray analysis is the unavoidable deterioration of the specimen under bombardment by X-rays. The earliest X-ray diffraction models of molecular complexes such as the ribosome relied heavily on components from thermophiles, microbes that grow at high temperatures. Because these organisms have evolved to grow under higher thermal stress, their macromolecular complexes form more stable crystals than do their homologues in organisms growing at moderate temperatures.

X-ray diffraction analysis of crystals from a wide range of sources was made possible by **cryocrystallography**. In cryocrystallography, as in cryo EM, crystals are frozen rapidly to liquid nitrogen temperature. The frozen crystals have greatly decreased thermal vibrations and diffusion, thus decreasing the radiation damage to the molecules. Models based on cryocrystallography can present multisubunit structures such as the bacterial ribosome complexed with transfer RNAs and messenger RNA. Much of our knowledge of microbial genetics (Chapters 7–12) and metabolism (Chapters 13–16) is based on crystal structures of key macromolecules.

TO SUMMARIZE:

- **X-ray diffraction analysis**, or **X-ray crystallography**, uses X-ray diffraction (interference patterns) from crystallized macromolecules to determine structure at atomic resolution.
- **Cryocrystallography** uses frozen crystals with greatly decreased thermal vibrations and diffusion, enabling the determination of structures of large macromolecular complexes, such as the ribosome.
- **Molecular visualization** by crystallography can only model the "appearance" of a molecule at atomic resolution. Different models emphasize different structural features and levels of resolution.

Concluding Thoughts

The tools of microscopy and molecular visualization described in this chapter have shaped our current understanding of microbial cells—how they grow and divide, organize their DNA and cytoplasm, and interact with other cells. Our current models of cell structure and function are explored in Chapter 3. In Chapter 4, we learn how cells use their structures to obtain energy, reproduce, and develop dormant forms that can remain viable for thousands of years.

CHAPTER REVIEW

Review Questions

1. What principle defines an object as "microscopic"?
2. Explain the difference between detection and resolution.
3. How do eukaryotic and prokaryotic cells differ in appearance under the light microscope?
4. Explain how electromagnetic radiation carries information and why different kinds of radiation can resolve different kinds of objects.
5. Define how light interacts with an object through absorption, reflection, refraction, and scattering.
6. Explain how refraction enables magnification of an image.
7. Explain how magnification increases resolution and why "empty magnification" fails to increase resolution.
8. Explain how angle of aperture and resolution change with increasing lens magnification.
9. Summarize the optical arrangement of a compound microscope.
10. Explain how to focus an object and how to tell when the object is in or out of focus.
11. Explain the relative advantages and limitations of wet mount and stained preparation for observing microbes.
12. Explain the significance (and limitations) of the Gram stain for bacterial taxonomy.
13. Explain the basis of dark-field, phase-contrast, and fluorescence microscopy. Give examples of applications of these advanced techniques.
14. Explain the difference between transmission and scanning electron microscopy and the different applications of each.

Chapter 3

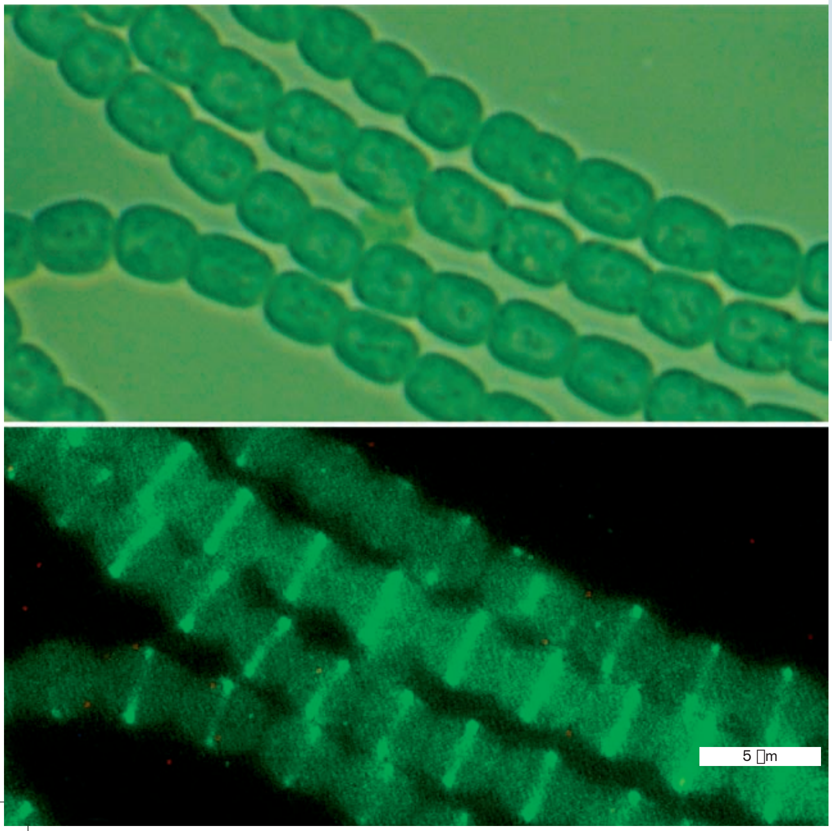
Cell Structure and Function

3.1 The Bacterial Cell: An Overview
3.2 How We Study the Parts of Cells
3.3 The Cell Membrane and Transport
3.4 The Cell Wall and Outer Layers
3.5 The Nucleoid and Gene Expression
3.6 Cell Division
3.7 Specialized Structures

Microbial cells face extreme challenges from their environment, enduring rapid changes in temperature and salinity, and pathogens face the chemical defenses of their hosts. To meet these challenges, microbes build complex structures, such as a cell envelope with tensile strength comparable to steel. Within the cytoplasm, molecular devices such as the the ribosome build and expand the cell.

With just a few thousand genes in its genome, how does a bacterial cell grow and reproduce? Bacteria coordinate their DNA replication through the DNA replisome and the cell fission ring. Other devices, such as flagellar propellers, enable microbial cells to compete, to communicate, and even to cooperate in building biofilm communities.

Discoveries of cell form and function have exciting applications for medicine and biotechnology. The structures of ribosomes and cell envelope materials provide targets for new antibiotics. And devices such as the rotary ATP synthase inspire “nanotechnology,” the design of molecular machines.



The filamentous cyanobacterium *Anabaena* sp. was engineered to make a cell division protein, FtsZ, fused to green fluorescent protein (GFP). FtsZ-GFP proteins form a ring-like structure around the middle of each cell, where it prepares to divide. *Source*: Samer Sakr, et al. 2006. *J. Bacteriol.* 188.

The microbial cell has formidable tasks: to obtain nutrients faster than its competitors, to protect itself from toxins and predators, and to reproduce itself. These tasks are accomplished by the cell's molecular parts.

To study the cell requires microscopy as well as isolating cell parts. Chapter 3 presents an overview of the bacterial cell, then explains how such views derive from cell fractionation and genetic analysis. We explore the structures common to most microbial cells, as well as more specialized devices such as light-harvesting complexes and magnetosomes. We dissect the cell's complex outer layers and see how they interact with the replicating chromosome to accomplish cell fission. Many of the cell's structures offer targets for antibiotic design as well as opportunities for biotechnology. Overall, this chapter focuses on prokaryotes, with reference to eukaryotes for comparison (eukaryotic microbes are covered in Chapter 20). Our discussion assumes an elementary knowledge of cell biology (reviewed in Appendices 1 and 2).

WWW **The Microbial Biorealm** online provides a quick, readable reference for microbial species, including those mentioned in this book.

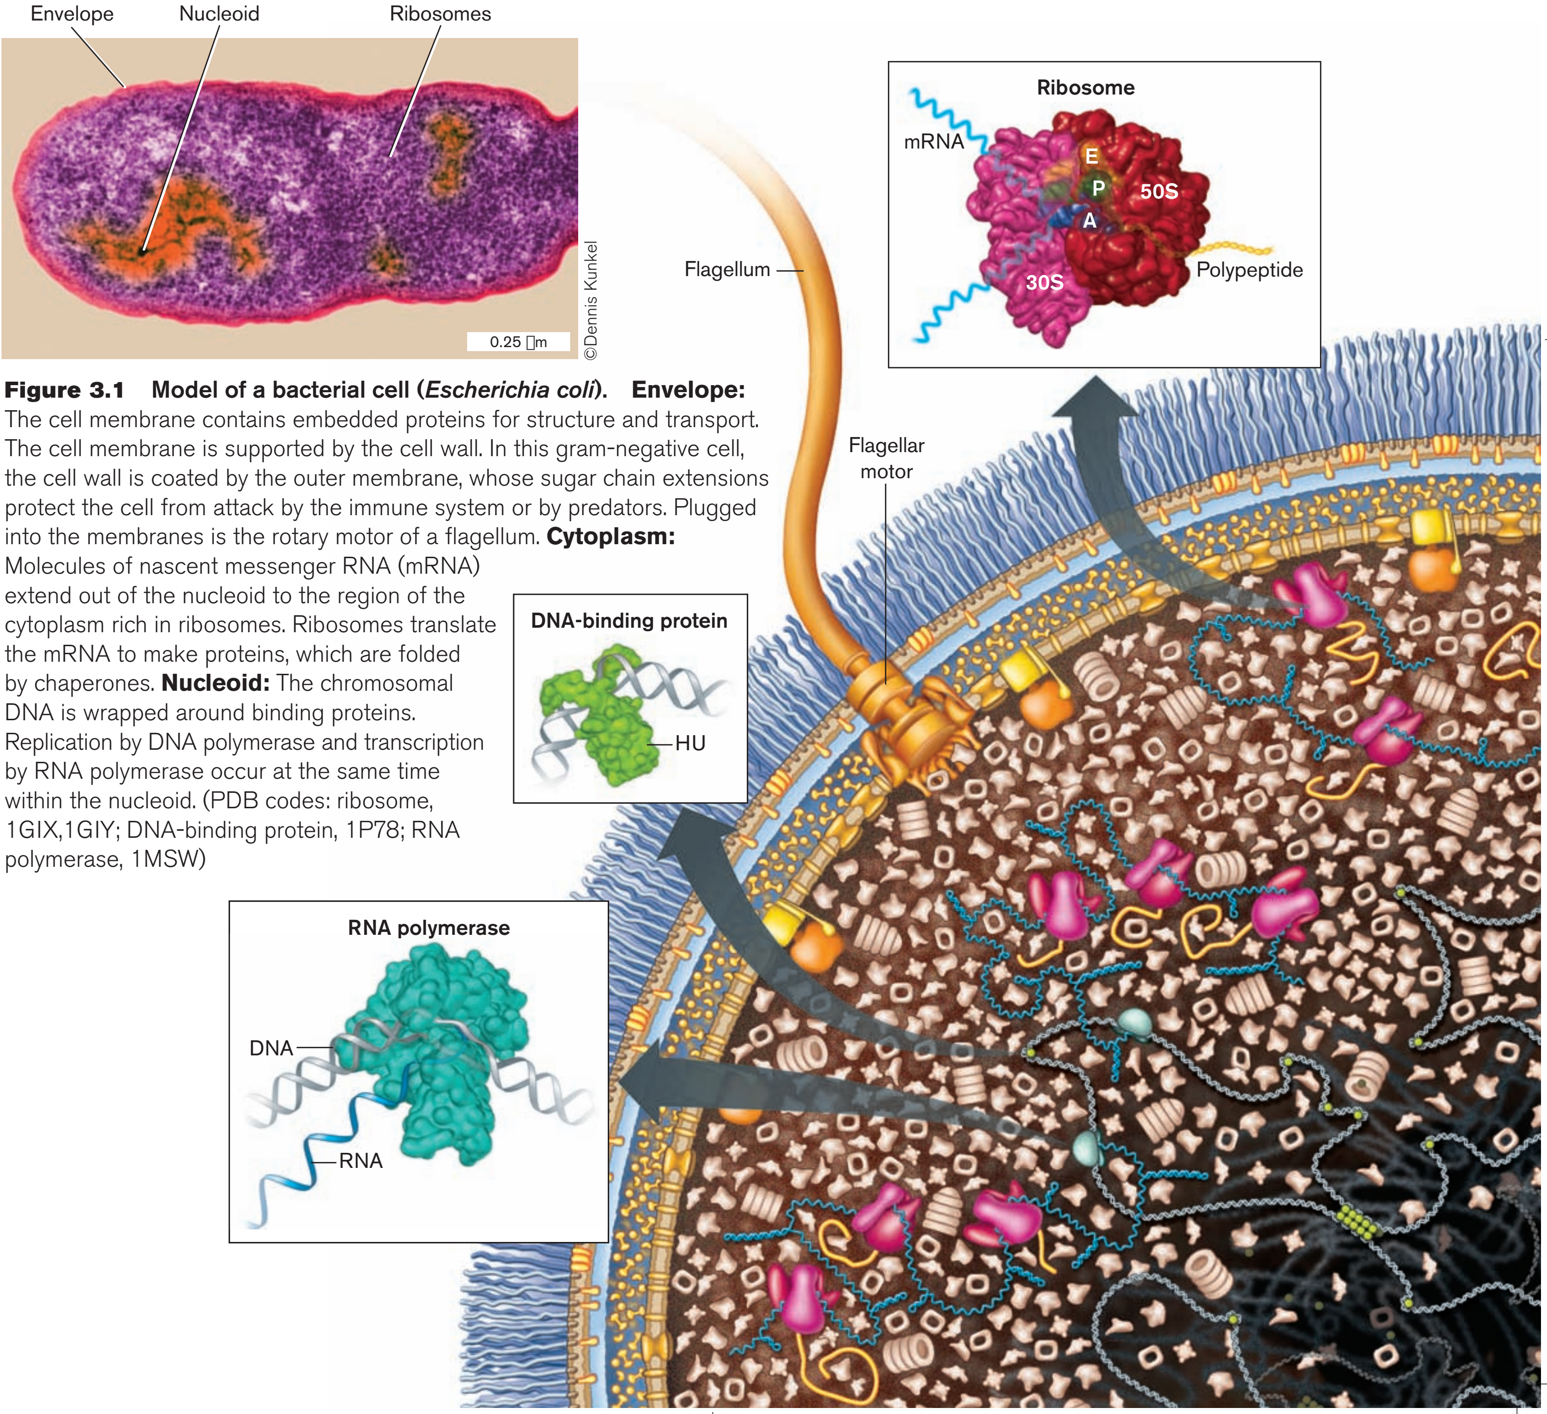


Figure 3.1 **Model of a bacterial cell (*Escherichia coli*). Envelope:** The cell membrane contains embedded proteins for structure and transport. The cell membrane is supported by the cell wall. In this gram-negative cell, the cell wall is coated by the outer membrane, whose sugar chain extensions protect the cell from attack by the immune system or by predators. Plugged into the membranes is the rotary motor of a flagellum. **Cytoplasm:** Molecules of nascent messenger RNA (mRNA) extend out of the nucleoid to the region of the cytoplasm rich in ribosomes. Ribosomes translate the mRNA to make proteins, which are folded by chaperones. **Nucleoid:** The chromosomal DNA is wrapped around binding proteins. Replication by DNA polymerase and transcription by RNA polymerase occur at the same time within the nucleoid. (PDB codes: ribosome, 1GIX,1GIY; DNA-binding protein, 1P78; RNA polymerase, 1MSW)

3.1 The Bacterial Cell: An Overview

Prokaryotic cells show a wide range of form, whose diversity is explored in Chapters 18 and 19. At the same time, most prokaryotes share fundamental traits:

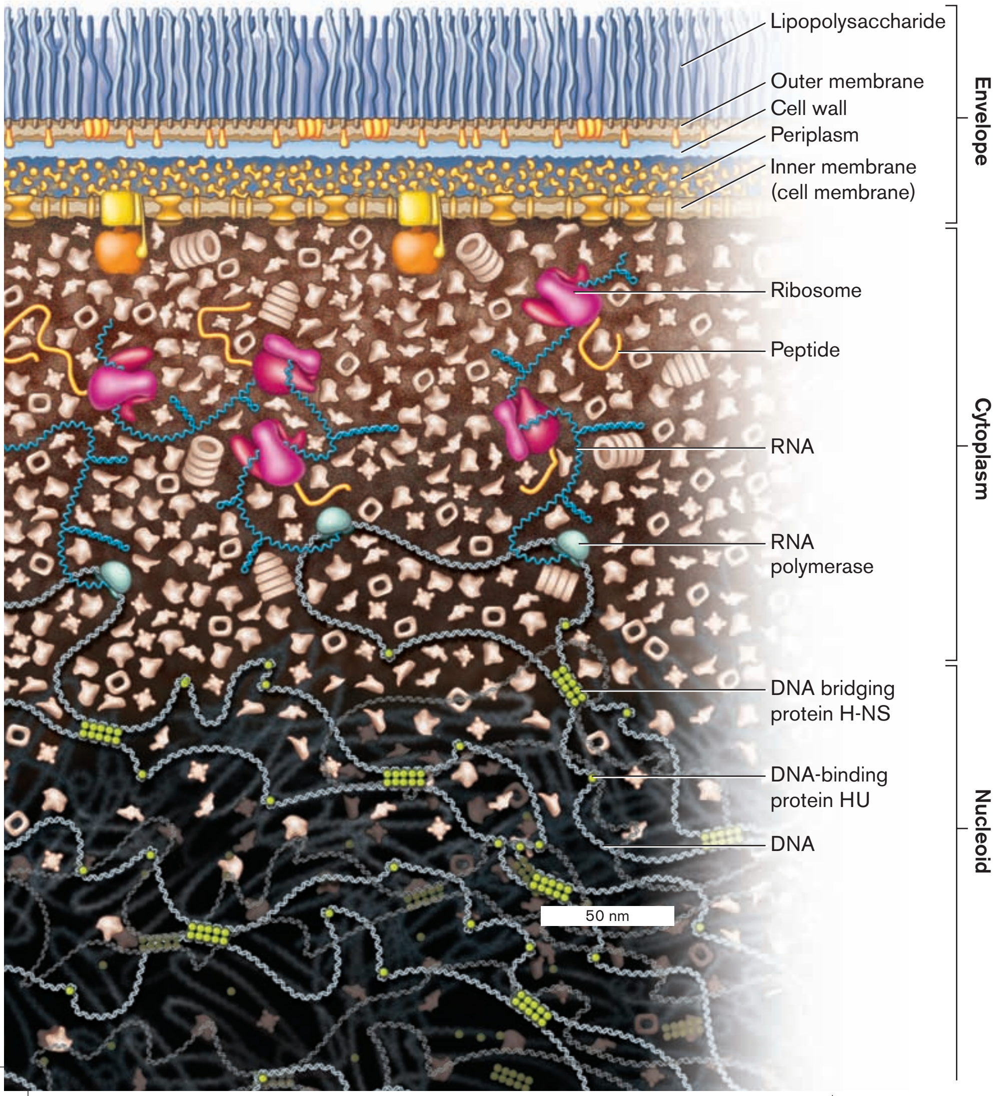
- **Thick, complex outer envelope.** The envelope protects the cell from environmental stress and predators. It also mediates exchange with the environment and communication with other organisms.
- **Compact genome.** Prokaryotic genomes are compact, with relatively little noncoding DNA. Small genomes maximize the production of cells from limited resources.
- **Tightly coordinated cell functions.** The cell's subcellular parts work together in a highly coordinate mechanism. Coordinate action enables high reproduction rate.

In the early twentieth century, the cell was envisioned as a bag of "soup" full of floating ribosomes and enzymes. Modern research shows that in fact the cell's parts fit together in a structure that is ordered, though flexible.

A Model of the Bacterial Cell

Here we present a model of the bacterial cell (**Fig. 3.1**). This model offers an interpretation of how the major components of one bacterial cell fit together. The model represents *Escherichia coli*, but its general features apply to many kinds of bacteria. Remember that we cannot literally "see" the molecules within a cell, but microscopy and subcellular analysis generate a remarkably detailed view.

Within the bacterial cell, the cytoplasm consists of a gel-like network composed of proteins and other macromolecules. The cytoplasm is contained by a **cell membrane** (or **inner membrane**, for a gram-negative cell). The membrane is composed of phospholipids, hydrophobic proteins, and other molecules. The cell membrane prevents



Bacterial Cell Components

Outer membrane proteins:
- Sugar porin (10 nm)
- Braun lipoprotein (8 nm)

Inner membrane proteins:
- Glycerol porin
- Secretory complex (Sec)
- ATP synthase (20 nm diameter in inner membrane; 32 nm total height)

Periplasmic proteins:
- Arabinose-binding protein (3 nm x 3 nm x 6 nm)
- Acid resistance chaperone (HdeA) (3 nm x 3 nm x 6 nm)
- Disulfide bond protein (DsbA) (3 nm x 3 nm x 6 nm)

Cytoplasmic proteins:
- Pyruvate kinase (5 nm x 10 nm x 10 nm)
- Phosphofructokinase (4 nm x 7 nm x 7 nm)
- Proteasome (12 nm x 12 nm x 15 nm)
- Chaperonin GroEL (18 nm x 14 nm)
- Other proteins

Transcription and translation complexes:
- RNA polymerase (10 x 10 x 16 nm)
- Ribosome (21 x 21 x 21 nm)

Nucleoid components:
- DNA (2.4 nm wide x 3.4 nm/10 bp)
- DNA-binding protein (3 x 3 x 5 nm)
- DNA-bridging protein (3 x 3 x 5 nm)

cytoplasmic proteins from leaking out and maintains gradients of ions and nutrients. It is covered by a **cell wall**, a rigid structure composed of polysaccharides linked covalently by peptides (peptidoglycan). The cell wall forms a single cage-like molecule that surrounds the cell.

In gram-negative bacteria such as *E. coli*, the cell wall consists of a single layer of peptidoglycan, a polymer of sugars and peptides. The cell wall extends within the **periplasm**, an aqueous layer containg proteins such as sugar transporters. Outside the cell wall lies an **outer membrane** of phospholipids and **lipopolysaccharides (LPSs)**, a class of lipids attached to long polysaccharides (sugar chains). LPS and other polysaccharides can generate a thick **capsule** surrounding the cell. The capsule polysaccharides form a slippery mucous layer that inhibits phagocytosis by macrophages (see Section 26.3). The cell wall and outer membrane constitute the **envelope**.

The envelope includes cell surface proteins that enable the bacteria to interact with specific host organisms. For example, *E. coli* cell surface proteins enable colonization of the human intestinal epithelium, whereas *Sinorhizobium* cell surface proteins enable colonization of legume plants for nitrogen fixation. Another common external structure is the **flagellum**, a helical protein filament whose rotary motor propels the cell in search of a more favorable environment.

Within the cell, the cell membrane and envelope provide an attachment point for one or more chromosomes. The chromosome is organized within the cytoplasm as a system of looped coils called the **nucleoid**. Unlike the round, compact nucleus of eukaryotic cells, the bacterial nucleoid is not bounded by a membrane, and so the coils of DNA can extend throughout the cytoplasm. Loops of DNA from the nucleoid are transcribed by RNA polymerase to form messenger RNA (mRNA) as well as small functional RNA molecules (sRNA). As the mRNA transcripts grow, they bind ribosomes to start synthesizing polypeptide chains. As the polypeptides grow, protein complexes called chaperones help them fold into their functional conformations.

Microbial Eukaryotes

How do eukaryotic microbes, such as euglenas and amebas, compare with prokaryotes? Most eukaryotic cells that have been studied are much larger than prokaryotes; some amebas are actually visible to the unaided eye. Yet DNA-based surveys of natural environments, such as the ocean and soil, reveal eukaryotes as small as the smallest bacteria. Thus, eukaryotic cells extend over the full size-range encompassed by prokaryotes, in addition to reaching much larger sizes.

Like bacteria, microbial eukaryotes typically possess a thick outer covering. Fungi possess cell walls of polysaccharide, whereas protists have a **pellicle**, consisting of membranous layers reinforced by protein microtubules. Other kinds of eukaryotic cell surface are reinforced by inorganic materials, such as the silicate shells of diatoms.

Eukaryotic microbes contain subcellular organelles composed of membranes that are more extensive and specialized than those of prokaryotes. Examples include the nuclear membrane, golgi, mitochondria, and chloroplasts (reviewed in Appendix 2). These organelles perform some of the physiological functions that are provided by organ systems in multicellular organisms, such as circulation, digestion, and excretion. Mitochondria and chloroplasts are the products of ancestral engulfment of prokaryotic cells, followed by evolution of endosymbiosis, as explained in Chapter 17. Eukaryotic microbial diversity is explored in Chapter 20.

Biochemical Composition of Bacteria

The bacterial cell model indicates shape and size, but tells little about chemical composition. Chemistry explains, for example, why wiping a surface with ethanol eliminates microbial life, whereas water has little effect. Water is a universal constituent of cytoplasm, but is excluded by cell membranes. Ethanol, however, dissolves both polar and nonpolar substances; thus, ethanol disintegrates membranes and destroys the secondary structure of proteins.

All cells share common chemical components:

- **Water**, the fundamental solvent of life
- **Essential ions**, such as potassium, magnesium, and chloride ions
- **Small organic molecules**, such as lipids and sugars that are incorporated into cell structures and that provide nutrition by catabolism
- **Macromolecules**, such as nucleic acids and proteins, which contain information, catalyze reactions, and mediate transport, among many other functions

Cell composition varies with species, growth phase, and environmental conditions. **Table 3.1** summarizes the chemical components of a cell for the model bacterium *Escherichia coli* during exponential growth.

Small molecules. The *E. coli* cell consists of about 70% water, the essential solvent required to carry out fundamental metabolic reactions and to stabilize proteins. The water solution contains inorganic ions, predominantly potassium, magnesium, and phosphate. Inorganic ions store energy in the form of transmembrane gradients, and they serve essential roles in enzymes. For example, a magnesium ion is required at the active site of RNA polymerase to help catalyze incorporation of ribonucleotides into RNA.

Table 3.1 Molecular composition of a bacterial cell, *Escherichia coli*, during balanced exponential growth.[a]

Component	Percentage of total weight[b]	Approximate number of molecules/cell	Number of different kinds
Water	70%	20,000,000,000	1
Proteins	16%	2,400,000	2,000[c]
RNA: rRNA, tRNA, and other small regulatory RNA (sRNA),	6%	250,000	200
mRNA	0.7%	4,000	2,000[c]
Lipids: phospholipids (membrane)	3%	25,000,000	50
lipopolysaccharide (outer membrane)	1%	1,400,000	1
DNA	1%	2[d]	1
Metabolites and biosynthetic precursors	1.3%	50,000,000	1,000
Peptidoglycan (murein sacculus)	0.8%	1	1
Inorganic ions	0.1%	250,000,000	20
Polyamines (mainly putrescine and spermine)	0.1%	6,700,000	2

[a] Values shown are for a hypothetical "average" cell cultured with aeration in glucose medium with minimal salts at 37°C.

[b] The total weight of the cell (including water) is about 10^{-12} gram (g), or 1 picogram (pg).

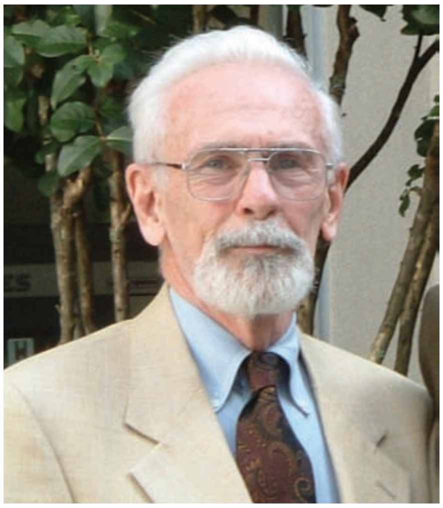
[c] The number of kinds of mRNA and of proteins is difficult to estimate because some genes are transcribed at extremely low levels and because RNA and proteins include kinds that are rapidly degraded.

[d] In rapidly growing cells, cell fission typically lags approximately one generation behind DNA replication; hence, two identical DNA copies per cell.

Source: Modified from Neidhardt, F., and H. E. Umbarger. 1996. Chemical composition of *Escherichia coli*, p. 14. In *Escherichia coli* and *Salmonella*: Cellular and Molecular Biology, 2nd ed. ASM Press, Washington, DC.

The cell also contains many kinds of small charged organic molecules, such as phospholipids and enzyme cofactors. A major class of organic cations is the **polyamines**, molecules with multiple amine groups that are positively charged when the pH is near neutral. Polyamines balance the negative charges of the cell's DNA, and they stabilize ribosomes during translation.

Macromolecules. Many cells show similar content of water and small molecules, but their specific character is defined by their macromolecules, especially their proteins. Proteins vary among different species; and a given species makes very different proteins, depending on environmental conditions such as temperature, nutrient levels, and entry into a host organism. Individual proteins, encoded by specific genes, are found in very different amounts, from 10 per cell to 10,000 per cell. The total proteins encoded by a genome, capable of expression in the cell, are known collectively as the **proteome**. Early attempts to define the proteome of a cell were conducted by Fred Neidhardt (**Fig. 3.2**) and colleagues at the University of Michigan, who created the first protein catalog of *E. coli* using **two-dimensional polyacrylamide gel electrophoresis** (**2-D PAGE** or **2-D gels**) (**Fig. 3.3**).



Frederick C. Neidhardt, U. of Michigan

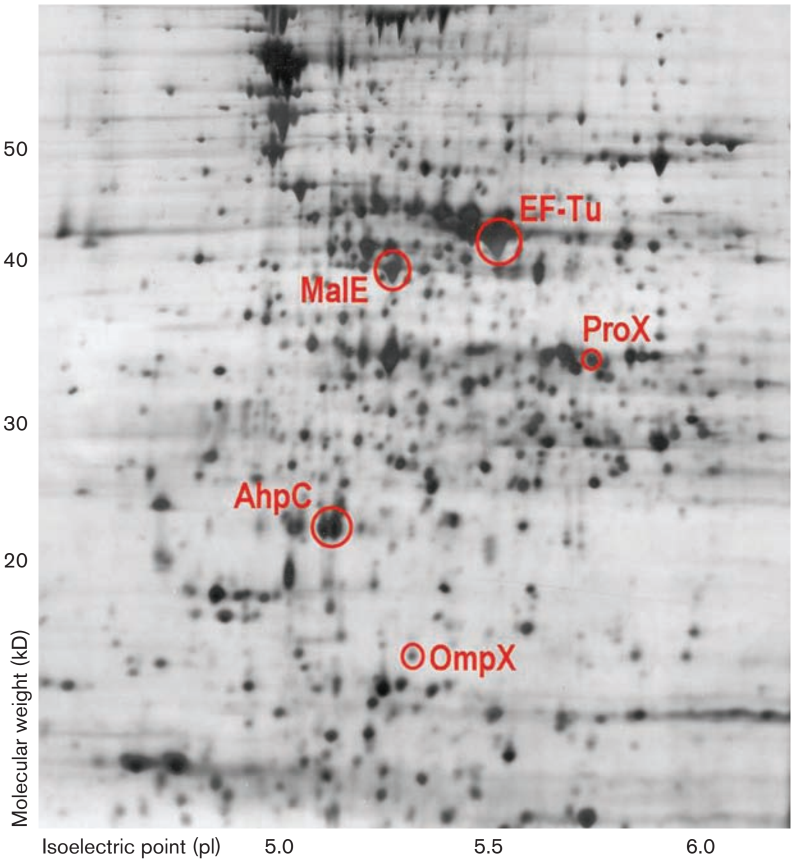
Figure 3.2 **Proteins of *E. coli*.** Fred Neidhardt and colleagues at the University of Michigan, Ann Arbor, used 2-D gel electrophoresis to create the first protein catalog of *E. coli*.

To obtain 2-D gels, cells are lysed by sonication or detergent to release and solubilize as many proteins as possible. The proteins are then subjected to two forms of separation, isoelectric focusing followed by electrophoresis. In **isoelectric focusing**, proteins are placed in a gel that has a pH gradient, and they migrate along the gradient until they reach the point where the number of positively charged residues equals the number of negatively charged residues. At this point, their net charge is zero (that is, the pH equals the protein's isoelectric point), and the protein stops moving. In **electrophoresis**, proteins deposited in an electrical field migrate toward a positive electrode. The proteins are coated with a reagent (SDS, or sodium dodecyl sulfate) to confer a uniform negative charge so that their distance of migration depends on molecular weight (roughly a logarithmic function). The proteins are then stained for detection, and the protein spots can be identified, either by N-terminal protein sequencing or by mass spectrometry.

In a 2-D gel of *E. coli* (**Fig. 3.3**), about 500 different proteins can be distinguished. The most highly expressed proteins include ribosomal proteins and translation factors such as elongation factor Tu (EF-Tu). Outer membrane proteins such as OmpX and ProX also show high concentration. Conversely, many proteins of the inner (cell) membrane are too insoluble in water to appear, and some important regulators are present at levels too low to be seen. Nevertheless, 2-D gels are useful for identifying changes in protein expression that occur under different environmental conditions or when bacteria are invading host cells.

Protein synthesis is directed by DNA and RNA. The content of nucleic acids in *E. coli* is nearly 8% by weight, much higher than in multicellular eukaryotes. For microbes, the high nucleic acid content is advantageous, allowing the cell to maximize reproduction of its chromosome while minimizing resources for protein-rich cytoplasm. The high level of nucleic acids is actually toxic to human consumers, who lack the enzymes to digest the uric acid waste product of digested nucleotides. That is why most kinds of bacteria cannot be eaten as a major part of the diet.

Other kinds of macromolecules are found in the cell wall and outer membrane. The bacterial cell wall consists of **peptidoglycan**, an organic polymer that constitutes nearly 1% of the cell mass, approximately the same mass as that of DNA. This shows the importance (for most species) of maintaining turgor pressure in dilute environments, where water would otherwise enter by osmosis, causing osmotic shock.



Joan Slonczewski, Kenyon College

Figure 3.3 Proteins of *E. coli*. 2-D gel of proteins of *Escherichia coli* grown aerobically in a casein-yeast extract medium. Proteins were identified by N-terminal sequence and by mass spectroscopy. DnaK is a cytoplasmic chaperone; EF-Tu is an elongation factor for translation; MalE is an outer membrane maltose-binding protein; ProX and OmpX are periplasmic transporters; and AhpC is an antioxidant stress protein.

THOUGHT QUESTION 3.1 Which molecules occur in the greatest number in a prokaryotic cell? The smallest number? Why does a cell contain 100 times as many lipid molecules as strands of RNA?

TO SUMMARIZE:

- **Prokaryotic cells** are protected by a thick cell envelope.
- **Compact genomes** maximize reproductive potential with minimal resources.
- **The model bacterial cell** contains a highly ordered cytoplasm in which DNA replication, RNA transcription, and protein synthesis occur coordinately.
- **The biochemical composition of bacteria** includes relatively high nucleic acid content, as well as proteins, phospholipids, and other organic and inorganic constituents.
- **Proteins in the cell** vary, depending on the species and environmental conditions.

3.2 How We Study the Parts of Cells

How can we determine how all the macromolecules listed in **Table 3.1** interact and work together? Electron microscopy largely defines how we "see" the cell's interior as a whole. In **Figure 3.1**, we clearly saw major parts of *B. thuringiensis*, such as the endospore and the parasporal crystal. But smaller parts, such as the ribosomes, appear only as small, densely packed particles. Furthermore, even higher-resolution images from electron microscopy cannot tell us the chemical composition of ribosomes or how they function in the living cell.

To study ribosome function requires isolation and analysis of subcellular parts:

- **Subcellular fractionation** enables isolation of cell parts such as ribosomes and membranes so that we can study their form and function.
- **Structural analysis** by X-ray crystallography and related methods reveals the form of cell components.
- **Genetic analysis** dissects the function of cell components based on construction of mutant cells with altered function.

In this section, we present these methods as applied to a key example of cellular function, that of the bacterial ribosome. Each method has its particular strengths and limitations to reveal form and function.

Isolating Parts of Cells

Cellular components, such as ribosomes and flagellar motors, can be isolated readily from cells. The cells must be broken open by techniques that allow subcellular components to remain intact. Here are examples of such techniques:

- **Mild detergent lysis.** Cells can be lysed with a detergent capable of dissolving membranes but not denaturing proteins.
- **Freezing and thawing.** Freezing and then thawing is another way to open cells gently, releasing particles such as ribosomes.
- **Sonication.** Cells can be lysed by intense ultrasonic vibrations above the range of human hearing.
- **Enzymes.** Enzymes such as lysozyme can break the cell wall, allowing the cell to be lysed by mild osmotic shock.

The ultracentrifuge. Different parts of the cell can be isolated by **subcellular fractionation**. A key tool of subcellular fractionation is the **ultracentrifuge**, a device in which solutions containing cell components are rotated in tubes at high speed. The high rotation rate generates centrifugal forces strong enough to separate subcellular particles (**Fig. 3.4A**). The ultracentrifuge was invented

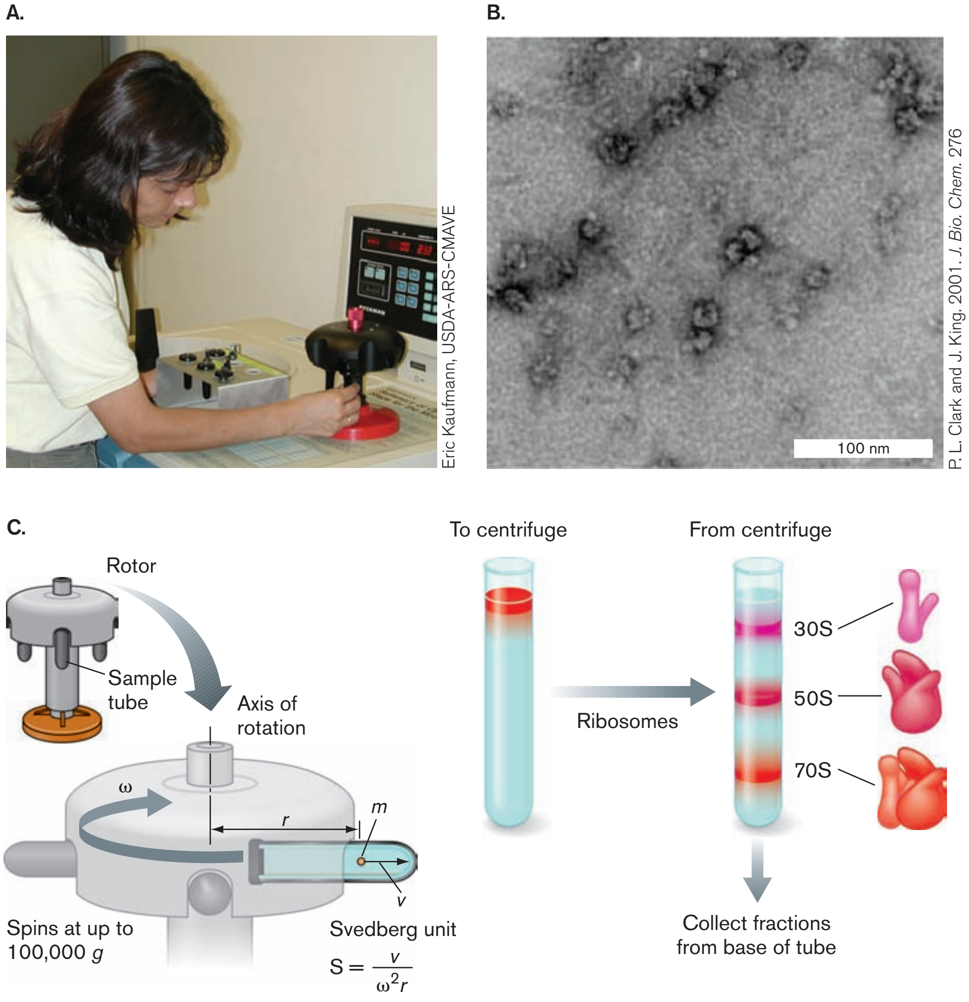


Figure 3.4 **Subcellular fractionation by ultracentrifugation.** **A.** An ultracentrifuge is used to fractionate cell components. **B.** *Salmonella* ribosomes (TEM) isolated from the cytoplasm by ultracentrifugation through a linear sucrose density gradient. Polysomes consist of two or more ribosomes attached to mRNA. **C.** High-speed rotation generates high centrifugal forces, measured in units of gravity (*g*). The Svedberg unit (S) offers a measure of particle size based on its rate of travel in a tube subjected to high *g* force. The Svedberg coefficient (number of S units; for example, 30S) is defined in terms of the velocity of the particle in the tube (*v*), the radius of the rotor (*r*), and the rotational velocity (□). The coefficient of S for a given particle depends on its mass (*m*) and its shape. After centrifugation, fractions are collected from the base of the centrifuge tube. The fractions contain radiolabeled ribosomes. The largest particles (whole ribosomes) sediment near the bottom of the tube, whereas the smaller particles (separate 50S and 30S subunits) appear in upper fractions.

Eric Kaufmann, USDA-ARS-CMAVE

P. L. Clark and J. King. 2001. *J. Bio. Chem.* 276

by the Swedish physicist Theodor Svedberg (1884–1971), who won the 1926 Nobel Prize in Chemistry for the use of ultracentrifugation to separate proteins.

Modern ultracentrifuges have titanium rotors that spin in a vacuum to avoid frictional heating, generating forces up to 100,000 times gravity (100 k *g*). For fractionation, cells are first lysed by one of the methods previously described to obtain a cell **lysate**, a general term for the contents of a broken cell. The cell lysate is placed in tubes containing a high-density solution, such as sucrose or cesium chloride solution, in which suspended particles sediment slowly. Under a high *g* force, however, particles sediment at different rates, depending on their size and density.

The **sedimentation rate** is the rate at which particles of a given size and shape travel to the bottom of the tube under centrifugal force. The sedimentation rate is measured by the Svedberg unit, S, which is given by the particle's rate of sedimentation (v), the radius at which the tube rotates (r), and the rotational velocity (ω):

$$S = v/(\omega^2 r)$$

For a given type of particle in suspension, the sedimentation rate also depends on the particle's mass and shape. The contribution of particle mass and shape is defined as its **Svedberg coefficient**; for example, the coefficient of the small subunit of the ribosome is 30, for a sedimentation value of 30S. The value of the Svedberg coefficient increases with the average cross-sectional area of the particle. For bacterial ribosomes, ultracentrifugation yields intact ribosomes (70S) as well as separated ribosomal subunits, the large subunit (50S) and the small subunit (30S). Within cells, ribosomes normally exist as a mixture of joined and separate subunits.

To isolate the ribosomes, a cell lysate is layered onto a tube of sucrose solution, whose density decreases the sedimentation rate and increases the separation of particles of different size (**Fig. 3.4A**). The fractions shown in **Figure 3.4C** were drained sequentially from the base of the tube after centrifugation. The heaviest particle, the 70S ribosome, appears in the fractions nearest the bottom of the tube because it travels fastest under the centrifugal force.

THOUGHT QUESTION 3.2 Why does the Svedberg coefficient of the intact ribosome (70S) differ from the sum of the individual subunits of the ribosome (30S and 50S)?

The ribosomes can be seen in collected fractions by electron microscopy (**Fig. 3.4B**). In some cases, two or more ribosomes are connected by a strand of messenger RNA (mRNA). This multiple-ribosome structure, called a polysome, gives our first clue as to the intracellular organization of the translation apparatus within a bacterial cell (see Fig. 3.1), where a number of ribosomes translate each mRNA at the same time.

Furthermore, ribosomes isolated by centrifugation can translate messenger RNA in cell-free systems. Experiments in cell-free systems provide the basis of much of our knowledge of protein synthesis (see Chapter 8).

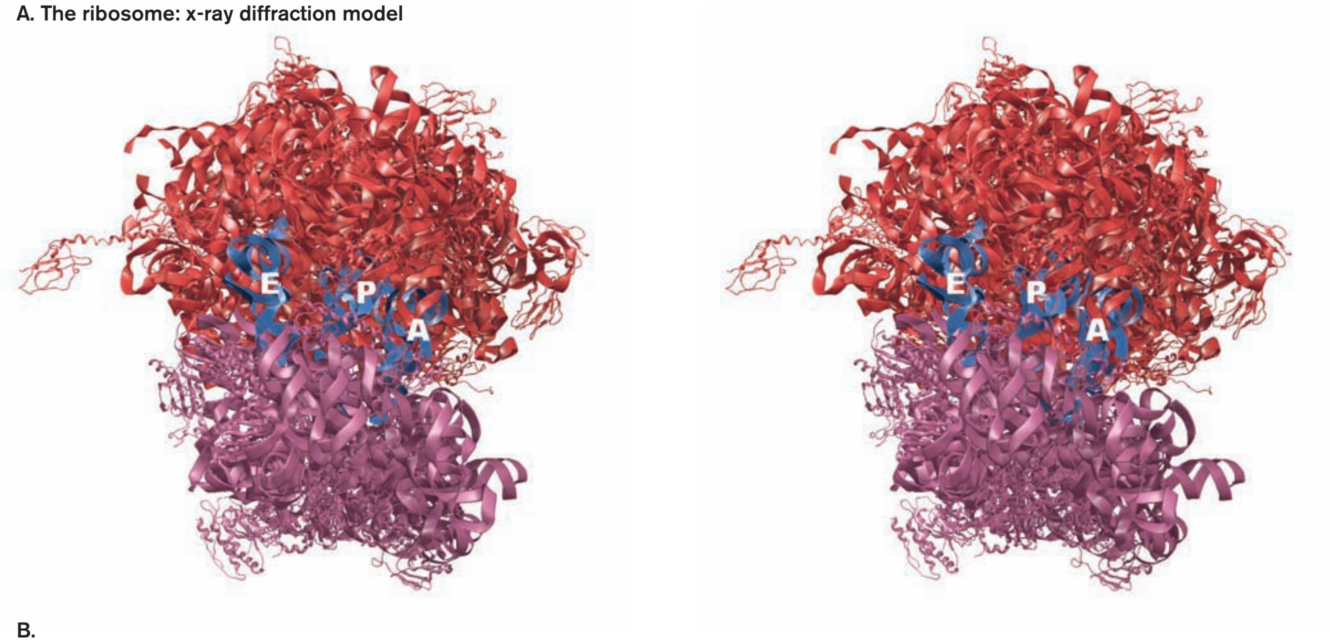
Limitations of subcellular fractionation. Subcellular fractionation yields clues about internal structure but provides little information about processes that require overall integrity of the cell. For example, the role of the transmembrane electrochemical potential, or proton potential, in ATP synthesis was obscured for many years because biochemists were unable to isolate a cytoplasmic complex responsible for it. Transmembrane ion gradients were in fact observed within membrane vesicles—spheres of membrane isolated by cell disintegration and centrifugation. But it was harder to demonstrate that the entire cell membrane of an intact cell supports a proton potential.

Crystallographic Analysis Reveals Structure

Isolated ribosomes can be crystallized for structure analysis by X-ray diffraction crystallography. A crystallographic model of the 30S ribosomal subunit is shown in **Figure 3.5A**. The 30S subunit consists of ribosomal RNA (rRNA) and 27 different proteins, each of which is encoded by a particular gene. The sequences of all the ribosomal genes, with their predicted protein and RNA products, were fitted with X-ray crystallography data to build a three-dimensional model of the 30S subunit. This model includes three bound transfer RNA (tRNA) molecules, each at a key position for translation: the acceptor site (A) for incoming aminoacyl-tRNA; the peptide site (P) attached to the growing peptide chain; and the exit site (E), where tRNA is released from the ribosome.

A similar model was obtained of the 30S ribosomal subunit bound to streptomycin, an antibiotic produced by *Streptomyces* bacteria (**Fig. 3.5B**). In this model, the streptomycin molecule contacts a particular ribosomal protein, S12. The contact with S12 distorts the structure of the A site and thus halts protein synthesis. Only the ribosomes of bacteria, not of eukaryotes, have the precise shape to bind streptomycin; thus, this antibiotic kills bacterial pathogens without harming the human patient. Studying ribosome structure enables us to design new antibiotics.

Limitations of crystallography. As discussed in Chapter 2, crystallographic analysis applies only to isolated particles and under conditions in which its full function cannot be observed. The technique can solve structures



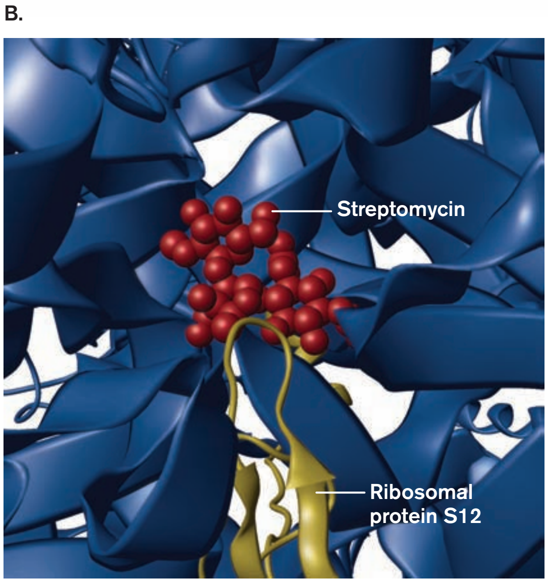


Figure 3.5 **X-ray diffraction models relate structure to function.** **A.** The 30S ribosomal subunit, X-ray diffraction model of the 16S RNA (stereo view) showing the acceptor (A) site, the peptide (P) site, and the exit (E) site. To view, place a piece of cardboard vertically between the two images. Position your eyes on opposite sides of the cardboard and force them to focus behind the images. The images will merge and produce a 3-D image. (PDB codes: 1GIX, 1GIY) **B.** When the ribosome is crystallized with streptomycin, the antibiotic molecule binds to protein S12, near the A site. Streptomycin interferes with the tRNA binding to the A site.

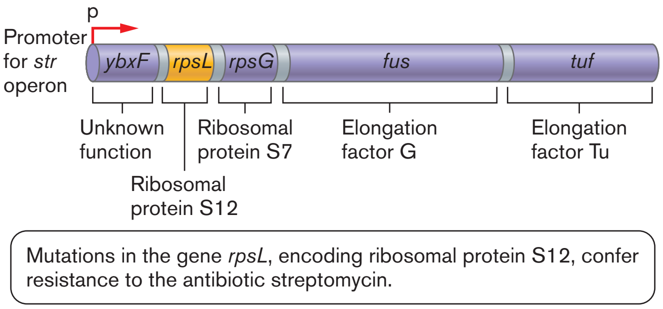

Mutations in the gene *rpsL*, encoding ribosomal protein S12, confer resistance to the antibiotic streptomycin.

Figure 3.6 **Genetic analysis of the streptomycin-resistant ribosome.** The *str* operon has genes encoding components of the ribosome. A mutation in *rpsL*, the gene encoding ribosomal protein S12, alters the protein's interaction with streptomycin. The mutant gene makes the bacteria resistant to the antibiotic.

only for proteins and nucleic acids capable of crystallization. It remains impractical for proteins of flexible, nonrigid structure and for many membrane-soluble proteins.

Genetic Analysis Reveals Function

The crystal structure of a macromolecule only yields clues as to function; it does not show the structure in action. The function of cell components can be dissected by **genetic analysis**. In genetic analysis, mutant strains are selected for loss of a given function, or a strain can be intentionally mutated so as to lose or alter a gene.

An example of genetic analysis is the use of ribosome-encoding genes to show how ribosome function is blocked by the antibiotic streptomycin. The genes specifying each ribosomal protein and RNA (rRNA) are organized in operons of genes under one promoter, such as the *str* operon (**Fig. 3.6**). The *str* operon was named for streptomycin resistance, a phenotype conferred by mutations in the gene *rpsL*. Mutations conferring streptomycin resistance were known for decades before the structural basis was discovered. These mutations were mapped to the gene *rpsL* encoding the protein S12, whose position in the 30S subunit was shown by X-ray crystallography (see **Fig. 3.5B**). The S12 protein forms part of the ribosome's tRNA acceptor (A) site, which receives the incoming aminoacyl-tRNA. Mutation in the gene encoding S12 generates a protein of altered shape, permitting function in the presence of streptomycin. Thus, genetic analysis and crystallography were combined to demonstrate the precise mode of action of an important antibiotic.

An exciting extension of genetic analysis is the construction of strains with "reporter genes" fused to genes encoding structures of interest. An example of a reporter gene is green fluorescent protein, which fluoresces at the site of the fused protein. Fluorescent reporter genes enable us to observe the function of proteins within a live cell. In Section 3.6, we will discuss the use of fluorescent reporter genes to observe chromosome replication and cell division. The methods of gene manipulation are discussed in Chapters 8 and 12.

THOUGHT QUESTION 3.3 What are the advantages and limitations of biochemical and genetic approaches to cell structure and function?

TO SUMMARIZE:

- **Subcellular fractionation** isolates cell parts for structural, biochemical, and genetic analysis.
- **X-ray crystallography** shows the three-dimensional form of cell components at the atomic level.
- **Genetic analysis** shows which genes and proteins are responsible for functions of subcellular complexes such as the ribosome. Mutation of a gene leads to altered function of the cell.

3.3 The Cell Membrane and Transport

The structure that defines the existence of a cell is the cell membrane (**Fig. 3.7**). The cell membrane consists of a phospholipid bilayer containing lipid-soluble proteins. Overall, the membrane serves two kinds of function: It contains the cytoplasm within the external medium, mediating transport between the two; and it carries many proteins with specific functions, such as biosynthetic enzymes and environmental signal receptors.

Membranes Consist of Phospholipids and Proteins

Cell membranes are composed of approximately equal parts phospholipids and proteins. Each phospholipid possesses a charged phosphate-containing "head" that contacts the water interface, as well as a hydrophobic "tail" packed within the bilayer. A phospholipid consists of glycerol with ester links to two fatty acids and a phosphoryl polar head group (for review, see Appendix 2). The polar head group may have a side chain such as ethanolamine in **phosphatidylethanolamine**, the major phospholipid of *E. coli* (**Fig. 3.8**). Lipid biosynthesis is a key process of cells; for example, a bacterial enzyme for fatty acid biosynthesis, enoyl reductase, is the target of triclosan, a common antibacterial additive in detergents and cosmetics.

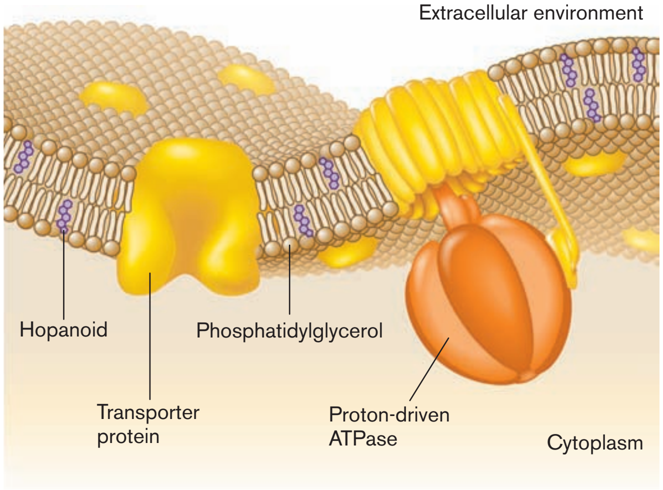

Figure 3.7 Bacterial cell membrane. The cell membrane consists of a phospholipid bilayer, with hydrophobic fatty acid chains directed inward, away from water. The bilayer contains stiffening agents such as hopanoids, which serve the same function as cholesterol in eukaryotic membranes. Half the volume of the membrane consists of proteins.

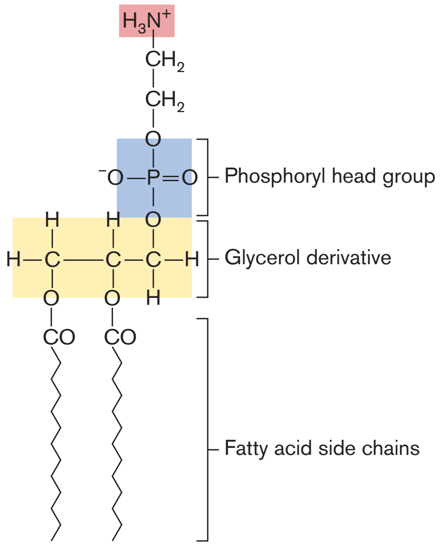
In the bilayer, all phospholipids face each other tail to tail, keeping their hydrophobic side chains away from the water inside and outside the cell. The two layers of phospholipids in the bilayer are called **leaflets**. One leaflet of phospholipids faces the cell interior, whereas the other faces the exterior. As a whole, the phospholipid bilayer imparts fluidity and gives the membrane a consistent thickness (about 10 nm).

The cell membrane can be thought of as a two-dimensional fluid within which float a vast array of hydrophobic proteins and smaller molecules such as hopanoids (see Fig. 3.7). Membrane proteins serve numerous functions that define the capabilities of the cell, including transport, communication with the environment, and structural support. Examples include:

- **Structural support.** Some membrane proteins anchor together different layers of the cell envelope (see Section 3.4). Other proteins attached to membranes form part of the cytoskeleton. Still others form the base of structures that extend out from the cell, such as pili,



Phosphatidylethanolamine

Figure 3.8 Phosphatidylethanolamine. A major bacterial phospholipid consists of glycerol with ester links to two fatty acids and a phosphoethanolamine.

filaments, and flagella; these enable adherence and motility.

- **Detection of environmental signals.** In *Vibrio cholerae*, the causative agent of cholera, ToxR is a transmembrane protein whose amino-terminal part reaches into the cytoplasm. When ToxR detects acidity and elevated temperature—signs of the host digestive tract—its amino-terminal domain binds to DNA at a sequence that activates expression of cholera toxin and other virulence factors.
- **Secretion of virulence factors and communication signals.** Membrane proteins form secretion complexes to export toxins and cell signals across the envelope. For example, symbiotic nitrogen-fixing rhizobia require membrane proteins NodI and NodJ to transport nodulation signals out to the host plant roots, where they induce formation of root nodules containing the bacteria.

Proteins embedded within a membrane must have a hydrophobic portion that is soluble within the membrane. Typically, several hydrophobic alpha helices thread back and forth through the membrane. Other regions of peptide extend outside the membrane, containing charged and polar amino acids that interact favorably with water. The combination of hydrophobic and hydrophilic regions effectively locks the protein into the membrane.

Transport across the Cell Membrane

Overall, the cell membrane acts as a barrier to sequester water-soluble proteins of the cytoplasm. The membrane's specific components, particularly proteins, determine which substances cross the membrane between the cytoplasm and the outside. Selective transport is essential for cell survival; it means the ability to acquire scarce nutrients while excluding toxins.

Osmosis. Most cells maintain a concentration of total **solutes** (molecules in solution) that is higher inside the cell than outside. As a result, the internal concentration of water is lower than the concentration outside the cell. Because water can cross the membrane, but its charged solutes cannot, water tends to diffuse across the membrane into the cell, causing expansion of cell volume, in a process called **osmosis.** The resulting pressure on the cell membrane is called **osmotic pressure** (reviewed in Appendix 2). Osmotic pressure will cause a cell to burst, or lyse, in the absence of a countering pressure such as that provided by the cell wall.

Various solutes cross the membrane by different means. Nonspecific transport, or passive diffusion, requires dissolving in the phospholipid bilayer. Specific transport—for example, of nutrients and toxins—requires specific transport proteins. The presence of specific transporters depends on the microbial species and environmental conditions.

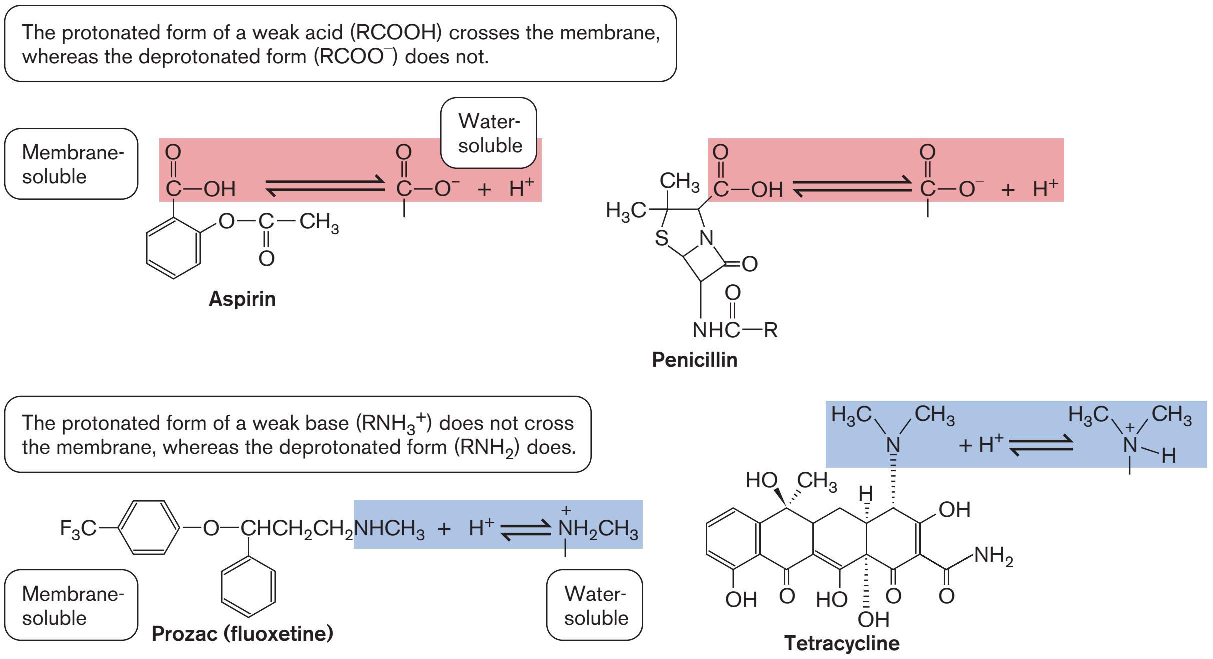
Passive diffusion. Small uncharged molecules, such as O_2, CO_2, and water, easily permeate the membrane. Some molecules, such as ethanol, also disrupt the membrane, an action that can make such molecules toxic to cells. By contrast, strongly polar molecules, such as sugars, generally cannot penetrate the hydrophobic interior of the membrane and require transport mediated by specific proteins. Water molecules permeate the membrane, but their rate of passage is increased by protein channels called aquaporins.

Membrane-permeant weak acids and bases. A special case of movement across cell membranes is that of **membrane-permeant weak acids** and **weak bases**, which exist in equilibrium between charged and uncharged forms:

$$\text{Weak acid:}\quad HA \rightleftharpoons H^+ + A^-$$

$$\text{Weak base:}\quad B + H_2O \rightleftharpoons BH^+ + OH^-$$

Weak acids and weak bases cross the membrane in their uncharged form, HA (weak acid) or B (weak base). On the other side, upon reentering aqueous solution, they dissociate (HA to A^- and H^+) or reassociate with H^+ (B to BH^+). In effect, they conduct acid (H^+) or base (OH^-) across the membrane, causing acid or alkali stress. A high-proton concentration outside the cell will increase the amount of uncharged weak acid that can freely enter the cell. Thus, if the H^+ concentration (acidity) outside the cell is higher than inside, it will drive weak acids into the cell.



The protonated form of a weak acid (RCOOH) crosses the membrane, whereas the deprotonated form ($RCOO^-$) does not.

The protonated form of a weak base (RNH_3^+) does not cross the membrane, whereas the deprotonated form (RNH_2) does.

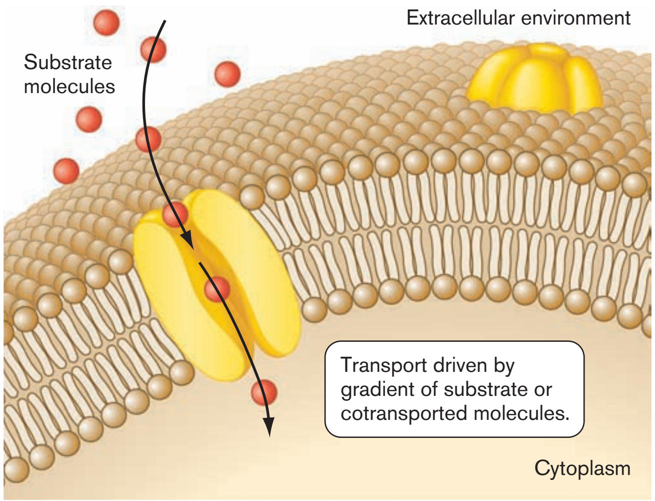
Figure 3.9 Common drugs are membrane-permeant weak acids and bases. In its charged form, each drug is soluble in the bloodstream. The uncharged form is hydrophobic and penetrates the cell membrane.

Many key substances in cellular metabolism are membrane-permeant weak acids and bases, such as acetic acid. Most pharmaceutical drugs—therapeutic agents delivered to our tissues via the bloodstream—are weak acids or bases whose uncharged forms exist at sufficiently low concentration to cross the membrane without disrupting it. Examples of weak acids that deprotonate (acquiring negative charge) at neutral pH include aspirin (acetylsalicylic acid) and penicillin (**Fig. 3.9**). Examples of weak bases that protonate (acquiring positive charge) at neutral pH include Prozac (fluoxetine) and tetracycline.

THOUGHT QUESTION 3.4 Amino acids have acidic and basic groups that can dissociate. Why are they *not* membrane-permeant weak acids or weak bases? Why do they fail to cross the phospholipid bilayer?

Transport proteins. Proteins enable transport that is highly selective; that is, a given protein will transport only certain nutrients or ions (**Fig. 3.10**). Molecules that carry net charge, such as inorganic ions (Na^+, Cl^-), require specific transport by **transport proteins**, or **transporters**. So do organic molecules that carry charge at cytoplasmic pH, such as amino acids.

Transporters are highly specific to different ions and organic substances under different environmental conditions. Much of the character and ecological niche of a microbe—the nutrients it can consume, the drugs it can resist—depend on its set of transporters encoded by its genome. Transporters evolve in families common to many species; thus, analysis of known genomes predict the transport capabilities in a newly sequenced genome (discussed in Chapter 8). Organisms that live in complex, changing environments express numerous transporters. For exam-



Extracellular environment
Substrate molecules
Transport driven by gradient of substrate or cotransported molecules.
Cytoplasm

Figure 3.10 Membrane transport proteins. Transport proteins enable the uptake of nutrients into the cell. Uptake can be powered by movement down a gradient of substrate or of a cotransported molecule such as sodium ions. Alternatively, transport may be powered by a coupled chemical reaction that spends energy, such as ATP hydrolysis.

ple, the genome of *Streptomyces coelicolor*, a soil-dwelling actinomycete bacterium that produces several antibiotics, shows over 400 different transporters. These include exporters for toxic ions such as arsenate and chromate, uptake of oligosaccharides and peptides, and multiple-drug pumps.

Transport proteins act by various mechanisms, such as a structural channel, or pore, that allows a nutrient molecule to enter the cell or a toxin to be exported. Transport may be passive or active. In **passive transport**, molecules accumulate or dissipate along their concentration gradient. **Active transport**, that is, transport from lower to higher concentration, requires expenditure of energy. The energy for active transport may be obtained by cotransport of another substance down its gradient from higher to lower concentration. For example, many transporters couple uptake of amino acids to uptake of sodium ions. Alternatively, transport may be powered by a coupled chemical reaction that spends energy, such as ATP hydrolysis. Further transport mechanisms are discussed in Chapter 4.

A medically important example of active transport is that of drug efflux proteins powered by the hydrogen ion gradient. Efflux proteins pump antibiotics such as tetracycline out of the bacterial cell, enabling harmful bacteria to grow in the presence of antibiotics. Pathogens and cancer cells evolve multiple drug resistance transporters that enable them to survive chemotherapy.

Transmembrane Ion Gradients Store Energy

Ions such as H^+ or Na^+ usually exist in very different concentrations inside and outside the cell. The ion gradient (ratio of concentrations) across the cell membrane can store energy obtained from metabolizing food or from photosynthesis. For example, membrane proteins such as cytochrome oxidases use energy from respiration to pump hydrogen ions across the cell membrane, generating a hydrogen ion gradient. The hydrogen ion gradient plus the charge difference (voltage potential) across the membrane form an **electrochemical potential**. Because this electrochemical potential includes the hydrogen ion gradient, it is called the proton potential. The proton potential, or proton motive force, drives various cell devices, such as the rotary flagella and efflux pumps that expel antibiotics. Most importantly, the proton potential drives the membrane-bound **ATP synthase** (**Fig. 3.11**). The role of the proton potential in metabolism is discussed in detail in Chapters 13 and 14.

The membrane-bound ATP synthase, also called F_1F_o ATP synthase, provides most of the ATP for aerobic respiring cells such as *E. coli*; and essentially the same complex mediates ATP generation in our own mitochondria. The complex of peptides includes a channel (F_o) for hydrogen ions, which drive rotation of the ATPase complex (F_1). Rotation of F_1 mediates the formation of ATP.

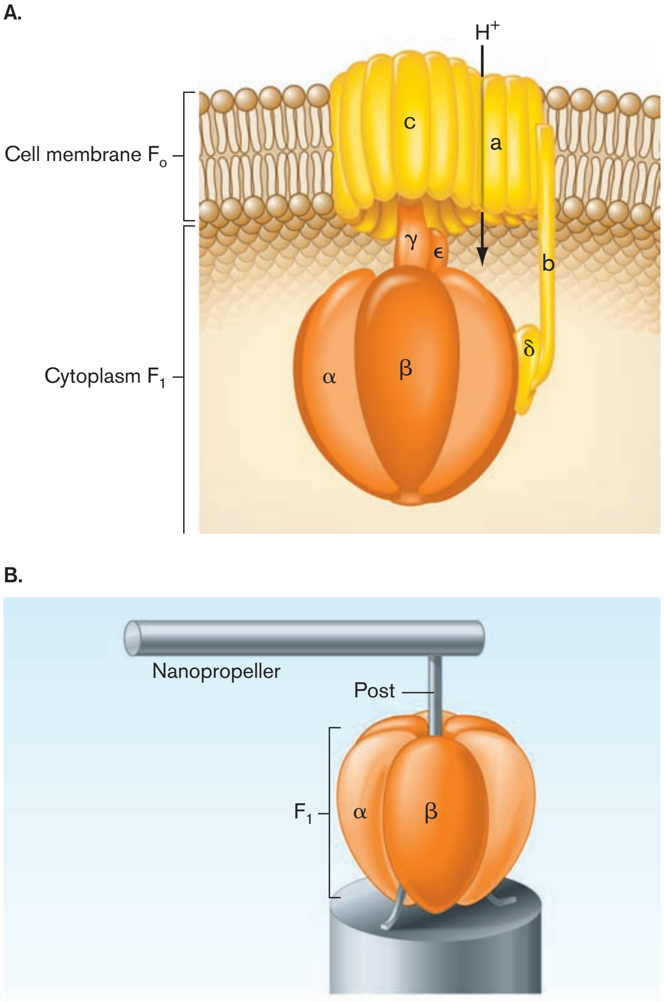


Figure 3.11 Bacterial membrane ATP synthase. A. The F_1F_o complex of ATP synthase is embedded in the cell membrane. The F_o channel/rotor admits hydrogen ions; the H^+ current flow across the membrane is driven by the concentration and charge differences between inside and outside the cell. The flow of H^+ causes the rotation of F_1. Rotation of F_1 drives conversion of ADP + P_i to ATP. **B.** An artificial "biomolecular motor" was built from an ATPase F_1 unit attached to a nickel post and a nanopropeller.

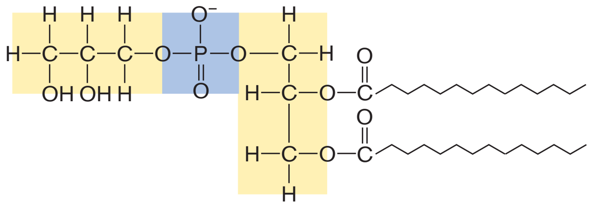
The idea that a living organism could contain rotating parts was highly controversial when such parts were first discovered in bacterial flagella (discussed in Section 3.7). Before this discovery, scientists had believed that living body parts could not rotate and that only humans had "invented the wheel." The discovery of rotary biomolecules has inspired advances in nanotechnology, the engineering of microscopic devices. For example, a "biomolecular motor" was devised using an ATP synthase F_1 complex to drive a metal submicroscopic propeller (**Fig. 3.11B**). In the future, such biomolecular design may be used to create microscopic robots that enter the bloodstream to perform microsurgery.

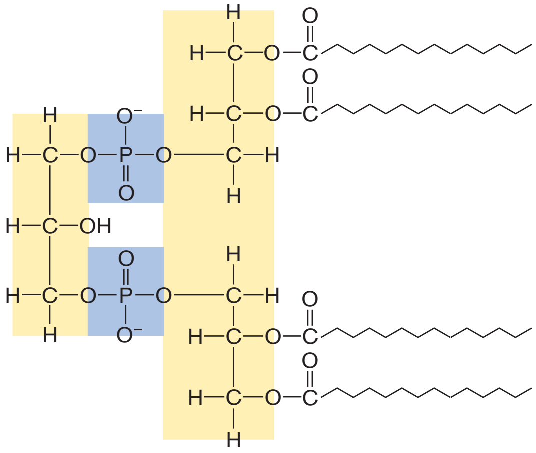
Membrane Lipids Differ in Structure and Function

Membranes require a certain uniformity to maintain structural integrity and function. Yet individual membrane lipids differ remarkably in structure. Membrane lipids help determine whether an organism grows in a Yellowstone hot spring or in the human lungs, where it may cause pneumonia. Phospholipids vary with respect to their phosphoryl head groups and with respect to their hydrocarbon side chains. Some membrane lipids lack phosphate altogether, substituting other polar groups; and some replace mobile side chains with fused rings.

Phosphoryl head groups. At the pH of most biological systems, the phosphoryl head group carries net negative charge, called a **phosphatidate** (**Fig. 3.12A**). The negatively charged phosphatidate can contain various organic groups, such as glycerol to form **phosphatidylglycerol**. A more complex phosphatidate is **cardiolipin**, or **diphosphatidylglycerol**, actually a double phospholipid linked by a glycerol (**Fig. 3.12B**). Cardiolipin increases in concentration in bacteria grown to starvation or stationary phase, possibly because its extended structure stabilizes the membrane.



Phosphatidylglycerol



Cardiolipin (diphosphatidylglycerol)

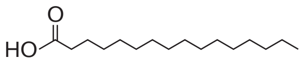
Figure 3.12 **Phospholipid head groups.** Bacterial membranes contain phospholipids with several kinds of polar head groups. Common examples include phosphatidylglycerol (negatively charged, a phosphatidate), cardiolipin (a double phospholipid joined by a third glycerol), and phosphatidylethanolamine (with a positively charged amine).

Other phospholipids have a positively charged head group, such as phosphatidylethanolamine. Phospholipids with positive charge or with mixed charges are concentrated in portions of the membrane that interact with DNA, which has negative charge. Also, some transporter proteins require interaction with positively charged phospholipids.

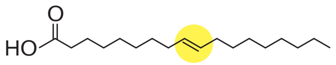
The fatty acid component of phospholipids also varies greatly among bacteria. Certain soil bacteria and pathogens such as *Mycobacterium tuberculosis* have several hundred different kinds of fatty acids. Fatty acid structures that stiffen the membrane are increased under stress conditions, such as starvation or acidity.

Variant fatty acid structures in phospholipids enhance survival under environmental stress. The most common bacterial fatty acids are hydrogenated chains of varying length, typically between 6 and 22 carbons. These chains pack neatly to form a smooth layer. Some fatty acid chains, however, are partly unsaturated (possess one or more carbon-carbon double bonds). If the unsaturated bond is *cis*, meaning that both alkyl chains are on the same side of the bond, the unsaturated chain has a "kink," as in oleic acid (**Fig. 3.13**). The kinked chains do not pack as closely as the straight hydrocarbon chains and thus make the membrane more "fluid." This is why, at room temperature, unsaturated vegetable oils are fluid, whereas highly saturated butterfat is solid. The enhanced fluidity of a kinked phospholipid improves the function of the membrane at low temperature; hence, bacteria can respond to cold and heat by increasing or decreasing their synthesis of unsaturated phospholipids.

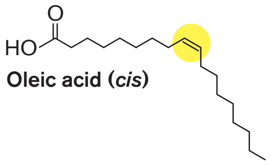
Another interesting structural variation is cyclization of part of the chain to create a stiff planar ring with decreased fluidity. The double bond of unsaturated fatty acids can incorporate a carbon from *S*-adenosyl-L-



Palmitic acid



Oleic acid (*trans*)



Oleic acid (*cis*)

Cyclopropane fatty acid

Figure 3.13 **Phospholipid side chains.** Bacterial lipid side chains include palmitic acid, oleic acid, and cyclopropane fatty acid.

methionine to form a three-membered ring, becoming a cyclopropane fatty acid (see **Fig. 3.13**). Bacteria convert unsaturated fatty acids to cyclopropane during starvation and acid stress, conditions under which membranes require stiffening. Cyclopropane conversion is an important factor in the pathogenesis of *Mycobacterium tuberculosis* (causative agent of tuberculosis) and in the acid resistance of food-borne toxigenic *E. coli*. Many other structural variants are seen in different species, such as branched chains, hydroxyl and sulfate groups, and polycyclic groups. The less common forms are highly characteristic of particular species and strains. Thus, fatty acid profiles are used to identify certain kinds of pathogens, such as anthrax spores.

Terpene derivatives stiffen membranes. In addition to phospholipids, membranes include planar molecules that fill gaps between hydrocarbon chains (**Fig. 3.14**). These stiff, planar molecules reinforce the membrane, much as steel rods reinforce concrete. In eukaryotic membranes, the reinforcing agents are sterols, such as **cholesterol**. In bacteria, the same function is filled by pentacyclic (five-ring) hydrocarbon derivatives called **hopanoids**, or **hopanes**. Hopanoids appear in geological sediments, where they indicate ancient bacterial decomposition; they provide useful data for petroleum exploration.

Figure 3.14 Hopanoids add strength to membranes. Hopanoids fit between the fatty acid side chains of membranes and limit their motion, thus stiffening the membrane. A hopanoid has five fused rings and an extended hydroxylated tail.

Variations in phospholipid side-chain structures reach their extreme in archaea, many of which inhabit the planet's most extreme environments. All archaeal phospholipids replace the ester link between glycerol and fatty acid with an ether link, C—O—C (**Fig. 3.15**). Ethers are much more stable than esters, which hydrolyze easily in water. Another modification is that archaeal hydrocarbon chains are branched **terpenoids**, polymeric structures derived from isoprene, in which every fourth carbon extends a methyl branch. The branches strengthen the membrane by limiting movement of the hydrocarbon chains.

The most extreme hyperthermophiles, which live beneath the ocean at 110°C, have terpenoid chains linked at the tails, creating a tetraether monolayer. In some

Figure 3.16 Synthesis of terpene-derived lipids. Archaeal lipids are synthesized from isoprene chains. Two isoprene units (five carbons in each) link to form a terpene (ten carbons). Terpenoid multimers, such as the triterpene derivative squalene, generate the lipid chains of archaea, in which most of their double bonds have been hydrogenated. In bacteria, squalene cyclizes to form hopanes and hopanoids, and in eukaryotes, squalene is converted to cholesterol.

species, the terpenoids cyclize to form cyclopentane rings. These planar rings stiffen the membrane under stress to an even greater extent than the cyclopropyl chains of bacteria. For more on archaeal cells, see Chapter 19.

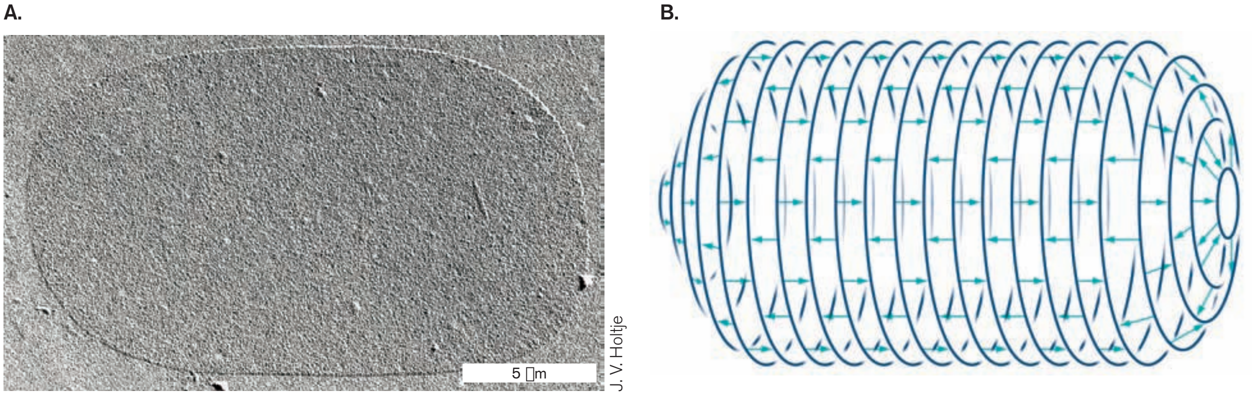
Both cholesterol and hopanoids are synthesized from the same precursor molecules as the unique lipids of archaea (**Fig. 3.16**). It may be that cholesterol and hopanoids persist in bacteria and eukaryotes as derivatives of lipids once possessed by a common ancestor of bacteria, eukaryotes, and archaea.

TO SUMMARIZE:

- **The cell membrane** consists of a phospholipid bilayer containing hydrophobic membrane proteins. Membrane proteins serve diverse functions, including transport, cell defense, and cell communication.
- **Small uncharged molecules**, such as oxygen, can penetrate the cell membrane by diffusion.
- **Weak acids and weak bases** exist partly in an uncharged form that can diffuse across the membrane and increase or decrease, respectively, the H^+ concentration within the cell.
- **Polar molecules and charged molecules** require membrane **proteins to mediate** transport. Such facilitated transport can be active or passive.
- **Active transport** requires input of energy from a chemical reaction or from an ion gradient across the membrane. **Ion gradients** generated by membrane pumps store energy for cell functions.
- **Diverse fatty acids** are found in different microbial species and in microbes grown under different environmental conditions.
- **Archaeal membranes have ether-linked terpenoids**, which confer increased stability at high temperature and acidity. Some species have cyclized terpenoids, which generate a lipid monolayer.

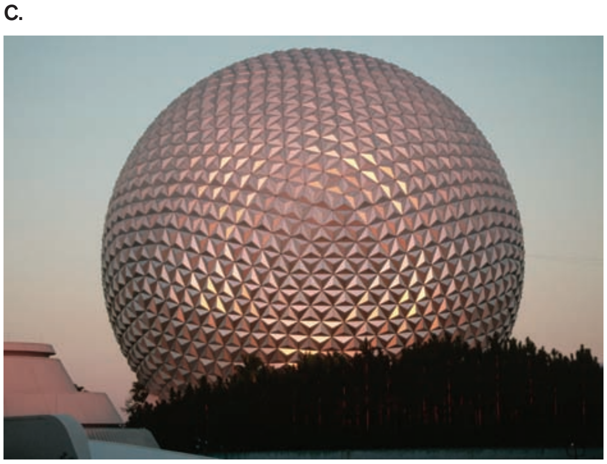
3.4 The Cell Wall and Outer Layers

A few prokaryotes, such as the mycoplasmas, have a cell membrane with no outer layers. In most bacteria and archaea, however, the cell envelope includes at least one structural supporting layer outside the cell membrane.



J. V. Holtje

Figure 3.17 The peptidoglycan sacculus. A. Isolated sacculus from *Escherichia coli* (TEM). **B.** The structure of the sacculus consists of glycan chains (parallel rings) linked by peptides (arrows). The spaces between links are open, porous to large molecules. **C.** Sacculus structure resembles the skeleton of a geodesic dome such as that of Epcot Center at Walt Disney World.



©Kit Kittle/Corbis

The most common structural support is the cell wall. Many species possess additional coverings, such as an outer membrane and capsule.

The Cell Wall Is a Single Molecule

The cell wall confers shape and rigidity to a bacterial cell and helps it withstand the intracellular turgor pressure that can build up as a result of osmotic pressure. The bacterial cell wall, also known as the **sacculus**, consists of a single interlinked molecule that encloses the entire cell. The sacculus has been isolated from *E. coli* and visualized by TEM (**Fig. 3.17A**). In the image shown, the isolated sacculus appears flattened on the sample grid like a deflated balloon. Its geometric structure encloses maximal volume with minimal surface area, analogous to a geodesic dome such as that of Epcot Center. The properties of the cell wall, or sacculus, are largely opposite to those of the membrane: a unimolecular, cage-like structure (**Fig. 3.17B**), highly porous to ions and small organic molecules.

Peptidoglycan structure. Most bacterial cell walls are composed of peptidoglycan, a polymer of peptide-linked chains of amino sugars. Peptidoglycan is synonymous with **murein** ("wall molecule") and consists of parallel polymers of disaccharides cross-linked with peptides of four amino acids, called **glycan** chains (**Fig. 3.18**). Peptidoglycan, or murein, is unique to bacteria, although archaea build analogous structures whose overall physical nature is similar. (Archaeal cell wall structures are presented in Chapter 19.)

Glycan chains are linked by peptide cross-bridges. The long chains of peptidoglycan consist of repeating units of the disaccharide composed of *N*-acetylglucosamine (an amino sugar derivative) and *N*-acetylmuramic acid (glucosamine plus a lactic acid group; see **Fig. 3.18**). The lactate group of muramic acid forms an amide link with the amino terminus of a short peptide containing four to six amino acid residues. The peptide extension can form **cross-bridges** connecting parallel strands of glycan.

The peptide contains two amino acids in the unusual D mirror form, D-glutamate and D-alanine, a hint that peptidoglycan evolved very early in life's history, before the bias toward the L form had been established. The third amino acid, *m*-diaminopimelic acid, has an extra amine group. It is also used by cells as a biosynthetic precursor of lysine. The fourth and sometimes the fifth amino acids are D-alanine. The second amino group of *m*-diaminopimelic acid is needed to form a cross-link with the COOH of D-alanine from a neighboring peptide. The cross-link forms by removal of a second D-alanine (fifth in the chain). The cross-linked peptides of neighboring glycan strands form the cage of the sacculus.

The details of peptidoglycan structure vary among bacterial species. Some gram-positive species, such as *Staphylococcus aureus* (a cause of toxic shock syndrome) have peptides linked by bridges of pentaglycine instead of the D-alanine link to *m*-diaminopimelic acid. In gram-negative species, the *m*-diaminopimelic acid is linked to the outer membrane, as discussed shortly.

Peptide cross-bridge forms with release of D-alanine. Blocked by penicillin.

Cross-bridge formation blocked by vancomycin, which binds D-ala-D-ala and prevents release of terminal D-alanine.

Figure 3.18 **Peptidoglycan cross-bridge formation.** A disaccharide unit of glycan has an attached peptide of four to six amino acids. The amino terminus of the peptide forms an amide bond with the lactate group of muramic acid. On the peptide, the extra amino group of *m*-diaminopimelic acid can cross-link to the carboxyl terminus of a neighboring peptide. The addition of D-alanine to the peptide is blocked by vancomycin, and the cross-bridge formation by transpeptidase is blocked by penicillin.

Peptidoglycan synthesis as a target for antibiotics. Synthesis of peptidoglycan requires many genes encoding enzymes to make the special sugars, build the peptides, and seal the cross-bridges. Because peptidoglycan is unique to bacteria, these biosynthetic enzymes make excellent targets for antibiotics (see **Fig. 3.18**). For example, the transpeptidase that cross links the peptides is the target of penicillin. Vancomycin, a major defense against *Clostridium difficile* and drug-resistant staphylococci, prevents cross-bridge formation by binding the terminal D-ala-D-ala dipeptide, thus preventing release of the terminal D-alanine.

Unfortunately, the widespread use of such antibiotics selects for evolution of resistant strains. One of the most common agents of resistance is the enzyme beta-lactamase, which cleaves the lactam ring of penicillin, rendering it ineffective as an inhibitor of transpeptidase. Strains resistant to vancomycin, on the other hand, contain an altered enzyme that adds lactic acid to the end of the branch peptides in place of the terminal D-alanine. The altered enzyme is no longer blocked by vancomycin. As new forms of drug resistance emerge, researchers continue to seek new antibiotics that target cell wall formation (discussed in Chapter 27).

Gram-Positive and Gram-Negative Bacteria

Most bacteria have additional envelope layers that provide structural support and protection from predators and host defenses (**Fig. 3.19**). Additional molecules are attached to the cell wall and cell membrane, in some cases interpenetrating them. Envelope composition defines two major

Figure 3.19 Cell envelope: gram-positive and gram-negative. A. The gram-positive cell has a thick cell wall with multiple layers of peptidoglycan, threaded by teichoic acids. The cell wall may be covered by an S-layer. In some gram-positive species, carbohydrate filaments form a capsule. The gram-negative cell has a single layer of peptidoglycan covered by an outer membrane. Some gram-negative species include an S-layer or a capsule (not shown). The cell membrane of gram-negative species is called the inner membrane. **B.** Gram-positive envelope of *Bacillus subtilis* (TEM), showing cell membrane, cell wall, and capsule. **C.** Gram-negative envelope of *Pseudomonas aeruginosa* (TEM), showing inner membrane, thin cell wall in the periplasm, and outer membrane.

categories of bacteria distinguished by the Gram stain (discussed in Chapter 2):

- **Gram-positive bacteria** have a thick cell wall with multiple layers of peptidoglycan, interpenetrated by teichoic acids. Gram-positive species make up the phylum Firmicutes, such as *Bacillus thuringiensis* and *Streptococcus pyogenes*, the cause of "strep throat."
- **Gram-negative bacteria** have a thin cell wall (single layer of peptidoglycan) enclosed by an outer membrane. Gram-negative species make up the phylum Proteobacteria, such as *Escherichia coli* and nitrogen-fixing rhizobia.

Outside these two groups, however, many bacterial species do not fit the Gram stain models; consider, for example, the mycobacterial envelope (**Special Topic 3.1**). Archaeal cell envelopes are highly diverse, and they do not fit the Gram models.

THOUGHT QUESTION 3.5 The actual thickness of the cell wall is difficult to determine based solely on electron microscopic observation of the envelope layers. Devise a biochemical experiment that can show the number of layers of peptidoglycan in cells of a given species.

Special Topic 3.1 The Unique Cell Envelope of Mycobacteria

Cell envelopes of exceptional complexity are found in mycobacteria, such as *M. tuberculosis* and *M. leprae*, the causative agents of tuberculosis and leprosy, respectively. Some features of mycobacterial cell walls also appear in actinomycetes, a large and diverse family of soil bacteria, many of which produce antibiotics and other industrially useful products.

Figure 1 shows two unusual classes of lipids found in mycobacteria. Mycolic acids contain a hydroxy acid backbone with two hydrocarbon chains, one comparable in length to typical membrane lipids (about 20 carbons), the other about threefold longer. The long chain includes ketones, methoxyl groups, and cyclopropane rings. Only one type of mycolic acid is shown; hundreds of different forms are known. The phenolic glycolipids include a phenol group, also linked to sugar chains.

The mycobacterial cell wall includes peptidoglycan linked to chains of galactose, called galactans (**Fig. 2**). The galactans are attached to arabinans, polymers of the five-carbon sugar arabinose. The arabinan-galactan polymers are known as arabinogalactans. Arabinogalactan biosynthesis can be inhibited by ethambutol, a major drug against tuberculosis.

The ends of the arabinan chains form ester links to mycolic acids. Mycolic acids provide the basis for acid-fast staining, in which cells retain the dye carbolfuchsin, an important diagnostic test for mycobacteria and actinomycetes (shown in Chapter 2). In *M. tuberculosis* and *M. leprae*, the mycolic acids form a kind of bilayer interleaved with phenolic glycolipids. The extreme hydrophobicity of the phenol derivatives generates a waxy surface that prevents phagocytosis by macrophages.

Overall, the thick, waxy envelope excludes many antibiotics and offers exceptional protection from host defenses, enabling the pathogens of tuberculosis and leprosy to colonize their hosts over long periods. However, the mycobacterial envelope also retards uptake of nutrients. As a result, *M. tuberculosis* and *M. leprae* grow extremely slowly and are a challenge to culture in the laboratory.

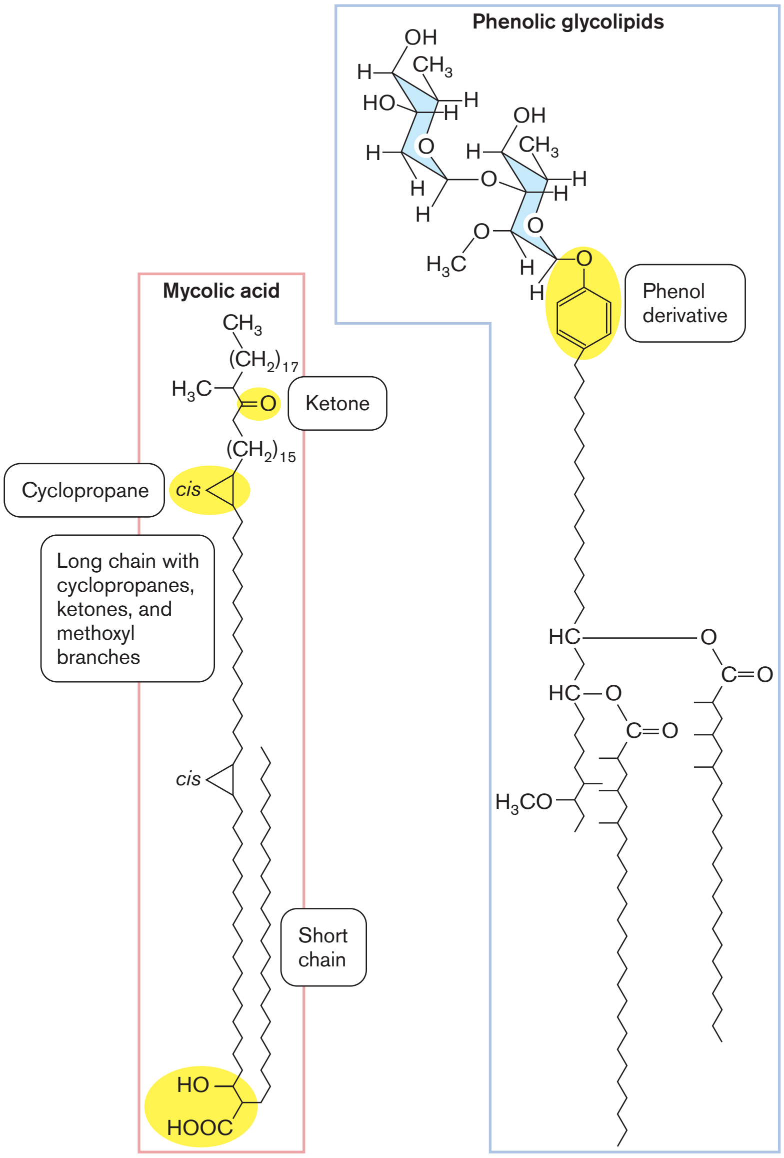

Figure 1 Mycobacterial envelope lipids. *Mycobacterium tuberculosis* possesses unusual envelope components, such as mycolic acids and phenolic glycolipids. These highly hydrophobic molecules form a waxy outer coating that protects cells from host defenses.

Figure 2 Mycobacterial envelope structure. A complex cell wall includes a peptidoglycan layer linked to a chain of galactose polymer (galactan) and arabinose polymer (arabinan). Arabinan forms ester links to mycolic acids, which form an outer bilayer with phenolic glycolipids. Outside the outer bilayer is a capsule of loosely associated phospholipids and phenolic glycolipids.

The Gram-Positive Cell Envelope

A section of a gram-positive cell envelope is shown in **Figure 3.19**. The gram-positive cell wall consists of multiple layers of peptidoglycan, up to 40 in some species. No space appears between the peptidoglycan layers, although the outer band of envelope appears more dense. The peptidoglycan is reinforced by **teichoic acids** threaded through its multiple layers (**Fig. 3.20**). Teichoic acids are chains of phosphodiester-linked glycerol or ribitol, with sugars or amino acids linked to the middle OH groups. The negatively charged cross-threads of teichoic acids, as well as the overall thickness of the gram-positive cell wall, help retain the Gram stain.

Outside the cell wall, gram-positive cells are often encased in a slippery **capsule** consisting of loosely bound polysaccharides. The capsule can be visualized under the light microscope by using a negative stain consisting of suspended particles of India ink, which the capsule excludes (shown in **Fig. 2.24C**).

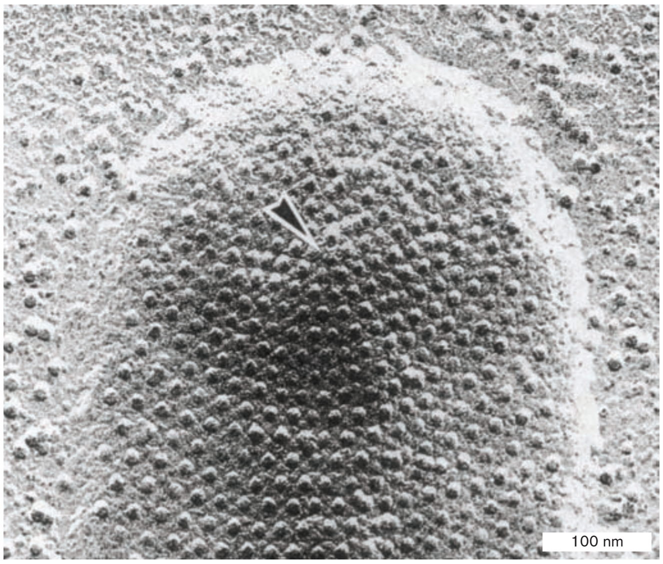
Figure 3.20 Teichoic acids. Teichoic acids in the gram-positive cell wall consist of glycerol or ribitol phosphodiester chains. The middle hydroxyl group of each glycerol or ribitol is typically linked to D-alanine, to D-lysine, or to a sugar such as galactose or *N*-acetylglucosamine.

The S-layer. An additional protective layer commonly found in gram-positive cells, as well as in archaea, is the surface layer, or **S-layer**. The S-layer is a crystalline layer of thick subunits consisting of protein or glycoprotein (proteins with attached sugars) (**Fig. 3.21**). S-layers are found in most archaea, as well as in many gram-positive and gram-negative bacteria freshly isolated from natural sources.

Each subunit of the S-layer contains a pore large enough to admit a wide range of molecules. The subunits form a smooth layer on the cell wall or outer membrane (see **Fig. 3.21**). The proteins are arranged in a highly ordered array, either hexagonally or tetragonally. They present a formidable physical barrier to predators or parasites. The S-layer is rigid, but it also flexes and allows substances to pass through it in either direction.

If S-layers are common, why were they observed only recently? Bacterial cell structures are generally studied in laboratory cultures. Upon repeated subculturing, however, bacteria lose the genetic ability to synthesize S-layer proteins. Genetic loss of a structure not required in laboratory culture, resulting from accumulation of deleterious mutations, is an example of **reductive evolution**, also known as **degenerative evolution**. Loss of a trait occurs in the absence of selective pressure for genes encoding the trait (discussed in Chapter 17). For example, the mycoplasmas are close relatives of gram-positive bacteria, yet they have permanently lost their cell walls as well as the S-layer. Mycoplasmas have no need for cell walls because they are parasites living in host environments, such as the human lung, where they are protected from osmotic shock.



Paul Messner, et al. 1986. *Journal of Bacteriology* 166(3):1046

Figure 3.21 The S-layer. The archaeon *Thermoproteus tenax* has a single tetraether membrane encased by an S-layer (SEM). Note the regular pattern of tiled proteins.

THOUGHT QUESTION 3.6 Why would laboratory culture conditions select for evolution of cells lacking an S-layer?

THOUGHT QUESTION 3.7 Suppose that one cell out of a million has a mutant gene blocking S-layer synthesis, and suppose that the mutant strain can grow twice as fast as the S-layered parent. How many generations would it take for the mutant strain to constitute 90% of the population?

The Gram-Negative Outer Membrane

A gram-negative cell envelope is seen in **Fig. 3.19C**. The thin layer of peptidoglycan is believed to be a single sheet based on calculations of molecular density. The peptidoglycan is covered by an outer membrane. The gram-negative outer membrane confers defensive abilities and toxigenic properties on many pathogens, such as *Salmonella* species and enterohemorrhagic *E. coli* (strains that cause hemorrhaging of the colon). Between the outer and inner (cell) membranes is the periplasm.

Lipoproteins and lipopolysaccharide (LPS). The inward-facing leaflet of the outer membrane has a phospholipid composition similar to that of the cell membrane (in gram-negative species, it is called the **inner membrane** or inner cell membrane). The outer membrane's inward-facing leaflet includes lipoproteins that connect the outer membrane to the peptide bridges of the cell wall. The major lipoprotein is called **murein lipoprotein**, also known as Braun lipoprotein (**Fig. 3.22A**). Murein lipoprotein consists of a protein with an N-terminal cysteine triglyceride inserted in the inward-facing leaflet of the outer membrane. The C-terminal lysine forms a peptide bond with the *m*-diaminopimelic acid of peptidoglycan (murein).

The outward-facing leaflet, however, consists of a special kind of phospholipid called **lipopolysaccharide** (**Fig. 3.22B**). The LPS lipids have shorter fatty acid chains than those of the inner cell membrane, and some are branched. LPS is of crucial medical importance because it acts as an **endotoxin**. An endotoxin is a cell component that is harmless so long as the pathogen remains intact, but when released by a lysed cell, endotoxin overstimulates host defenses, inducing potentially lethal endotoxic shock. Thus, antibiotic treatment of an LPS-containing pathogen can kill the cells but can also lead to death of the patient.

In LPS the fatty acids are esterified to **glucosamine**, an amino sugar found also in peptidoglycan. Two glucosamine dimers each condense with two fatty acid chains, which makes four fatty acid chains in all. Like the glycerol of phospholipid, each glucosamine of LPS connects to a phosphate, whose negative charge interacts with water.

Figure 3.22 Lipoprotein and lipopolysaccharide. **A.** Murein lipoprotein consists of a protein with an N-terminal cysteine triglyceride inserted in the inward-facing leaflet of the outer membrane. The protein's C-terminal lysine forms a peptide bond with the *m*-diaminopimelic acid of the peptidoglycan (murein) cell wall. **B.** Lipopolysaccharide (LPS) consists of branched and unbranched short-chain fatty acids linked to a dimer of phosphoglucosamine (also called disaccharide diphosphate). The disaccharide is linked to a core polysaccharide extending out from the cell, which is attached to about 40 repeating units of a distinct polysaccharide known as O antigen.

One of the glucosamines is attached to a **core polysaccharide**, a sugar chain that extends outside the cell. The core polysaccharide consists of about five sugars with side chains such as phosphoethanolamine. It extends to the **O polysaccharides**, a chain of as many as 200 sugars. The O polysaccharide may extend longer than the cell itself. These polysaccharide chains form a layer that helps bacteria resist phagocytosis by white blood cells.

Proteins of the outer membrane. The outer membrane also contains unique proteins not found in the inner membrane. The various layers of the cell envelope need to maintain distinct identities and properties that distinguish them from each other and from the cytoplasm and periplasm. The composition of the inner and outer membranes and aqueous compartments is characterized by ultracentrifugation. Fractions containing various cell components show that each protein is confined to a specific component of the cell (**Table 3.2**). For example, the proton-translocating ATPase is found

Table 3.2 **Subcellular location of proteins in gram-negative bacteria.**

Cell fraction	Proteins (examples)
Cytoplasm	Glycolytic enzymes Biosynthesis of amino acids Cytoplasmic chaperones
Inner membrane (cell membrane)	Proton-translocating ATPase Electron transport chain Porins for water and glycerol
Periplasm (periplasmic space)	Sugar taxis receptors Periplasmic chaperones
Outer membrane	Porins for sugars and peptides Sugar-binding proteins

only in the inner membrane fractions, whereas sugar-binding proteins are only in the outer membrane.

THOUGHT QUESTION 3.8 Why would the proteins listed in **Table 3.2** be confined to specific cell fractions? Why could a protein not function throughout the cell?

Outer membrane proteins of pathogens are important targets for vaccine development. For example, the outer membrane proteins were characterized for *Borrelia burgdorferi*, the cause of Lyme disease. In the experiment shown in **Figure 3.23**, fractions of *Borrelia* outer membrane are separated from whole cells by density gradient centrifugation. The sample is located on a tube of sucrose solution whose concentration (and density) increases with depth in the tube. Within the gradient, suspended fragments of membrane migrate to the position where their density equals that of the solution. The outer membrane fractions collect at a density different from that of fractions containing unbroken cells. The gradient contents are then removed sequentially through an opening at the base of the tube. Once isolated, the outer membrane components are separated by gel electrophoresis to reveal distinctive proteins that may serve as vaccine targets.

NOTE: Another type of gradient centrifugation, called equilibrium density gradient centrifugation, uses a cesium chloride solution that forms a gradient when subjected to centrifugal force. Cesium chloride gradients are used most commonly to separate DNA molecules such as plasmids (discussed in Chapter 7).

Outer membranes contain a class of transporters called **porins** that permit entry of nutrients such as sugars and peptides. Outer membrane porins have a distinctive cylinder of beta sheets, also known as a beta barrel. A typical outer membrane porin exists as a trimer of beta barrels, each of which acts as a pore for nutrients. **Figure 3.24** shows a model of the sucrose porin based on a crystal structure.

Cells express different outer membrane porins under different environmental conditions. In a dilute environment, cells express porins of large pore size, maximizing the uptake of nutrients. In a rich environment—for example, within a host—cells downregulate expression of large porins and express porins of smaller pore size, selecting only smaller nutrients and avoiding the uptake of toxins. For example, the porin regulation system of gram-negative bacteria enables them to grow in the intestinal region containing bile salts—a hostile environment for gram-positive bacteria.

Periplasm. The outer membrane is porous to most ions and many small organic molecules, but it prevents passage of proteins and other macromolecules. Thus, the region between the inner and outer membranes of gram-negative cells, including the cell wall, defines a separate membrane-bounded compartment of the cell known as the periplasm (see **Fig. 3.19**). The periplasm contains specific enzymes and nutrient transporters not found within the cytoplasm, such as periplasmic binding protein for sugars, amino acids, or other nutrients. Periplasmic proteins are subjected to fluctuations in pH and salt concentration, because the outer membrane is porous to ions.

The porin comprises three beta barrel channels (red, yellow, and blue). Each transports a molecule of sucrose through its channel. To view, place a piece of cardboard vertically between the two images. Position your eyes on opposite sides of the cardboard and force them to focus behind the images. The images will merge and produce a 3-D image. (PDB code: 1A0S)

Eukaryotic Microbes: Protection from Osmotic Shock

The problems confronting bacteria, such as adjusting to environmental change, also challenge eukaryotes. A key example is osmotic shock. Eukaryotic microbes possess their own structures to avoid osmotic shock. Algae form cell walls of cellulose fibers, and fungi form walls of chitin. Diatoms form intricate exoskeletons of silicate.

Other eukaryotes, however, such as amebas and ciliated protists, possess a flexible outer coating, the pellicle. The pellicle allows great flexibility of shape; it enables uptake of large particles by endocytosis and of larger objects, even entire cells, by phagocytosis. Thus, eukaryotic cells have the nutritional option of engulfing prey, an option unavailable to prokaryotes and to eukaryotes with cell walls. Eukaryotic microbes that lack a cell wall possess a **contractile vacuole** to pump water out of the cell, avoiding osmotic shock (**Fig. 3.25**). The vacuole takes up water from the cytoplasm through an elaborate network of intracellular channels, and then expels the water through a pore.

THOUGHT QUESTION 3.9 What do you think are the advantages and disadvantages of a contractile vacuole, compared with a cell wall?

TO SUMMARIZE:

- **The cell wall maintains turgor pressure.** The cell wall is porous, but its rigid network of covalent bonds protects the cell from osmotic shock.
- **The gram-positive cell envelope** has multiple layers of peptidoglycan, interpenetrated by teichoic acids.

- **The S-layer**, composed of proteins, is highly porous, but can prevent phagocytosis and phage infection. In archaea, the S-layer serves the structural function of a cell wall.
- **The capsule**, composed of polysaccharide and glycoprotein filaments, protects cells from phagocytosis. Either gram-positive or gram-negative cells may possess a capsule.
- **The gram-negative outer membrane** regulates nutrient uptake and excludes toxins. The envelope layers include protein pores and transporters of varying selectivity.
- **Eukaryotic microbes** are protected from osmotic shock by polysaccharide cell walls or by a contractile vacuole.

3.5 The Nucleoid and Gene Expression

An important function of the cell envelope is to contain and protect the cell's genome. **Figure 3.26** compares the organization of chromosomal material in enteropathogenic *E. coli* cells with that in a cultured human cell that they have colonized. In this thin-section TEM, each bacterium contains a filamentous nucleoid region that extends through the cytoplasm. In contrast, the nucleus of the eukaryotic cell, only a fraction of which is visible in the figure, is many times larger than the entire bacterial cell, and the chromosomes it contains are separated from the cytoplasm by the nuclear membrane.

In Prokaryotes, DNA Is Organized in the Nucleoid

All living cells on Earth possess chromosomes consisting of DNA. The genetic functions of microbial DNA are discussed in detail in Chapters 7–12. Here we focus on the physical organization of DNA within the nucleoid of the prokaryotic cell (**Fig. 3.27**).

NOTE: The prokaryotic genome typically consists of a single circular chromosome, but some species have a linear chromosome or multiple chromosomes. In this chapter, we focus on the simple case of a single circular chromosome.

In a bacterial cell, the DNA is organized in loops called domains. All domains connect back to a central point. The central point is the **origin of replication (*ori*)**, which is attached to the cell envelope at a point on the cell's "equator," halfway between the two poles (**Fig. 3.28**). DNA is replicated by DNA polymerase; the process

Figure 3.27 The nucleoid. The *E. coli* nucleoid appears as clear regions that exclude the dark-staining ribosomes and contain DNA strands (colorized orange in TEM).

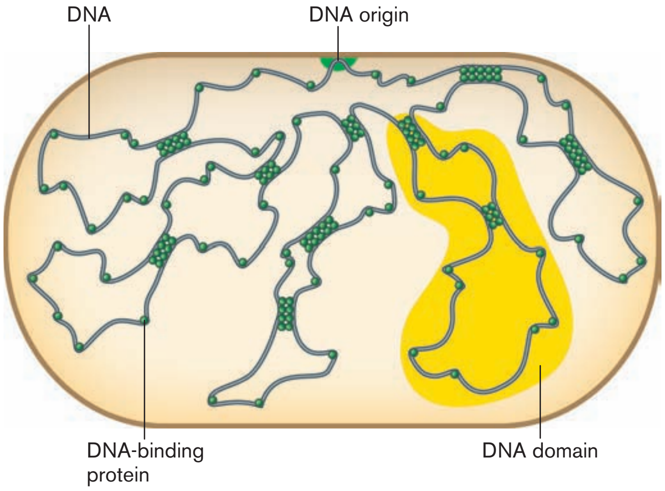

Figure 3.28 Nucleoid organization. The nucleoid forms approximately 50 loops of chromosome called domains, which radiate from the center (shown shaded). Within each domain, the DNA is supercoiled and partly compacted by DNA-binding proteins (shown in green).

is covered in more detail in Chapter 7. At the origin, the DNA double helix begins to unzip, and replication proceeds outward in both directions. Growing cells replicate their DNA continuously, with no resting phase; in fact, the two replicated origins may split again to begin a second round of replication before the first is completed.

NOTE: In biology, the word *domain* is used in several different ways, each referring to a defined portion of a larger entity.

- **DNA domains** of the nucleoid are distinct loops of DNA that extend from the origin.
- **Protein domains** are distinct functional or structural regions of a protein.
- **Taxonomic domains** are genetically distinct classes of organisms, such as bacteria, archaea, and eukaryotes.

How does all the cell's DNA fit neatly into the nucleoid? The DNA is compacted over several levels by supercoiling and by DNA-binding proteins.

Supercoiling. The chromosome includes a number of extra twists, called **supercoils** or superhelical turns, beyond those inherent in the structure of the DNA duplex (double helix). The supercoiling causes portions of DNA to double back and twist upon itself, which results in compaction. Supercoiling is generated by enzymes such as gyrase and maintained by DNA-binding proteins (shown in green in **Fig. 3.28**). The enzyme gyrase is a major target for antibiotics such as quinolones, used, for example, to treat bacterial pneumonia and urinary tract infections.

In bacteria, as in eukaryotic cells, the direction of the extra turns opposes the natural twist of the duplex. Turns that oppose the natural twist are called negative superhelical turns. Negative superhelical turns actually unwind the DNA slightly and help expose the base pairs for transcription. In archaea, however, most supercoiling is in the positive direction, tending to wind the DNA more tightly and therefore increase stability of the duplex. The increased stability of positive supercoils is an advantage for archaea growing in extreme environments, such as temperatures above 100°C.

DNA-binding proteins. Prokaryotic DNA is condensed by winding around various classes of binding proteins (see **Fig. 3.28**). Some binding proteins, such as Hns and Hu, also function as regulators of gene expression. Binding proteins can respond to the state of the cell; for example, under starvation conditions, when most transcription of RNA ceases, the binding protein Dps is used to organize the DNA into a protected crystalline structure. Such "biocrystallization" by Dps and related proteins may be a key to the extraordinary ability of microbes to remain viable for long periods in stationary phase or as endospores.

Transcription and Translation Are Tightly Coupled

The information encoded in DNA is "read" by the processes of transcription and translation to yield gene products. Within the prokaryotic cell, DNA transcription to RNA is coupled tightly to RNA translation to proteins.

DNA transcription to RNA. The initial product of a gene is a single strand of ribonucleic acid (RNA), produced when DNA is transcribed by RNA polymerase (**Fig. 3.29**). In some cases, the newly made RNA has a function of its own, such as one of the RNA components of a ribosome, the cell's protein-making machine. For most genes, however, the RNA is a messenger RNA (mRNA)

that immediately binds to a ribosome for translation to generate a polypeptide, a linear sequence of amino acid residues (discussed in Chapter 8).

mRNA translation to protein. A growing bacterial cell typically invests 40% of its energy in translation of mRNA by ribosomes. The ribosome, with its large number of protein and RNA components, is probably the most complex subcellular machine to be discovered (**Fig. 3.30**). Its task of converting the four-letter RNA code into 20 amino acids requires the assistance of 27 different transfer RNAs (tRNAs) and an equal number of aminoacyltransferase enzymes, each encoded by a different gene. Each amino acid is brought by a tRNA to fit into the acceptor site within the ribosome, sandwiched between the 30S and 50S subunits. The amino acid is then transferred onto a peptide chain, where the peptide bond forms. The process of translation is discussed further in Chapter 8.

Because of its complexity, the ribosome is targeted by many kinds of antibiotics. For example, tetracyclines block aminoacyl-tRNA from arriving at the 30S subunit. Erythromycin blocks peptide elongation at the 50S subunit.

Coupling of transcription and translation. In prokaryotes, translation is tightly coupled to transcription; the ribosomes bind to mRNA and begin translation even before the mRNA strand is complete. Thus, a growing bacterial cell is full of mRNA strands dotted with ribosomes. These composite mRNA-ribosome structures are known as **polysomes**. Polysomes can be observed as the mRNA elongates, attached by RNA polymerase to the DNA strand (**Fig. 3.31**).

In rapidly growing bacteria, both transcription and translation occur at top speed while the DNA itself is being replicated. This remarkable coordination of replication, transcription, and translation is a hallmark of the prokaryotic cell; it explains why some bacteria can double in as little as 10 minutes.

As peptide chains are synthesized, some kinds bind to **chaperones**, enzyme complexes that help fold the new peptide into its functional tertiary structure (see **Fig. 3.30**). Chaperones were first discovered in *E. coli* as "heat-shock proteins," expressed at high temperature to protect proteins from denaturation by heat. Since then, chaperones have been discovered in all organisms, including humans, where chaperone defects are associated with genetic diseases.

In eukaryotes, note that transcription and translation occur only during interphase, when the cell is not undergoing division. Within the nucleus, nascent (elongating) mRNA is translated by ribosomes, which check the transcript for errors and target faulty transcripts for destruction. The majority of eukaryotic translation, however, occurs outside the nucleus, in the cytoplasm.

Figure 3.31 **Protein synthesis and secretion.** Bacterial transcription of DNA to RNA is coordinated with translation of RNA to make proteins. Even before the RNA chain is complete, ribosomes bind to commence translation. Growing peptides destined for the membrane bind the signal recognition particle (SRP) for insertion into the membrane. The DNA is compacted by binding proteins (shown in green), but it is also pulled outward by the nascent chains of RNA (blue) and membrane-inserted peptides (orange). Each mRNA is translated by multiple ribosomes, called a polysome (highlighted yellow).

Inserting proteins in the membrane. Some of the newly translated proteins are destined for the membrane or for secretion outside the cell. Proteins destined for membrane insertion must be hydrophobic and hence are poorly soluble in the aqueous cytoplasm where translation occurs. How can proteins that are insoluble in water be folded correctly in the cytoplasm? In prokaryotes, membrane and secreted proteins are synthesized in association with the cell membrane (**Fig. 3.31**).

Protein secretion in prokaryotes is managed by several different classes of protein complexes, many of which export toxins and virulence factors, as discussed in Chapter 8. One major secretion system relies on a signal sequence, a short N-terminal sequence rich in hydrophobic residues that heads the coding sequence of a growing polypeptide. As translation begins, the signal sequence binds to a **signal recognition particle (SRP)**, an RNA-protein complex, plus other helper proteins. The SRP complex transfers the polypeptide-ribosome-mRNA complex bearing the signal sequence to the secretory complex within the cell membrane. Translation then continues at the cell membrane, and as it does so, the water-insoluble protein progressively translocates into or across the membrane.

In eukaryotes, membrane proteins are synthesized at the surface of the endoplasmic reticulum (ER). From the ER, eukaryotic proteins are packaged within the Golgi complex for transport to the cell membrane.

3.6 Cell Division

Cell division, or cell fission, requires highly coordinated growth and expansion of all the cell's parts. Unlike eukaryotes, prokaryotes synthesize RNA and proteins continually while the cell's DNA undergoes replication. Bacterial DNA replication is coordinated with the expansion of the cell wall and ultimately the separation of the cell into two daughter cells. The DNA replication process is outlined here as it relates to cell division; molecular details are discussed in Chapter 7.

DNA Is Replicated Bidirectionally

In prokaryotes, a circular chromosome begins to replicate at its origin, or *ori* site, a sequence of base pairs on the genetic map. Replication proceeds in both directions (bidirectionally) all around the circle. Some prokaryotes have linear chromosomes, but their replication is poorly understood.

At the origin, the DNA double helix begins to unzip, forming two replication forks. At each replication fork, DNA is synthesized by DNA polymerase (**Fig. 3.32**). The replication fork is propagated by **helicase**, which unwinds the DNA helix ahead of replication, and primase, which generates RNA primers. The complex of DNA polymerase with its accessory components is called a **replisome**. The replisome actually includes two DNA polymerase enzymes, one to replicate the "leading strand," the other for the "lagging strand." The actual lag time is short compared with the overall time of replication; thus, as the replisome travels along the DNA, it converts one helix into two progeny helices almost simultaneously.

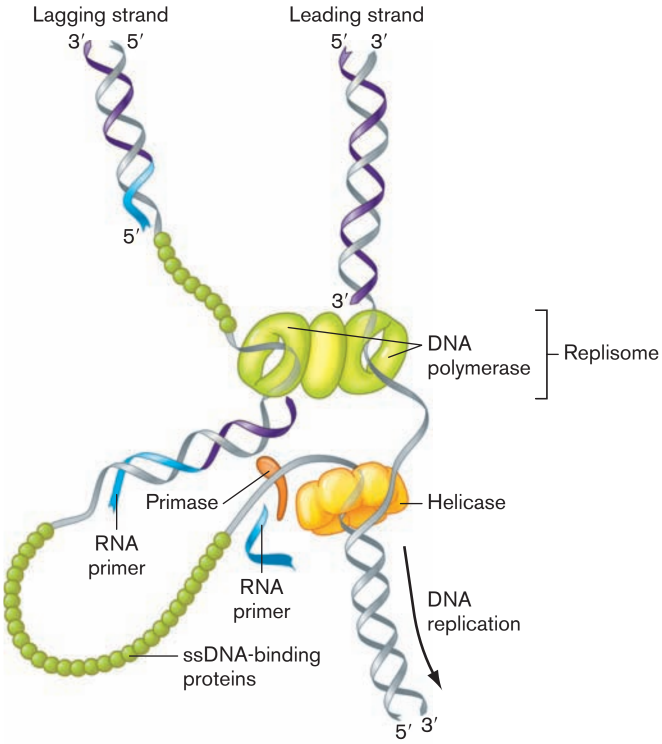

Figure 3.32 DNA replication. DNA replication proceeds by unzipping the helix and synthesizing a complement for each strand. The replisome consists of two DNA polymerase complexes, one of which synthesizes the leading strand, while the other synthesizes the lagging strand. Further details are discussed in Chapter 7.

NOTE: Each replisome contains two DNA polymerase complexes (for leading and lagging strands), and each dividing nucleoid requires two replisomes (for bidirectional replication), thus four DNA polymerase complexes overall.

Within the cell, replication proceeds outward in both directions around the genome. Thus, bidirectional replication requires two replisomes, one for each replicating fork. A long-standing question has been: Do the two replisomes move oppositely around the DNA, or do they stay in the middle while the DNA helices slide through them?

Figure 3.33 The replisome and the DNA origin. **A.** Melanie Berkmen, working in the laboratory of Alan Grossman, obtains the fluorescence micrographs shown. **B.** Fluorescence microscopy reveals the DNA origin, labeled blue by a protein fused to cyan fluorescent protein, binding at a sequence near the origin (Ori-CFP). Replisomes are labeled yellow by fusion of a DNA polymerase subunit to yellow fluorescent protein (Pol-YFP) in dividing cells of *Bacillus subtilis*. The cell envelope is labeled red with the membrane stain FM4-64.

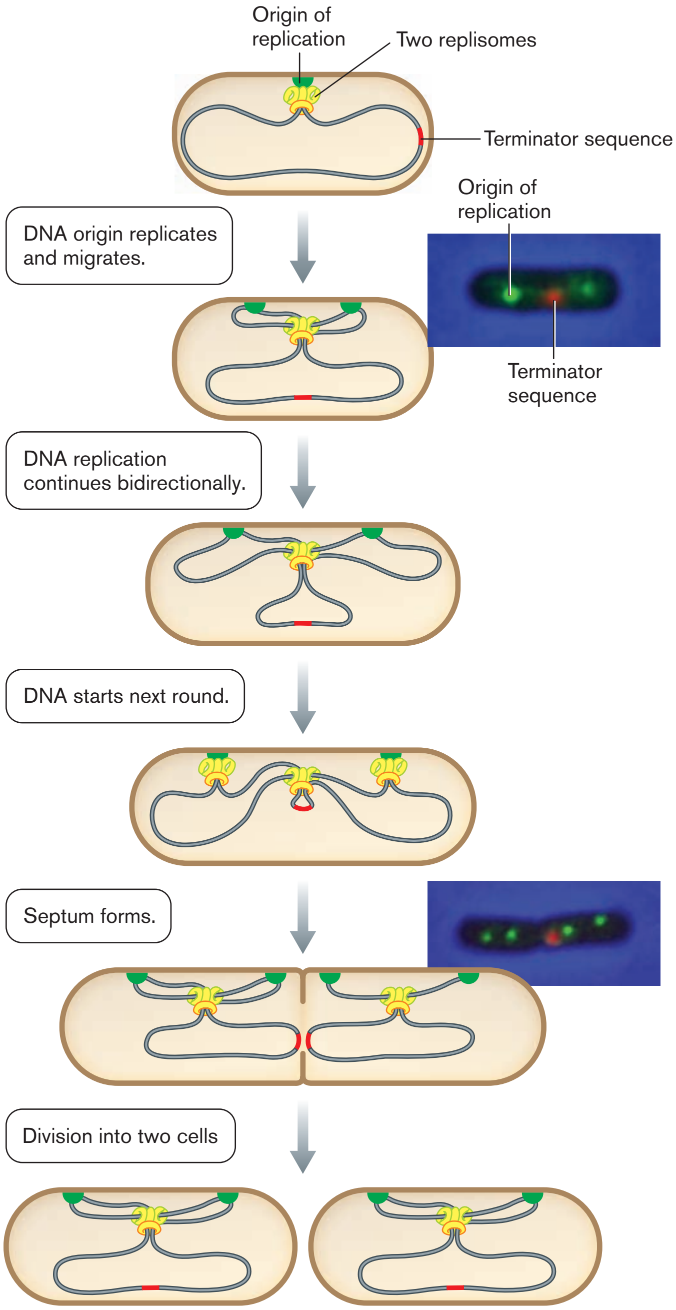

Figure 3.34 Replisome movement within a dividing cell. The DNA origin of replication sites (green) move apart in the expanding cell as the pair of replisomes (yellow) stay near the middle, where they replicate around the entire chromosome, completing the terminator sequence last (red). ▶ *Source*: Ivy Lau, et al. 2003. *Molecular Microbiology* 49:731.

To answer this question, fluorescence microscopy is used to observe the process of DNA replication within a growing cell of *Bacillus subtilis* (**Figure 3.33**). The DNA origin of replication (*ori*) and the pair of replisomes are labeled by fluorescence. The origin of replication is labeled blue by a hybrid protein fused to a gene encoding cyan fluorescent protein (CFP). The CFP protein binds to a promoter sequence cloned in *B. subtilis* near its origin site. The pair of replisomes are labeled yellow by a hybrid protein expressed from a gene encoding a DNA polymerase subunit fused to a gene encoding yellow fluorescent protein (YFP). The replisomes usually locate together near the center of the cell, but sometimes they separate, visible as two yellow spots.

The fluorescence data are consistent with a model in which two replisomes are located at the midpoint of the growing cell (**Fig. 3.34**▶). Each of the two replisomes forms a replicating fork that directs two daughter strands of DNA toward opposite poles. The two copies of the DNA origin of replication (green), attached to the cell envelope, move apart as the cell expands. The termination site (red) remains in the middle of the cell.

The two replisomes continue replication at both forks in the middle of the cell. Finally, as the termination site replicates, the two replisomes separate from the DNA. At each new *ori* site, however, two pairs of new replisomes have formed. The replication of the new *ori* sites begins, sometimes even before termination of the previous round of replication.

Note that the contents of the cytoplasm must expand coordinately with DNA replication for the cell to generate progeny equivalent to the parent. In a rod-shaped

The facing halves of each cell contain entirely new cell wall.

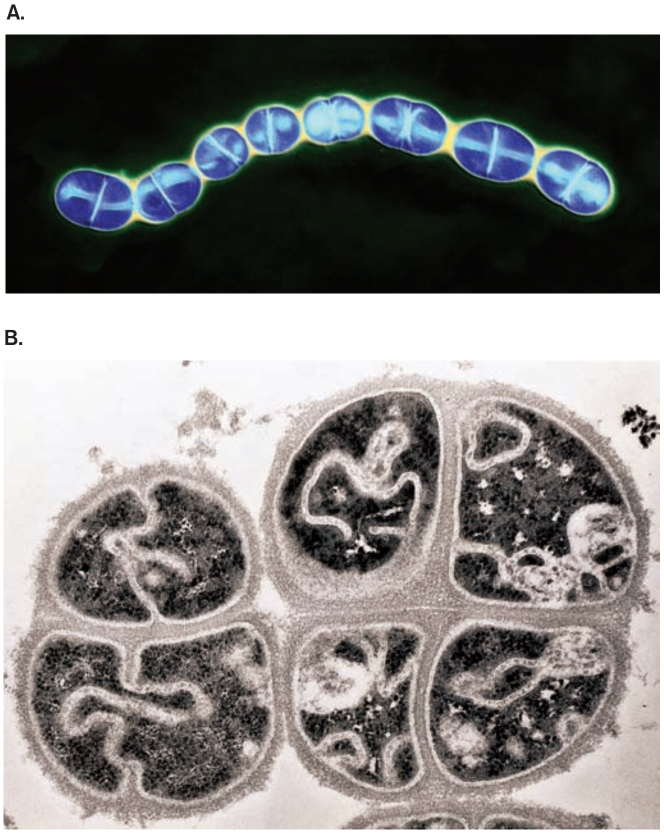
cell, the cell envelope and cell wall must elongate as well to maintain progeny of even girth and length.

Septation Completes Cell Division

For the cell to divide, DNA replication must be complete. Replication of the DNA termination site triggers growth of the dividing partition of the envelope, called the **septum**. The septum grows inward from the sides of the cell, at last constricting and sealing off the two daughter cells. This process is called **septation**. Septation and envelope extention require rapid biosynthesis of all envelope components, including membranes and cell wall. The biosynthetic enzymes required are all of great interest as antibiotic targets. Cell wall biosynthesis poses an interesting theoretical problem: How is it possible to expand the covalent network of the sacculus without breaking links to insert new material, thus weakening the wall? The answer remains unclear.

Septation of spherical cells. In spherical cells (cocci), such as *Staphylococcus aureus*, the process of septation generates most of the new cell envelope to enclose the expanding cytoplasm (**Fig. 3.35**). Furrows form in the cell envelope, in a ring all around the cell equator, as new cell wall grows inward. The wall material must compose two separable partitions. When the partitions are complete, the two progeny cells peel apart. The facing halves of each cell consist of entirely new cell wall.

The spatial orientation of septation has a key role in determining the shape and arrangement of cocci (**Fig. 3.36A**). When septation always occurs in parallel planes, such as in *Streptococcus* species, cells form chains. If septation occurs in random orientations, or if cells reassociate loosely after septation, they form compact hexagonal arrays similar to the grape clusters portrayed in classical paintings; hence the Greek-derived term **staphylococci**. Such clusters are found in colonies of *Staphylococcus aureus.* If subsequent septation occurs at right angles to the previous division, the cells may form tetrads and even cubical octads called sarcinae. Tetrads and sarcinae are formed by *Micrococcus* species (**Fig. 3.36B**).



Eye of Science/Photo Researchers, Inc.

Kwangshin Kim/Photo Researchers, Inc.

Figure 3.36 Septation orientation determines the arrangement of progeny cells. A. A chain of cocci results from septation in the same plane (*Streptococcus*, colorized TEM). **B.** Septation in two planes generates a tetrad (*Micrococcus tetragenus*, negative stain).

Septation of rod-shaped cells. In rod-shaped cells, unlike cocci, cell division requires the envelope to elongate before septation, followed by formation of a new polar envelope for each progeny cell. The process of septation involves an intricate series of molecular signals that is at the frontier of current research.

Certain mutant strains of *E. coli* form long filaments instead of dividing normally. This filamentation results from a failure to form a septum between cells. The mutant genes responsible for this behavior were called *fts* for "filamentation temperature sensitive" because the cells divide normally at the **permissive temperature** but fail to septate at the **restrictive temperature**, forming long filaments.

Some of the *fts* genes encode proteins directly involved in the formation of the septum. The most dramatic example is the protein FtsZ, which assembles to form the "Z ring," a constriction ring around the equator (**Fig. 3.37**). FtsZ is universally found in bacteria and archaea as a key septation protein. FtsZ is also an ancient homolog of tubulin, which is the major component of the mitotic apparatus in eukaryotes. The discovery of FtsZ is interesting because it implies that the processes of mitosis in eukaryotes and cell division in prokaryotes might have evolved from a common process in an ancestral cell. Other bacterial homologs of eukaryotic structural proteins suggest that bacteria possess a kind of cytoskeleton beneath the cell wall (**Special Topic 3.2**).

What signals the cell as to when and where to form the septum? What keeps the cell from septating at positions other than the equator? In fact, defective gene products can lead cells to divide incorrectly with a septum near the pole of the cell. This incorrect septation generates a "minicell," a small cellular compartment with no DNA. Genes whose defects lead to minicells are called *min* genes. In *E. coli*, the protein encoded by *minD* oscillates in rings from pole to pole (**Fig. 3.38**). The Min proteins somehow regulate the formation of the septum, ensuring symmetrical cell division.

Note, however, that normal division of bacteria is not always symmetrical. For example, *Bacillus* species undergo an asymmetrical cell division to form an endospore. In this process, one daughter nucleoid forms an inert endospore capable of remaining dormant but viable for many years (discussed in Chapter 4). Other bacteria expand their cells by polar extension; an example is *Corynebacterium diphtheriae*, the causative agent of diphtheria. Polar extension occurs at variable rates and direction, and thus generates irregularly shaped rods.

Special Topic 3.2 Bacteria Have a Cytoskeleton

A major distinction of prokaryotes was thought to be the lack of a cytoskeleton, a structural feature prominent in eukaryotes. Bacterial shape was thought to be maintained by the cell wall. In fact, bacterial shape and cell division require cytoskeletal proteins homologous to eukaryotic cytoskeletal components such as tubulin and actin. The first such protein recognized was the Z ring subunit FtsZ, an analog of tubulin. Further components of the bacterial cytoskeleton were revealed by several means: gene defects that confer the loss of cell shape, fluorescent labeling of the corresponding gene products in wild-type cells, and genomic analysis showing bacterial homologues of eukaryotic cytoskeletal components.

An example of a "shape loss" mutant is shown in **Figure 1**. The bacterium *Shigella* is an enteric pathogen closely related to *E. coli* that normally grows as a rod, or bacillus (see **Fig. 1A**). The opposite poles of the rod bind specific pole proteins, which are marked in the micrographs by fluorescent-labeled antibodies. A mutant strain of *Shigella* was isolated that grows as amorphous spheres (see **Fig. 1B**). Unlike the rod-shaped cells, the spherical mutants show multiple pole-marker proteins at undefined locations. The mutation eliminates expression of *mreB*, encoding the MreB cytoskeletal protein. Sequence analysis shows a strong relationship between MreB and the eukaryotic filament-forming protein actin.

How do MreB proteins maintain the rod shape of the bacterium? Like actin filaments in eukaryotes, MreB proteins form elongated structures beneath the cell membrane. **Figure 2A** shows how MreB proteins polymerize in a helical arrangement around the cell, thus determining the axis of elongation. Because MreB is required for rod elongation, its gene is absent from bacteria that normally grow as cocci, such as *Streptococcus*. In **Figure 2B**, the helical arrangement of MreB is observed by confocal fluorescence microscopy of *Caulobacter crescentus*, a pond-dwelling bacterium. The MreB proteins are labeled by fluorescent antibodies.

Crescent-shaped cells such as *C. crescentus* usually possess a third kind of shape-determining protein, CreS, in addition to FtsZ and MreB (see Fig. 2A). CreS is a homologue of the eukaryotic intermediate filament protein. CreS polymerizes along the inner curve of a crescent cell, as seen in **Figure 2C**. In the micrograph shown, CreS proteins are labeled by recombination of the *creS* gene with a gene encoding the green fluorescent protein (GFP). The result is a gene fusion expressing the hybrid protein CreS-GFP, which fluoresces green. In the confocal fluorescence micrograph, the CreS-GFP appears blue-green, whereas the cell membrane is labeled red by a membrane-binding fluorophore. The membrane-binding fluorophore reveals the overall crescent outline of the cell and the localization of CreS to the cell's inner curve.

Other bacterial proteins contributing to cell shape and division include the Min proteins, required for equal division of cells, and the Par proteins, which segregate replicated plasmids during cell division. In one group of bacteria, the phylum Verrumicrobia, a tubulin homolog has been discovered that forms tubules in vitro. Such tubules may contribute to the unusual extended shapes of Verrumicrobia.

CreS-GFP colocalizes with the membrane-specific stain FM4-64 (red fluorescence).

TO SUMMARIZE:

- **The nucleoid** region contains loops of DNA, supercoiled and bound to DNA-binding proteins.
- **Transcription of DNA** occurs in the cytoplasm, often simultaneously with DNA replication.
- **The ribosome translates RNA to make proteins**, which are folded by chaperones and in some cases secreted at the cell membrane.
- **DNA is replicated** bidirectionally by the replisome.
- **Cell expansion and septation** are coordinated with DNA replication.
- **Cell shape** is determined by the FtsZ "Z ring" and other cytoskeletal proteins.

3.7 Specialized Structures

We have introduced the major structures required to contain the cell, organize its contents, maintain its DNA, and express its genes. The cell envelope, the nucleoid, and the gene expression and protein translocation complexes are essential for all living prokaryotes. In addition to these fundamental structures, different species have evolved different kinds of specialized devices adapted to diverse metabolic strategies and environments.

Thylakoids and Carboxysomes Conduct Photosynthesis

Photosynthetic bacteria, also called phototrophs, need to collect as much light as possible to drive photosynthesis. Light is harvested by protein complexes called **phycobilisomes** (see Section 14.6). Some of the energy obtained is stored in the form of storage granules.

To maximize their photosynthetic membranes, phototrophs have evolved specialized systems of extensively folded intracellular membrane called **thylakoids** (**Fig. 3.39A**). Thylakoids consist of layers of folded sheets (lamellae) or tubes of membranes packed with photosynthetic proteins and electron carriers. Cyanobacteria containing thylakoids structurally resemble chloroplasts, which are believed to have evolved from a common ancestor of modern cyanobacteria.

The thylakoids conduct only the "light reaction" of photon absorption and energy storage. The energy obtained is rapidly spent to fix carbon dioxide, which occurs within **carboxysomes**. Carboxysomes are polyhedral, protein-covered bodies packed with the enzyme rubisco for CO_2 fixation.

Aquatic and marine phototrophs, as well as archaea, often possess **gas vesicles** to increase buoyancy and keep themselves high in the water column, near the sunlight (**Fig. 3.39B**). Gas vesicles are specialized vacuoles composed of specific proteins. The vesicles trap and collect gases such as hydrogen or carbon dioxide produced by the cell's metabolism.

Storage Granules

During times of starvation, phototrophs may digest their phycobilisomes for energy and as a source of nitrogen. Alternatively, energy is stored in storage granules composed of glycogen or other polymers, such as polyhydroxybutyrate (PHB) and poly-3-hydroxyalkanoate (PHA). PHB and PHA polymers are of interest as a biodegradable plastic, which bacteria are engineered to produce industrially. Similar storage granules are also produced by nonphototrophic soil bacteria.

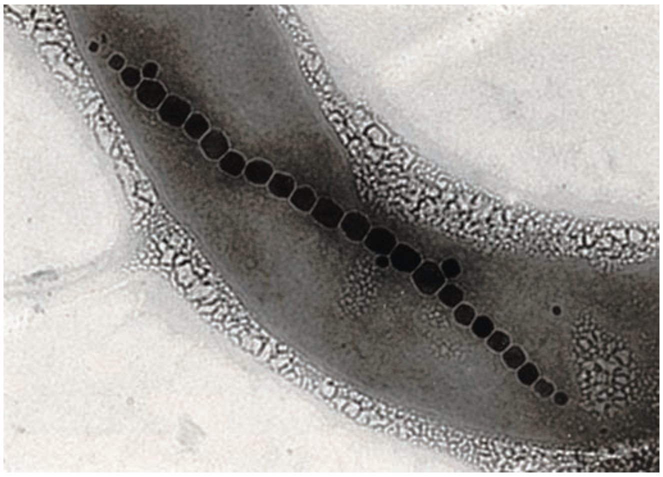
Figure 3.40 External sulfur particles. Sulfur globules dot the surface of *Thermoanaerobacter sulfurigignens*, an anaerobic thermophilic bacterium that gains energy by reducing thiosulfate ($S_2O_3^{2-}$) to elemental sulfur (S^0).

Another type of storage device is sulfur, granules of elemental sulfur produced by purple and green phototrophs through photolysis of hydrogen sulfide (H_2S). Instead of disposing of the sulfur, the bacteria store it in granules, either within the cytoplasm (purple phototrophs) or as "globules" attached outside of the cell. Sulfur-reducing bacteria also make extracellular sulfur globules (**Fig. 3.40**). The sulfur may be usable as an oxidant when reduced substrates become available. Alternatively, the presence of potentially toxic sulfur granules may help cells avoid predation.

Magnetosomes of Magnetite Direct Motility

An unusual structure possessed by magnetotactic species of bacteria (bacteria showing magnetically directed motility) is the magnetosome. **Magnetosomes** are microscopic membrane-bounded crystals of the magnetic mineral magnetite, Fe_3O_4 (**Fig. 3.41**). They are found in anaerobic pond-dwelling organisms such as *Magnetospirillum gryphiswaldense*. The crystals generate a magnetic dipole moment along the length of a bacterium, constraining it to swim along a magnetic field. This magnetic orientation of swimming is called **magnetotaxis**, the ability to sense and respond to magnetism. Magnetotactic bacteria can be collected by placing a magnet within a jar of pond water; bacteria orienting by the field lines collect nearby.



The Sustainable Energy Research Group, U. of Southampton

Figure 3.41 Magnetotactic bacterium. A magnetospirillum is a spiral-shaped magnetotactic bacterium. The spiral cell contains a chain of magnetosomes, magnetite crystals (TEM).

The natural function of magnetosomes appears to be to orient bacterial swimming toward the bottom of the pond. Magnetotactic organisms are anaerobes, which prefer the lower part of the water column, where oxygen concentration is lowest. Because Earth's magnetic field lines point downward in the northern latitudes, bacteria that are magnetotactic swim "downward" toward magnetic north.

THOUGHT QUESTION 3.10 How would a magnetotactic species have to behave if it were in the Southern Hemisphere instead of in the Northern Hemisphere?

Magnetotactic bacteria are being studied for their potential applications in wastewater treatment. Through their anaerobic metabolism, some magnetotactic bacteria accumulate high concentrations of toxic metals from the water. They and the toxic metals they scavenge can then be removed by application of a magnetic field to attract and concentrate the bacteria.

Pili and Stalks Enable Attachment

In a favorable habitat, such as a running stream full of fresh nutrients or the epithelial surface of a host, it is advantageous for a cell to adhere to a substrate. **Adherence**, the ability to attach to a substrate, requires specific adherence structures, such as pili (protein filaments). As bacteria grow and proliferate, however, they face the question of whether to stay where they are or leave their present habitat, where nutrients may be depleted and waste products increased. In rapidly changing environments, cell survival requires **motility**, the ability to move and relocate. Motility requires structures such as rotary flagella. Some bacteria have it both ways by producing two kinds of progeny, one adherent, the other motile (see **Special Topic 3.3**).

The most common structures that bacteria use to attach to a substrate are **pili** (singular, **pilus**), or **fimbriae** (singular, **fimbria**), straight filaments of protein monomers called **pilin**. For example, fimbriae attach the

Special Topic 3.3 Two Kinds of Progeny: One Stays, One Swims

What if a single species encounters very different environments throughout its life history, some favorable, others unfavorable? Sometimes, adherence might be advantageous; at other times, motility would be desirable. Bacteria such as *E. coli* and *Salmonella* species possess more than one kind of filamentous structure: flagella for motility and pili for attachment once a favorable substrate is reached. An even more dramatic strategy for "having it both ways" is to generate two kinds of daughter cells: one that stays, and one that swims away. This strategy is exemplified by the flagellum-to-stalk transition of the aquatic bacterium *Caulobacter crescentus*.

Caulobacter crescentus exists in two forms, one with a stalk (stalked cell) and one with a single flagellum at one pole (swarmer cell). The swarmer cell swims about freely in an aqueous habitat, such as a pond or a sewage bed. After half an hour of swimming, the swarmer cell undergoes differentiation to shed its flagellum and replace it with a stalk (**Fig. 1**). Once attached, the stalked cell immediately starts to replicate its DNA.

How do the two progeny cells develop different forms? Lucy Shapiro and colleagues at Stanford University showed that the identities of swimmer and stalked cells are determined by the methylation state of their DNA (**Fig. 2**). The original DNA has methyl groups on its cytosine bases, added during the previous round of DNA replication. These methyl groups allow expression of genes needed for a stalked cell. As the DNA now undergoes a new round of replication, each daughter duplex receives a new unmethylated strand, base-paired with the old strand containing methyl groups. The original two parental strands differ in their methylation patterns; thus, the methylation patterns of the two daughter duplexes allow different gene expression in the two daughter cells, one of which is stalked, the other a swarmer. Once DNA synthesis is complete and the cells have differentiated into different forms, the

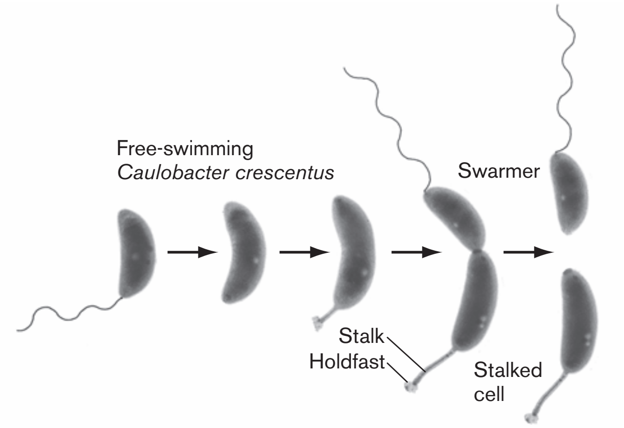


Figure 1 Asymmetrical cell division: A model for development. A swarmer cell of *C. crescentus* loses its flagellum and grows a stalk. The stalked cell divides to produce a swarmer cell. Photo courtesy of Yves Brun, Indiana University.

oral pathogen *Porphyromonas gingivalis* to gum epithelium, where they are associated with periodontal disease (**Fig. 3.42**). A different kind of pili, the **sex pili**, serve to attach a "male" donor cell to a "female" recipient cell for transfer of DNA. This process of DNA transfer is called conjugation. The genetic consequences of conjugation are discussed in Chapter 9.

Another kind of attachment organelle is a membrane-bound extension of the cytoplasm called a **stalk**. The tip of the stalk secretes adhesion factors called **holdfast**, which firmly attach the bacterium in an environment that has proved favorable. The mechanism of stalk and holdfast attachment has been extensively studied in iron-oxidizing bacteria that interfere with mining operations by producing massive biofilms. An example is *Gallionella ferruginea*, an iron-oxidizing species that grows a long stalk (**Fig. 3.43**). The long twisted stalks of adherent *Gallionella* cells become coated by iron hydroxides, and *Gallionella* contributes a major part of the process of biomineralization (biological crystallization of minerals) in iron mines.

new DNA becomes methylated, restoring the complementary methylation patterns in each cell.

The remaining stalked daughter cell undergoes another round of cell division to produce yet another swarmer cell, as well as a stalked cell. Each swarmer cell eventually converts to a stalked cell and reproduces progeny. By this means, *Caulobacter* can hedge its bets. Half its progeny always remain at a location that, however favorable, may eventually deteriorate, whereas the other half swims away to find a potentially better environment.

Caulobacter represents a simple example of cell differentiation that resembles phenomena seen in more complex developmental systems, such as DNA methylation during cell morphogenesis. Thus, it offers an informative model system for cell differentiation in the development of multicellular organisms.

Rotary Flagella Enable Motility and Chemotaxis

Bacteria and archaea that are motile generally swim by means of rotary **flagella** (singular, **flagellum**). Flagella are helical propellers that drive the cell forward like the motor of a boat. First shown by Howard Berg at the California Institute of Technology, the bacterial flagellar motor was the first rotary device to be discovered in a living organism.

Different bacterial species have different numbers and arrangements of flagella. **Peritrichous** cells, such as *E. coli* and *Salmonella* species, have flagella randomly distributed around the cell (**Fig. 3.44A**). The

flagella rotate together in a bundle behind the swimming cell (**Fig. 3.44B**) Lophotrichous cells, such as *Rhodospirillum rubrum*, have flagella attached at one or both ends. In monotrichous (polar) species, such as *Pseudomonas aeruginosa*, the cell has a single flagellum at one end.

Each flagellum is a spiral filament of protein monomers called flagellin. The filament is actually rotated by means of a motor driven by the cell's transmembrane proton current, the same proton potential that drives the membrane-bound ATPase. (Alternatively, the motor is driven by a sodium ion potential, particularly in marine bacteria such as *Vibrio cholerae*.) The flagellar motor is embedded in the layers of the cell envelope (**Fig. 3.45**). The motor is observed by electron microscopy, and its parts are defined by genetic analysis of mutants with aberrant motility. The motor actually possesses an axle and rotary parts, all composed of specific proteins. Much of the structure and function of the motor were elucidated by Scottish microbiologist Robert Macnab (1940–2003) at Yale University.

Flagellar motility benefits the cell by causing dispersal of progeny, decreasing competition. In addition, most flagellated cells have an elaborate sensory system that enables them to swim toward favorable environments (attractant signals, such as nutrients) and away from inferior environments (repellent signals, such as waste products). This sensory system is known as **chemotaxis**.

Chemotaxis requires a way for the cell to move toward attractants and away from repellents. This is accomplished by flagellar rotation either clockwise or counterclockwise relative to the cell (**Fig. 3.46A**). When a cell is swimming toward an attractant chemical, the flagella rotate counterclockwise (CCW), enabling the cell to swim smoothly for a long stretch. When the cell veers away from the attractant, receptors send a signal that allows one or more flagella to switch rotation clockwise (CW), against the twist of the helix. This switch in the direction of rotation disrupts the bundle of flagella, causing the cell to tumble briefly, ending up pointed in a random direc-

Swim toward attractant

Figure 3.46 Chemotaxis. A. In peritrichous bacteria, flagella are oriented in a bundle extending behind one pole, while their chemotactic receptors are concentrated at the opposite pole. When the cell veers away from the attractant, the receptors send a signal that allows one or more flagella to switch rotation from counterclockwise (CCW) to clockwise (CW). This switched rotation disrupts the bundle of flagella, causing the cell to tumble briefly before it swims off in a new direction. **B.** The pattern of movement resulting from alternating swimming and tumbling is a "biased random walk" in which the cell sometimes moves randomly but overall tends to migrate toward the attractant.

tion (**Fig. 3.46B**). The cell then swims off in the new direction. The resulting pattern of movement generates a "biased random walk" in which the cell tends to migrate toward the attractant.

THOUGHT QUESTION 3.11 Most strains of *E. coli* and *Salmonella* commonly used for genetic research actually lack flagella entirely. Why do you think this is the case? How can a researcher maintain a motile strain?

Note that bacterial flagella differ completely from the whiplike flagella and cilia of eukaryotes. Eukaryotic flagella are much larger structures containing multiple microtubules enclosed by a membrane. They move with a whiplike motion that forms a flat sine wave, propagated by ATP hydrolysis all along the flagellum.

TO SUMMARIZE:

- **Phototrophs** possess thylakoid membrane organelles packed with photosynthetic apparatus and carboxysomes for carbon dioxide fixation. Other subcellular structures may include sulfur granules from H_2S photolysis and gas vesicles for buoyancy in the water column.
- **Storage granules** store polymers for energy.
- **Magnetosomes** orient the swimming of magnetotactic anaerobic bacteria.
- **Adherence structures** enable prokaryotes to remain in an environment with favorable environmental factors. Major adherence structures include pili or fimbriae (protein filaments) and the holdfast (a cell extension).
- **Flagellar motility** occurs by rotary motion of helical flagella.
- **Chemotaxis** involves a biased random walk up a gradient of attractant substance or down a gradient of repellents.

Concluding Thoughts

Research techniques of cell fractionation and biochemistry, together with genetic analysis, continue to reveal the structure and function of cells. The intricate mechanisms derived by microbial evolution challenge the inventers of antibiotics as well as designers of molecular machines. As a journalist observed in *Science,* "When it comes to nanotechnology, physicists, chemists, and materials scientists can't hold a candle to the simplest bacteria."

CHAPTER REVIEW

Review Questions

1. What are the major features of a bacterial cell, and how do they fit together for cell function as a whole?
2. What fundamental traits do most prokaryotes have in common with eukaryotic microbes? What traits are different?
3. Give examples of how our views of ribosome structure and function have emerged from microscopy, cell fractionation, X-ray diffraction crystallography, and genetic analysis. Explain the advantages and limitations of each technique.
4. Outline the structure of the peptidoglycan sacculus, and explain how it expands during growth. Cite two different kinds of experimental data that support our current views of the sacculus.
5. Compare and contrast the structure of gram-positive and gram-negative cell envelopes. Explain the strengths and weaknesses of each kind of envelope.
6. Outline the process of DNA replication, and explain how it is coordinated with cell wall septation.
7. Explain how DNA transcription to RNA is integrated with translation and protein processing and secretion.
8. What are kinds of subcellular structures found in certain cells with different functions, such as magnetotaxis or photosynthesis?
9. Compare and contrast bacterial structures for attachment and motility. Explain the molecular basis of chemotaxis.

Chapter 4

Bacterial Culture, Growth, and Development

4.1 Microbial Nutrition
4.2 Nutrient Uptake
4.3 Culturing Bacteria
4.4 Counting Bacteria
4.5 The Growth Cycle
4.6 Biofilms
4.7 Cell Differentiation

The adage "To eat well is to live well" is as true for microbes as it is for humans. Microorganisms constantly struggle to survive in natural habitats because they compete for food. Yet a single microbial pathogen can multiply within the course of a day to cause deadly illness, and a few algae can abruptly bloom and cover the entire surface of a lake. In each of these cases, the population explosion results from the sudden availability of food. Over eons, bacteria have evolved ingenious strategies to find, acquire, and metabolize a wide assortment of potential food sources, ranging from glucose to mothballs. This metabolic diversity arose by necessity, from the need to find new sources of food ignored by competitors.

The remarkable plasticity of microbial genomes enables adaptation to new food sources. During the course of DNA replication, gene systems involved in the use of one food naturally undergo duplications and mutations, some of which sculpt new biochemical pathways capable of metabolizing novel substrates. This genomic flexibility raises hopes that we can engineer microbial biochemistry to remediate pollution and produce tomorrow's wonder drugs.

This elaborate bacterial colony is formed by an undomesticated strain of *Bacillus subtilis* isolated from soil. The complex architecture is the result of a tightly regulated developmental process and provides insight into the organization of bacterial communities. *Source*: Cover. 2004. *Journal of Bacteriology* 186(12).

Microorganisms need sources of carbon in order to grow. Understanding how they use food to increase their cell mass and, ultimately, cell number enables us to control their growth and manipulate them to make useful products. Yeast, for example, consume glucose and break it down to ethanol and carbon dioxide gas. These end products are merely waste to the yeast but are extremely important to humans who enjoy beer. Brewers have learned to control the amount of sugar supplied to yeast growing in fermentation vats to produce just the right amount of alcohol and CO_2, which produces beer's bubbling carbonation. Many a home brewer has learned the hard way that providing too much sugar (in malt) will cause yeast to make too much CO_2 gas, turning a homemade fermentor into an unpredictable explosive device.

Learning how bacteria grow has also provided a window through which to view the core processes of life. As a result of studying bacterial growth and nutrition, we now know how DNA replicates, how RNA is made, and how proteins are assembled. We have also learned that the availability of nutrients has influenced the evolution of sophisticated microbial processes designed to avoid or survive starvation. For example, bacteria communicate with each other to build elaborate multicellular reproductive structures, such as fruiting bodies, or complex multispecies biofilms, such as those that erode our teeth and rust the surface of ocean liners.

In this chapter, we consider the microbial biosphere and the basics of bacterial growth. We'll consider a variety of questions: How diverse is this biosphere? Is it true that we have identified only about 0.1% of the bacterial species that inhabit Earth? Where do bacteria get their energy? You might be surprised to learn that some bacteria gain energy from light (photosynthesis), whereas others gain energy from oxidizing sulfur. With so many microbes consuming nutrients, how has nature arranged biosystems to avoid depleting Earth of key compounds?

To understand the biochemistry behind metabolic diversity, we need to grow microbes. How do we ensure their growth and measure it? Some bacteria make elaborate, multicellular structures, whereas others form environmentally resistant fortresses called spores. In this chapter, we discuss how microbes obtain energy and nutrients for growth, and how cell populations develop. A more detailed treatment of mechanisms of energy gain and biosynthesis is presented in Chapters 13–15.

4.1 Microbial Nutrition

Bacterial cells, for all their apparent simplicity, are remarkably complex and efficient replication machines. One cell of *Escherichia coli*, for example, can divide into two cells every 20–30 minutes. At a rate of 30 min per division, one cell could potentially multiply to over 1×10^{14} cells in 24 hours—that is, 100 trillion organisms! Although 100 trillion cells would only weigh about 1 g, after another 24 hours (a total of two days) of replicating every 30 minutes, the mass of cells would explode to 10^{14} g, or 10^7 tons. So why are we not buried under mountains of *E. coli*?

Nutrient Supplies Limit Microbial Growth

One factor limiting growth is that microbes commonly encounter environments where essential nutrients are limited. **Essential nutrients** are those compounds a microbe cannot make itself but must gather from its environment if the cell is to grow and divide. Microbial cells obtain all the essential nutrients for growth from their immediate environment. Consequently, when an environment becomes depleted of one or more essential nutrients, the microorganism will stop growing. How various organisms cope with these periods of starvation until nutrients are restored is a rapidly developing field of microbiology.

All microorganisms require a minimum set of **macronutrients**, nutrients needed in large quantities. Six of these—carbon, nitrogen, phosphorus, hydrogen, oxygen,

Table 4.1 Growth factors and natural habitats of organisms associated with disease.

Organism	Diseases	Natural habitats	Growth factors
Shigella	Bloody diarrhea	Humans	Nicotinamide (NAD)[a]
Haemophilus	Meningitis, chancroid	Humans and other animal species, upper respiratory tract	Haemin, NAD
Staphylococcus	Boils, osteomyelitis	Widespread	Complex requirement
Abiotrophia	Osteomyelitis	Humans and other animal species	Vitamin K, cysteine
Legionella	Legionnaires' disease	Soil, refrigeration cooling towers	Cysteine
Bordetella	Whooping cough	Humans and other animal species	Glutamate, proline, cystine
Francisella	Tularemia	Wild deer; rabbits	Complex, cysteine
Mycobacterium	Tuberculosis, leprosy	Humans	Nicotinic acid (NAD),[a] alanine
Streptococcus pyogenes	Pharyngitis, rheumatic fever	Humans	Glutamate, alanine

[a] Both nicotinamide and nicotinic acid are derived from NAD, nicotinamide adenine dinucleotide.

and sulfur—make up the carbohydrates, lipids, nucleic acids, and proteins of the cell. Four other macronutrients are cations whose roles range from serving as enzyme cofactors (Mg^{2+}, Fe^{2+}, and K^{+}) to acting as regulatory signal molecules (Ca^{2+}). In addition to macronutrients, all cells require very small amounts of certain trace elements, called **micronutrients**. These include cobalt, copper, manganese, molybdenum, nickel, and zinc, which are ubiquitous contaminants on glassware and in water. As a result, these trace elements are not added to laboratory media unless heroic measures have been taken to first remove the elements from the medium. Micronutrients are required by cells because these elements are frequently essential components of enzymes or can themselves be components of cofactors. **Cofactors** are small molecules that fit into specific enzymes and aid in the catalytic process. Cobalt, for example, is part of the cofactor vitamin B_{12}. Some organisms, such as the laboratory "workhorse" bacterium *E. coli*, make all their proteins, nucleic acids, and cell wall and membrane components from this very simple blend of chemical elements and compounds. For many other microbes, this basic set of nutrients is not enough. One example is *Borrelia burgdorferi*, the causative agent of Lyme disease, which requires an extensive mixture of complex organic supplements to grow.

Microbes Evolved to Grow in Different Environments

Based in part on the ecological niche it inhabits, an organism may have evolved to require additional **growth factors** (**Table 4.1**), specific nutrients that are not required by all cells. For example, why should an organism like *Streptococcus pyogenes* make glutamic acid or alanine if those amino acids are readily available in its normal environment (such as, the human oral cavity)? Because it never needs to make these compounds, *S. pyogenes*, as a matter of efficiency, has lost the genes whose protein products synthesize glutamic acid and alanine. A **defined minimal medium** contains only those compounds needed for an organism to grow (**Table 4.2**). In the case of *S. pyogenes*, this would include glutamic acid and alanine in addition to the macro- and micronutrients mentioned earlier. Other organisms have adapted so well to their natural habitat that we still do not know how to grow them in the laboratory. For example, *Rickettsia prowazekii*, the causative agent of Rocky Mountain

Table 4.2 Composition of commonly used media.

Media	Ingredients per liter		Organisms cultured
Luria Bertani (complex)	Bacto tryptone[a]	10 g	Many gram-negative and gram-positive organisms

Figure 4.1 ***Rickettsia prowazekii* growing within eukaryotic cells.** **A.** *R. prowazekii* growing within the cytoplasm of a chicken embryo fibroblast (SEM). **B.** Giemsa stain of *R. prowazekii* growing within cultured human L cells.

spotted fever, grows only within the cytoplasm of eukaryotic cells (**Fig. 4.1**). This obligate intracellular bacterium lost key pathways needed for independent growth because the host cell supplies them. Despite extensive efforts to grow them outside a host cell (**axenic growth**), cells of *R. prowazekii* have proved uncooperative in this endeavor.

Although it will not grow in a defined medium, we can at least grow *Rickettsia* in the laboratory using eggs or animal cell tissue culture. But it is estimated that 99.9 % of all the microorganisms on Earth cannot be grown in the laboratory at all. How do we even know that these microbes exist if we cannot grow them? Evidence for their existence has been discovered only recently using newly developed tools of molecular biology. All known microorganisms have a set of genes, associated with ribosomes, whose DNA sequences are highly conserved across the phylogenetic tree. A DNA-amplifying procedure called polymerase chain reaction (PCR, described in Section 7.6) can be used to screen for the presence of these genes in soil and water samples. Comparing the DNA sequences of the PCR products with the DNA sequences of similar genes from known organisms reveals that nature harbors many microbes hitherto undiscovered because we cannot grow them in the laboratory. Even though the growth and nutritional requirements of these phantom microbes are unknown, modern genomic techniques can expose their existence. We can gain remarkable insight into the physiology of these “invisible,” nonculturable organisms by comparing their gene sequences, mined by PCR, with known gene sequences from culturable organisms that have well-characterized physiologies.

Microbes Build Biomass through Autotrophy or Heterotrophy

Maintaining life on this planet is an amazing process. All of Earth’s life-forms are based on carbon, which they acquire by delicately choreographed processes that recycle key nutrients. The carbon cycle, a critical part of this process, involves two counterbalancing metabolic groups of organisms, heterotrophs and autotrophs. Their pathways of metabolism are discussed in chapters 13 and 14.

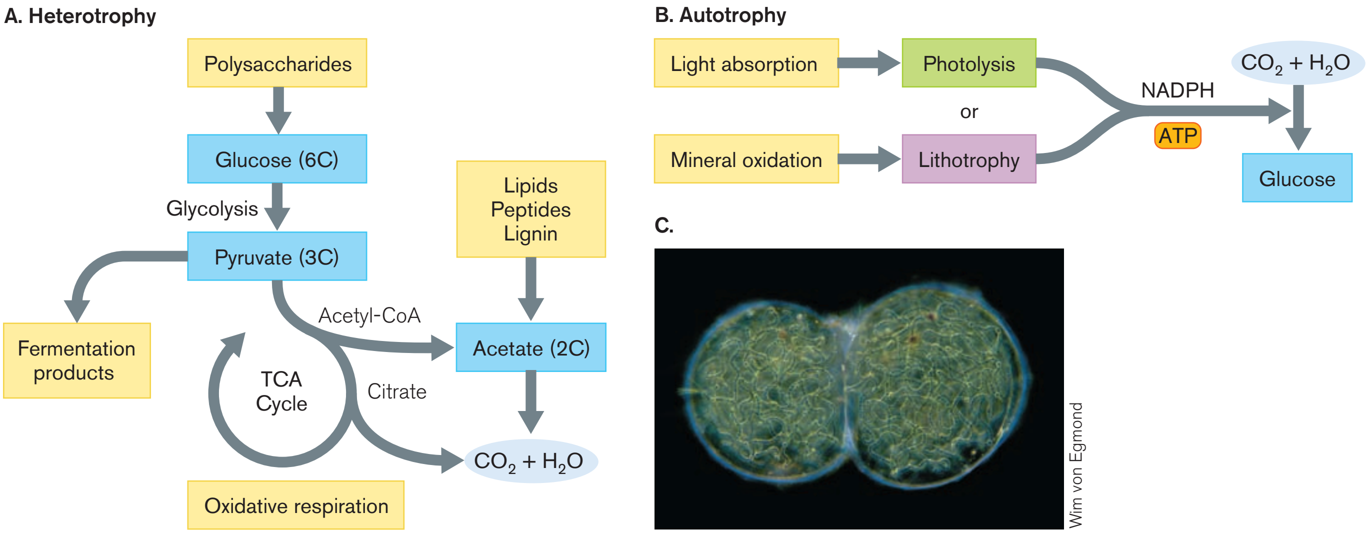
Heterotrophs (such as *E. coli*) rely on other organisms to form the organic compounds, such as glucose, that they use as carbon sources. During heterotrophic metabolism, organic carbon sources are disassembled to generate energy and then reassembled to make cell constituents such as proteins and carbohydrates. This process converts a large amount of the organic carbon source to CO_2, which is then released to the atmosphere. Thus, left on their own, heterotrophs would deplete the world of organic carbon sources (converting them to unusable CO_2) and starve to death. For life to continue, CO_2 must be recycled.

Autotrophs assimilate CO_2 as a carbon source, reducing it (adding hydrogen atoms; see Chapter 15) to make complex cell constituents made up of C, H, and O (for example, carbohydrates, which have the general formula CH_2O). These organic compounds can later be used as carbon sources by heterotrophs. As will be discussed below, autotrophs are subclassified, based on how they obtain energy, into **photoautotrophs**, organisms that use light for photosynthesis, and **chemoautotrophs** also known as **chemolithotrophs** or **lithotrophs** (literally, rock-eaters), organisms that gain energy by oxidizing inorganic substances such as iron or ammonia. Both photoautotrophs and chemoautotrophs carry out the autotrophic process of CO_2 fixation, which forms part of the carbon cycle between autotrophs and heterotrophs (**Fig. 4.2**).

THOUGHT QUESTION 4.1 In a mixed ecosystem of autotrophs and heterotrophs, what happens when a heterotroph allows the autotroph to grow and begin to make excess organic carbon?

Microbes Obtain Energy through Phototrophy or Chemotrophy

Although the macronutrients mentioned earlier provide the essential building blocks (in other words, carbon) to



Wim von Egmond

Figure 4.2 **The carbon cycle.** The carbon cycle requires both autotrophs and heterotrophs. **A.** Heterotrophs gain energy from degrading complex organic compounds, such as polysaccharides, to smaller compounds, such as glucose and pyruvate. The carbon from pyruvate moves through the tricarboxylic acid (TCA) cycle, and CO_2 is released. In the absence of a TCA cycle, the carbon can end up as fermentation products, such as ethanol or acetic acid. **B.** Autotrophs use light energy or energy derived from the oxidation of minerals to capture CO_2 and convert it to complex organic molecules. **C.** *Nostoc* is an autotroph. These cyanobacteria live in a gelatinous sphere. The spheres shown are colonies (approx. 1 mm diameter) that are just beginning to divide. The individual cyanobacteria are the small cells forming the long strands inside the spheres.

make proteins and other cell structures, those synthetic processes require an energy source. Depending on the organism, energy can be obtained from chemical reactions triggered by the absorption of light (**phototrophy**, or photosynthesis) or from oxidation-reduction reactions that transfer electrons from high-energy compounds to make products of lower energy (**chemotrophy**). Chemotrophic organisms include two classes that use different sources of electron donors: chemoautotrophs and chemoheterotrophs. Chemoautotrophs oxidize inorganic chemicals H_2, H_2S, NH_4, NO_2^-, and Fe^{2+} for energy. **Chemoheterotrophs** oxidize organic compounds such as sugars to obtain energy.

NOTE: The following prefixes for "-trophy" terms help distinguish different forms of energy-yielding metabolism.

Carbon source for biomass

Auto-	CO_2 is fixed and assembled into organic molecules.
Hetero-	Preformed organic molecules are acquired from outside and assembled.

Energy source

Photo-	Light absorption excites electron to high-energy state.
Chemo-	Chemical electron donors are oxidized.

Electron source

Litho-	Inorganic molecules donate electrons.
Organo-	Organic molecules donate electrons.

In chemotrophy, the amount of energy harvested from oxidizing a compound is directly related to the compound's reduction state. The more reduced the compound is, the more electrons it has to give up and the higher the potential energy yield. A reduced compound, such as glucose, can donate electrons to a less reduced (more oxidized) compound, such as nicotinamide adenine dinucleotide (NAD), releasing energy (in the form of donated electrons) and becoming oxidized in the process. NAD is a cell molecule critical to energy metabolism and is discussed, along with oxidation-reduction reactions, in Chapter 13.

In short, microbes are classified on the basis of their carbon and energy acquisition as follows:

- **Autotrophs.** Autotrophs build biomass by fixing CO_2 into complex organic molecules. Autotrophs gain energy through one of two general metabolic routes that either use or ignore light:
  Photoautotrophy generates energy through light absorption by the photolysis (light-activated breakdown) of H_2O or H_2S. The energy is used to fix CO_2 into biomass.
  Chemoautotrophy (or lithotrophy) produces energy from oxidizing inorganic molecules such as iron, sulfur, or nitrogen. This energy is also used to fix CO_2 into biomass.
- **Heterotrophs.** Heterotrophs break down organic compounds from other organisms to gain energy and to harvest carbon for building their own biomass. Heterotrophic metabolism can be divided into two classes, also based on whether light is involved.

Photoheterotrophy produces energy through photolysis of organic compounds. Organic compounds are broken down and used to build biomass.

Chemoheterotrophy (or organotrophy) yields energy and carbon for biomass solely from organic compounds. Chemoorganotrophy is commonly called heterotrophy.

Note that many species, particularly free-living soil and aquatic bacteria, can utilize more than one of these strategies, depending on environmental conditions. They do this by having multiple gene systems that are expressed under different conditions and whose products carry out different functions. For example, *Rhodospirillum rubrum* grows by photoheterotrophy when light is available and oxygen is absent; but when oxygen is available, the organism grows by respiration, without absorbing light.

The survival and metabolism of any one group of organisms depend on the survival and metabolism of other groups of organisms. Even metazoa (multicellular organisms) rely on microbial metabolism to survive. For example, the cyanobacteria, a type of photosynthetic microorganism that originated 2.5–3.5 billion years ago, produce most of the oxygen we and other metazoa breathe. In fact, cyanobacteria also form the base of the marine food chain. The autotrophic cyanobacteria fix carbon in the ocean and are eaten by heterotrophic protists. The protists then are devoured by fish that produce the CO_2 that is fixed by the cyanobacteria. The cyanobacteria also depend on the heterotrophic bacteria to consume the molecular oxygen that the cyanobacteria produce, since molecular oxygen is toxic to cyanobacteria.

Energy Is Stored for Later Use

Whatever the source, energy once obtained must be converted to a form useful to the cell. This form can be chemical energy, such as that contained in the high-energy phosphate bond in adenosine triphosphate (ATP), or electrochemical energy, where energy is stored in the form of an electrical potential existing between compartments separated by a membrane (see Chapter 14). Energy stored by an electrical potential across the membrane is known as the **membrane potential**. A membrane potential is generated when chemical energy is used to pump protons (and in some cases Na^+) outside of the cell, so that the proton (or Na^+) concentration is greater outside the cell than inside. This ion movement produces an electrical gradient across the cell membrane, making the inside of the cell more negatively charged than the outside. The energy stored in the membrane potential can be used directly to move nutrients into the cell via specific transport proteins (see Section 3.3), to drive motors that rotate flagella, and to drive synthesis of ATP.

The Nitrogen Cycle Depends on Bacteria and Archaea

Nitrogen is an essential component of proteins, nucleic acids, and other cellular constituents, and as such is required in large amounts by living organisms. Nitrogen gas (N_2) makes up nearly 79% of Earth's atmosphere, but nitrogen gas is unavailable for use by most organisms because the triple bond between the two nitrogen atoms is highly stable and requires considerable energy to split them. For nitrogen to be used for growth, it must first be "fixed," or converted to ammonium ions (NH_4^+). As with the carbon cycle, various groups of organisms collaborate to interconvert nitrogen gas, ammonium ions, and nitrate (NO_3^-) ions in what is called the nitrogen cycle. One group "fixes" atmospheric nitrogen while other bacteria do the opposite, transforming ammonia to nitrate (**nitrification**) and then converting nitrate to N_2 (**denitrification**) (**Fig. 4.3**). For the environmental significance of nitrogen metabolism, see Chapter 22.

Nitrogen-fixing bacteria may be free-living in soil or water or they may form symbiotic associations with plants or other organisms. A **symbiont** is an organism that lives in intimate association with a second organism. *Rhizobium*, *Sinorhizobium*, and *Bradyrhizobium* species, for example, are nitrogen-fixing symbionts in leguminous plants such as soybeans, chickpeas, and clover (**Fig. 4.4**). These plant symbionts take atmospheric nitrogen and convert it to the ammonia that the plant needs to form proteins and other essential compounds. This type of beneficial symbiosis is called mutualism. Although symbionts are the most widely known nitrogen-fixing bacteria, the majority of nitrogen in soil and marine environments is fixed by free-living bacteria and archaea.

Once fixed, how does nitrogen get back into the atmosphere? The nitrifying bacteria, such as *Pseudomonas*, *Alcaligenes*, and *Bacillus*, gain energy by oxidizing ammonia to produce nitrate (a form of chemoautotro-

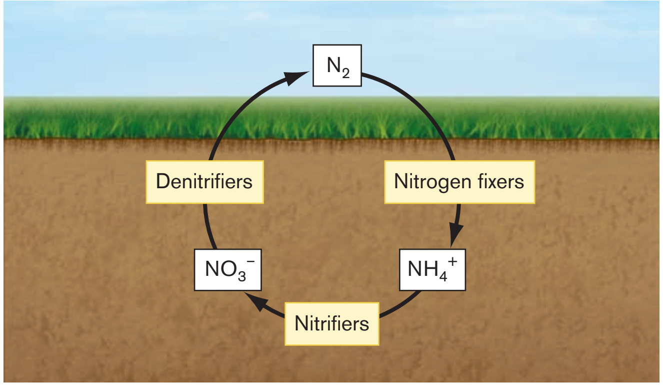


Figure 4.3 The nitrogen cycle. Dinitrogen gas (N_2) is fixed by species of bacteria (nitrogen fixers) that possess the enzyme nitrogenase. Other bacteria oxidize ammonia (NH_4^+) to generate energy. Still others use oxidized forms of nitrogen, such as NO_3^-, as an alternative electron acceptor in place of O_2.

Figure 4.4 ***Rhizobium* and a legume.** **A.** Symbiotic *Rhizobium* cells clustered on a clover root tip (SEM). The rhizobia shown here are clustered on the surface of the root. Soon they will start to invade the root and begin a symbiotic partnership that will benefit both organisms. **B.** Root nodules. After the rhizobia (approx. 0.9 μm × 3 μm) invade the plant root, symbiosis between plant and microbe produces nodules. Two partly crushed nodules (arrowheads) are shown with pink-colored contents. This color is caused by the presence of the pigment leghaemoglobin, which is found only in the nodules and is not produced by either the bacterium or the plant when grown alone.

phy). Denitrifying bacteria are heterotrophs that use the nitrate provided by the nitrifiers to produce a series of nitrogen compounds, ending with gaseous N_2. The activity of denitrifying bacteria results in a substantial loss of nitrogen into the atmosphere that roughly balances the amount of nitrogen fixation that occurs each year. As in the carbon cycle, this, once again, illustrates how nature manages to replenish the planet Earth.

Eukaryotic Microbes Include Consumers and Producers

Eukaryotic microbes such as protists and fungi are heterotrophic consumers (discussed in Chapter 20). Protists and fungi require complex organic molecules for growth; their lifestyle involves predation, parasitism, or scavenging the dead. Most protists and fungi need mitochondria, which are the products of an ancient symbiotic partnering with internalized prokaryotes (discussed in Section 17.6). Heterotrophic fungi possess the exceptional ability to digest complex organic compounds such as lignin, a major component of wood and bark. In marine and aquatic systems, protists form a huge part of the food chain, so that eating trout or swordfish means, in effect, consuming trillions of protists.

Just like photosynthetic bacteria, eukaryotic algae are photoautotrophs that produce biomass through photosynthesis. In addition to needing chloroplasts for photosynthesis, however, algae require mitochondria for energy production. (Recall that chloroplasts, like mitochondria, evolved from internalized bacteria; see Section 1.7.) Protist algae such as single-celled *Euglena* are **mixotrophic**, capable of utilizing photosynthesis or heterotrophic respiration, depending on environmental conditions.

TO SUMMARIZE:

- **Microorganisms** require certain essential macro- and micronutrients to grow.
- **Microbial genomes** evolve in response to nutrient availability.
- **Obligate intracellular bacteria** lose metabolic pathways provided by their hosts and develop requirements for growth factors supplied by their hosts.
- In the **global carbon cycle**, autotrophs use CO_2 as a carbon source, either through photosynthesis or through lithotrophy.
- **Autotrophs** make complex organic compounds that are consumed by heterotrophs.
- **Nitrogen fixers**, **nitrifiers**, **and denitrifiers** contribute to the nitrogen cycle.
- **All the preceding reactions** are carried out by prokaryotes (bacteria or archaea), whereas eukaryotes carry out only a limited range of heterotrophic and photosynthetic reactions.

4.2 Nutrient Uptake

Whether a microbe is propelled by flagella toward a favorable habitat or, lacking motility, drifts through its environment courtesy of Brownian movement, it must be able to find nutrients and move them across the membrane into the cytoplasm. The membrane, however, presents a daunting obstacle. Membranes are designed to separate what is outside the cell from what is inside. So, for a cell to gain sustenance from the environment, the membrane must be *selectively* permeable to nutrients the cell can use. A few compounds, such as oxygen and carbon dioxide, can passively diffuse across the membrane, but most cannot. Selective permeability is achieved in three ways:

- By the use of substrate-specific carrier proteins (**permeases**) in the membrane
- With the aid of dedicated nutrient-binding proteins that patrol the periplasmic space
- Through the action of membrane-spanning protein channels, or pores, that discriminate between substrates

Microbes must also overcome the problem of low nutrient concentrations in the natural environment (for example, lakes or streams). If the intracellular concentration of nutrients were no greater than the extracellular concentration, the cell would remain starved of most nutrients. To solve this dilemma, most organisms have evolved efficient transport systems that concentrate nutrients inside the cell relative to outside. However, moving molecules against a concentration gradient requires some form of energy.

In contrast to environments where nutrients are available but exist at low concentrations (for example, aqueous environments), certain habitats have plenty of nutrients, but those nutrients are locked in a form that cannot be transported into the cell. Starch, a large, complex carbohydrate, is but one example. Many microbes unlock these nutrient vaults by secreting digestive proteins that break down complex carbohydrates or other molecules into smaller compounds that are easier to transport. The amazing techniques that cells use to extrude these large digestive proteins through the membrane and into their surrounding environment are discussed in Chapter 8.

Facilitated Diffusion: Transport Down a Concentration Gradient

Although most transport systems use cellular energy to bring compounds into the cell, a few do not. Facilitated diffusion is a type of system that simply uses the concentration gradient of a compound to move that compound across the membrane from a compartment of higher concentration to a compartment of lower concentration. The best these systems can do is to equalize the internal and external concentrations of a solute; facilitated transport cannot move a molecule *against* its gradient.

The most important facilitated diffusion transporters are those of the aquaporin family that transport water and small polar molecules such as glycerol. Glycerol transport is performed by an integral membrane protein in *E. coli* called GlpF. The structure of a glycerol channel is shown in **Figure 4.5A**. This protein channel allows passive uptake

Figure 4.5 Facilitated diffusion. **A.** The glycerol transporter of *E. coli*, viewed from the external side of the membrane, consists of a tetramer of four dimer channels formed by hydrophobic alpha helices alternating back and forth across the cell membrane. Each channel (blue and yellow) contains a glycerol (magenta). (PDB code: 1FX8) **B.** Facilitated diffusion of glycerol through GlpF. The protein facilitates the movement of the compound from outside the cell, where glycerol is at high concentration, to inside the cell where the concentration of glycerol is low.

of glycerol, a polar molecule useful to cells for energy and for building phospholipids. The glycerol channel complex is viewed from the outer face of the membrane. The complex is a tetramer of four channels. Each channel transports a molecule of glycerol (magenta).

In the membrane, GlpF reversibly assumes two conformations. One form exposes the glycerol-binding site to the external environment, whereas the second form exposes this site to the cytoplasm. When the concentration of glycerol is greater outside than inside the cell, the form with the binding site exposed to the exterior is more likely to find and bind glycerol. After binding glycerol, GlpF changes shape, closing itself to the exterior and opening to the interior (**Fig. 4.5B**). Bound glycerol is then released into the cytoplasm (influx). Once the cytoplasmic concentration of glycerol equals the exterior concentration, bound glycerol can be released to either compartment. If the internal concentration exceeds the external concentration, a situation that can arise if a cell is moved from a high- to a low-glycerol environment, glycerol will move out of the cell (efflux). However, facilitated diffusion normally promotes glycerol influx, because the cell consumes the compound as it enters the cytoplasm, keeping cytoplasmic concentrations of glycerol low.

WWW | GlpF homolog

Active Transport by Membrane Transporters Requires Energy

Most forms of transport expend energy to take up molecules from outside the cell and concentrate them inside. The ability to import nutrients against their natural gradients is critical in aquatic habitats, where nutrient concentrations are low, and in soil habitats, where competition for nutrients is high.

The simplest way to use energy to move molecules across a membrane is to exchange the energy of one chemical gradient for that of another. The most common chemical gradients used are those of ions, particularly the positively charged ions Na^+ and K^+. These ions are kept at different concentrations on either side of the cell membrane. When an ion moves *down* its concentration gradient (from high to low), energy is released. Some transport proteins harness that free energy and use it to drive transport of a second molecule *up*, or against, its concentration gradient. This is called **coupled transport**.

The two types of coupled transport systems are **symport**, where the two molecules travel in the same direction, and **antiport**, in which the actively transported molecule moves in the direction *opposite* to the driving ion. An example of a symporter is the lactose permease LacY of *E. coli*, one of the first transport proteins whose function was elucidated. This work was carried out by the pioneering membrane biochemist H. Ronald Kaback. LacY moves lactose inward, powered by a proton that is also moving inward (symport). LacY proton-driven transport is said to be **electrogenic** because an unequal distribution of charge results (for example, symport of a neutral lactose molecule with H^+ results in net movement of positive charge).

An example of **electroneutral** coupled transport, in which there is no net transfer of charge, is that of the Na^+/H^+ antiporter. The Na^+/H^+ antiporter couples the export of Na^+ with the import of a proton (antiport). Because molecules of like charge are exchanged, there is no net movement of charge. The mechanism by which Na^+/H^+ antiporters function was elucidated by the Israeli biochemist Etana Padan. Sodium exchange is of universal importance for all organisms and is particularly critical for organisms living in a high-salt habitat (see Section 5.4).

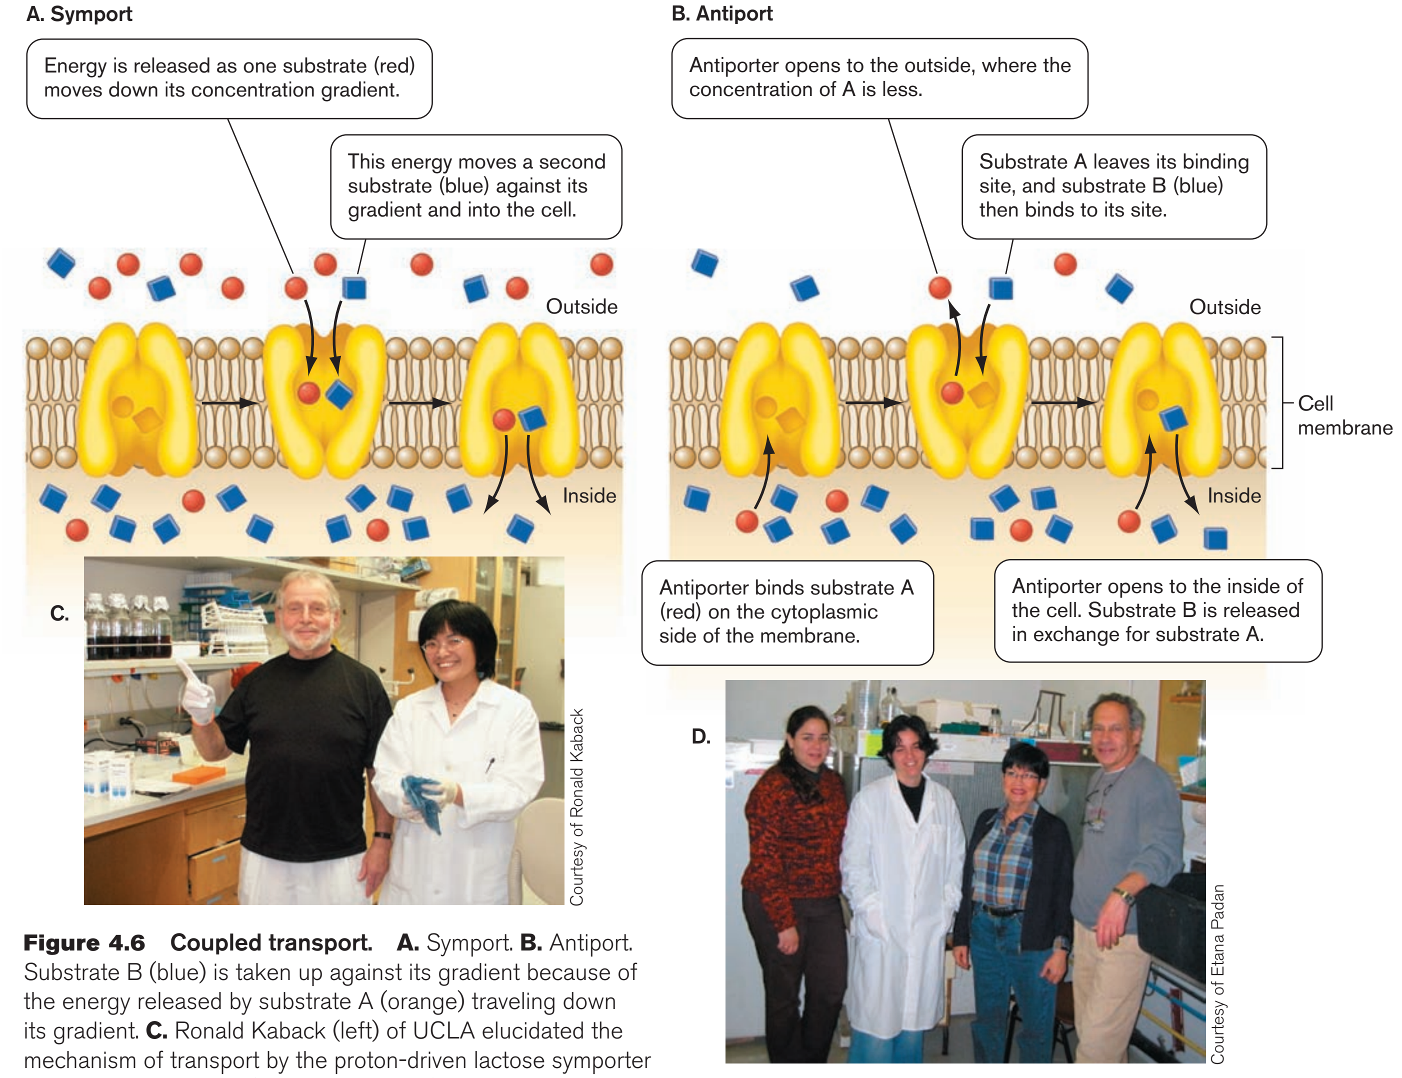
THOUGHT QUESTION 4.2 In what situation would antiport and symport be passive rather than active transport?

THOUGHT QUESTION 4.3 What kind of transporter, other than an antiporter, could produce electroneutral coupled transport?

Symport and antiport transporter proteins function by alternately opening one end or the other of a channel that spans the cell membrane. The channel contains solute-binding sites (**Figs. 4.6A** and **B**). When the channel is open to the high-concentration side of the membrane, the driving ion (solute) attaches to binding sites. The transport protein then changes shape to open that site to the low-concentration side of the membrane and the ion leaves. When and where the second (cotransported) solute binds depends on whether the transport protein is an antiporter or a symporter.

WWW | Movie on antiport

With all this ion traffic going on across the membrane, a careful accounting must be kept of how many ions are inside relative to outside. The cell must recirculate ions into and out of the cell to maintain certain gradients if the organism is to survive. Because key ATP-producing systems require an electrochemical gradient across the membrane, it is especially important to keep the interior of the cell negatively charged relative to the exterior. However, because the movement of many compounds is coupled to the import of positive ions, the electrochemical gradient will eventually dissipate, or depolarize, unless positive ions are also exported. Depolarization must be avoided



Energy is released as one substrate (red) moves down its concentration gradient.

This energy moves a second substrate (blue) against its gradient and into the cell.

Antiporter opens to the outside, where the concentration of A is less.

Substrate A leaves its binding site, and substrate B (blue) then binds to its site.

Antiporter binds substrate A (red) on the cytoplasmic side of the membrane.

Antiporter opens to the inside of the cell. Substrate B is released in exchange for substrate A.

Figure 4.6 Coupled transport. **A.** Symport. **B.** Antiport. Substrate B (blue) is taken up against its gradient because of the energy released by substrate A (orange) traveling down its gradient. **C.** Ronald Kaback (left) of UCLA elucidated the mechanism of transport by the proton-driven lactose symporter LacY. **D.** Etana Padan (second from right) of The Hebrew University of Jerusalem dissected the molecular mechanism of the Na^+/H^+ antiporter NhaA.

because a depolarized cell loses membrane integrity and cannot carry out the simple transport functions needed to sustain life. A healthy cell maintains a proper charge balance using the electron transport chain to move protons out of the cell and by exchanging negatively and positively charged ions as needed.

In addition to the direct linking of ion transport described for symport and antiport systems, ion circuitry is such that movement of one ion can be linked *indirectly* to movement of another molecule. For example, proton concentrations are typically greater outside than inside the cell. The inwardly directed proton gradient is called proton motive force. Proton motive force can impel the exit of Na^+ through the Na^+/H^+ antiporter. The resulting Na^+ gradient can drive the symport of amino acids into the cell. In this case, Na^+ moves back into the cell down its gradient, and the energy released is tied to the import of an amino acid against its gradient.

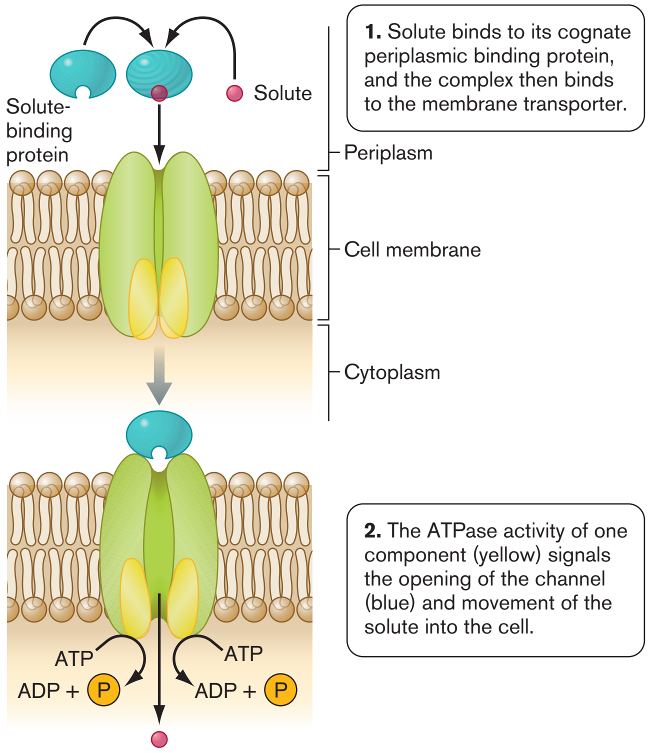
ABC Transporters Are Powered by ATP

As we pointed out in Section 3.3, a major function of proton transport is to create the proton motive force that powers ATP synthesis (for details on proton motive force, see Chapter 14). The energy stored in ATP, whether generated by the proton current or by cytoplasmic means such as fermentation, can drive membrane transport of nutrients.

The largest family of energy-driven transport systems is the **ATP-binding cassette** superfamily, also known as **ABC transporters**. These transporters are found in bacteria, archaea, and eukaryotes. It is impressive to note that nearly 5% of the *E. coli* genome is dedicated to producing the components of 70 different varieties of uptake and efflux ABC transporters. The uptake ABC transporters are critical for transporting nutrients such as maltose, histidine, arabinose, and galactose. The efflux ABC transporters are generally used as multidrug efflux pumps that allow microbes to survive exposures to hazardous chemicals. *Lactococcus*, for example, can use one pump, LmrP, to export a broad range of antibiotics, including tetracyclines, streptogramins, quinolones, macrolides, and aminoglycosides, conferring resistance to those drugs (see Section 27.6).

An ABC transporter typically consists of two hydrophobic proteins that form a membrane channel and two peripheral cytoplasmic proteins that contain a highly conserved amino acid motif involved with binding ATP. Any conserved amino acid sequence found in a family of proteins is viewed as a "cassette" because the sequence appears to have been inserted into those proteins for specific functions (hence, ATP-binding cassette). The ABC transporter superfamily contains both uptake and efflux transport systems. The uptake systems (but not the efflux systems) possess an additional, extracytoplasmic protein, called a **substrate-binding protein (SBP)**, that initially binds the substrate (also called solute). In gram-negative bacteria, these substrate-binding proteins float in the periplasmic space between the inner and outer membranes. In gram-positive bacteria, which lack an outer membrane, the proteins must be tethered to the cell surface.

ABC transport (**Fig. 4.7**) starts with the SBP snagging the appropriate solute, either as it floats by a gram-positive microbe or as the molecule enters the periplasm of a gram-negative cell. Most substrates nonspecifically enter the periplasm of gram-negative organisms through the outer membrane pores, although some high-molecular-weight substrates, like vitamin B_{12}, require the assistance of a specific outer membrane protein to move the substrate into the periplasm. Because SBPs have a high affinity for their cognate (matched) solutes, their use increases the efficiency of transport when concentrations of solute are low.



1. Solute binds to its cognate periplasmic binding protein, and the complex then binds to the membrane transporter.

2. The ATPase activity of one component (yellow) signals the opening of the channel (blue) and movement of the solute into the cell.

Figure 4.7 ABC transporters.

Once united with its solute, the SBP binds to the periplasmic face of the channel protein and releases the solute, which now binds to a site on the channel protein. This interaction triggers a structural (or conformational) change in the channel protein that is telegraphed to the nucleotide-binding proteins associated with the cytoplasmic side. On receiving this signal, the nucleotide-binding proteins start hydrolyzing ATP and send a return conformational change through the channel, signaling the channel to open its cytoplasmic side and allow the solute to enter the cell.

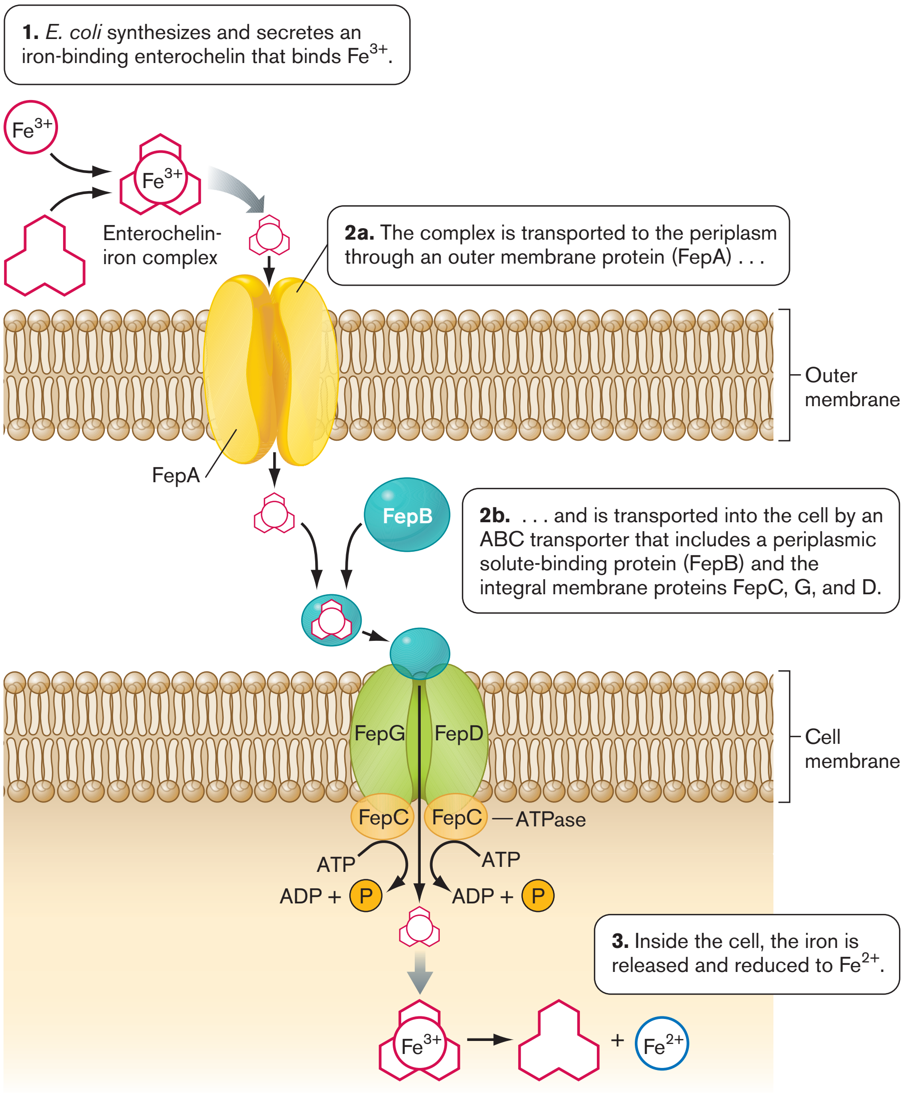
The three proteins that constitute ABC transporters appear to have arisen from a common ancestral porter and share a considerable amount of amino acid sequence homology. One unusual feature of ABC transporters is that although the membrane channel components and ATP-hydrolyzing components are generally present as distinctly separate polypeptides in *uptake* transporters, they are fused in *efflux* systems.

Siderophores Are Secreted to Scavenge Iron

Iron, an essential nutrient of most cells, is mostly locked up in nature as $Fe(OH)_3$, which is insoluble and unavailable for transport. Many bacteria and fungi have solved this transport dilemma by synthesizing and secreting specialized molecules called **siderophores** (Greek for "iron bearer") that have a very high affinity for whatever soluble ferric iron is available in the environment. These iron scavenger molecules are produced and sent forth by cells when the intracellular iron concentration is low (**Fig. 4.8**). In most gram-negative organisms, the siderophore binds iron in the environment, and the siderophore-iron complex then attaches to specific receptors in the outer membrane. At this point, either the iron is released directly and is passed to other transport proteins or the complex is transported across the cytoplasmic membrane by a dedicated ABC transporter. The iron is released intracellularly and reduced to Fe^{2+} for biosynthetic use. Other gram-negative microorganisms, such as *Neisseria gonorrhaeae* (the causative agent of gonorrhea), do not use siderophores at all but employ receptors on their surface that bind human iron complexes (for example, transferrin or lactoferrin) and wrest the iron from them.

Group Translocation against a Concentration Gradient

The ABC transporters we have just considered increase concentrations of solute inside the cell relative to the outside concentration. They move nutrients "uphill" against



1. *E. coli* synthesizes and secretes an iron-binding enterochelin that binds Fe^{3+}.

2a. The complex is transported to the periplasm through an outer membrane protein (FepA) . . .

2b. . . . and is transported into the cell by an ABC transporter that includes a periplasmic solute-binding protein (FepB) and the integral membrane proteins FepC, G, and D.

3. Inside the cell, the iron is released and reduced to Fe^{2+}.

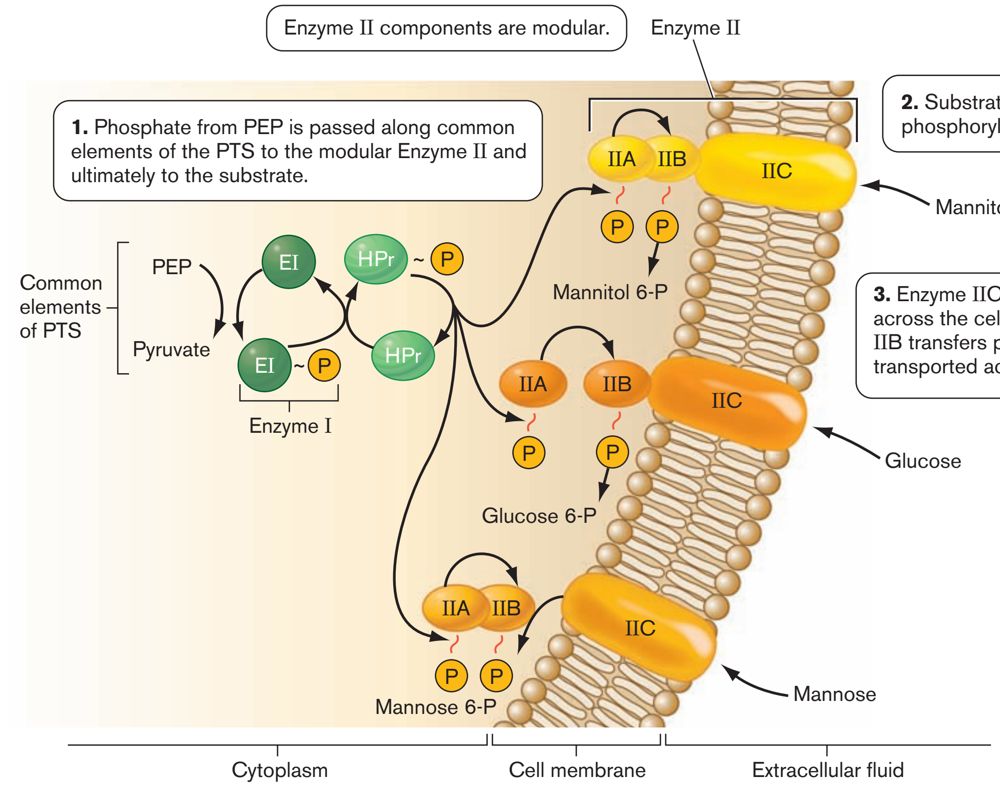
Figure 4.8 Siderophores and iron transport.

a concentration gradient. An entirely different system known as **group translocation** cleverly accomplishes the same result but without really moving a substance "uphill." Group translocation alters the substrate during transport by attaching a new group (for example, phosphate) on it. Because the modified nutrient inside the cell is a different chemical entity than the related compound outside, the parent solute entering the cell is always moving *down* its concentration gradient, regardless of how much solute has already been transported. Note that this process uses energy to chemically alter the solute. ABC transporters and group translocation systems both involve active transport, but group translocation systems are *not* ABC transporters.

The **phosphotransferase system (PTS)** is a well-characterized group translocation system present in many bacteria. It uses energy from phosphoenolpyruvate (PEP), an intermediate in glycolysis, to attach a phosphate to specific sugars during their transport into the cell. Glucose, for example, is converted during transport to glucose 6-phosphate. The system has a modular design that accommodates different substrates. There are common elements used by all sugars that are transported by the PTS system and elements that are unique to a given carbohydrate (**Fig. 4.9**). Common elements located in the cytoplasm include Enzyme I (PtsI) and a histidine-rich protein called HPr (PtsH). Enzyme I strips the high-energy phosphate from PEP and passes it to HPr, which in turn distributes the phosphate to various substrate-specific transport proteins called Enzyme II. A typical Enzyme II comprises three domains (A, B, and C) that may be fused together as a single polypeptide or assembled in a variety of combinations. Regardless of the configuration, the phosphorylated HPr (HPr-P) transfers its phosphate to the Enzyme IIA domains/proteins, which relay the phosphate to their cognate Enzyme IIB domains/proteins. Enzyme IIB finally delivers the phosphate to the specific sugar that has been transported into the cell by the Enzyme IIC domain embedded in the cytoplasmic membrane (for example, glucose is transported by Enzyme IIC and converted to glucose 6-phosphate by Enzyme IIB). In Chapter 9, we will see how this physiological system impacts the genetic control of many other systems.

Eukaryotes Transport Nutrients by Endocytosis

Like prokaryotic cells, eukaryotic cells possess antiporters and symporters and use ABC transport systems as multidrug efflux pumps, but they also employ another process, called endocytosis, which often precedes nutrient transport across membranes. The lack of a rigid cell surface allows areas of the cytoplasmic membrane to invaginate and pinch off to form membrane-enclosed vesicles called **endosomes** (see Appendix 2, **Fig. A2.8**). **Pinocytosis** is a form of endocytosis that pinches off small packets of medium to spawn small vacuoles (endosomes). Eukaryotic microbes such as amebas engulf prey bacteria by a



Enzyme II components are modular.

1. Phosphate from PEP is passed along common elements of the PTS to the modular Enzyme II and ultimately to the substrate.

2. Substrates are transformed by phosphorylation during transport.

3. Enzyme IIC transports substrate across the cell membrane. Enzyme IIB transfers phosphate to the sugar transported across the cell by IIC.

Figure 4.9 Group translocation: the phosphotransferase system (PTS) of *E. coli.* The phosphate group from PEP is ultimately passed to the substrate during transport. The common elements of the PTS are Enzyme I (PtsI) and HPr (histidine-rich protein; PtsH). Each Enzyme II is specific for a given substrate and consists of modular components. Enzyme II for mannitol is one protein with three domains: A, B, and C. Enzyme II for glucose is really two proteins: One protein contains the A domain, and the B and C domains are joined to form the second protein. Mannose Enzyme II is designed with the opposite arrangement. Its A and B domains are fused into one protein, whereas the membrane protein is simply the C domain.

form of endocytosis called **phagocytosis**, producing large vacuoles (**phagosomes**). Lysosomes, cytoplasmic vacuoles that contain various digestive enzymes, then fuse with phagosomes or endosomes, creating phagolysosomes. As a result of the fusion, digestive enzymes gain access to the endocytosed material, degrading it to a form and size that can be transported across the vacuolar membrane and into the cytoplasm.

TO SUMMARIZE:

- **Transport systems** move nutrients across semipermeable membranes.
- **Facilitated diffusion** helps solutes move across a membrane from a region of high concentration to one of lower concentration.
- **Antiporters and symporters** are coupled transport systems in which energy released by moving a driving ion (H^+ or Na^+) from a region of high concentration to one of low concentration is harnessed and used to move a solute against its concentration gradient.
- **ABC transporters** use the energy from ATP hydrolysis to move solutes “uphill” against their concentration gradients.
- **Siderophores** are secreted to bind ferric iron and transport it into the cell, where it is reduced to the more useful ferrous form. Siderophore-iron complexes enter cells with the help of ABC transporters.
- **Group translocation systems** chemically modify the solute during transport.
- **Eukaryotes use endocytosis**, a process in which small areas of the cytoplasmic membrane invaginate, trap extracellular fluid, and pinch off into the cytoplasm.

4.3 Culturing Bacteria

Microbes in nature usually exist in complex, multispecies communities, but for detailed studies, they must be grown separately in pure culture. It is nothing short of amazing—and humbling—that after 120 years of trying to grow microbes in the laboratory, we have succeeded in culturing only 0.1% of the microorganisms around us. Since the time of Koch in the late nineteenth century, microbiologists have used the same fundamental techniques to culture bacteria in the laboratory. It is true that improvements have been made, but the vast majority of the microbial world has yet to be tamed.

Bacteria Are Grown in Culture Media

For those organisms that can be cultured, we have access to a variety of culturing techniques that can be used for different purposes. Bacterial culture media may be either liquid or solid. A liquid, or broth, medium, in which organisms can move about freely, is useful when studying the growth characteristics of a single strain of a single species (that is, a **pure culture**). Liquid media are also convenient for examining growth kinetics and microbial biochemistry at different phases of growth. Solid media, usually gelled with agar, are useful when trying to separate mixtures of different organisms as they are found in the natural environment or in clinical specimens.

This organism is a plant pathogen that causes watermelon fruit blotch. **B.** Mixture of yellow-pigmented bacterial colonies, wrinkled bacterial colonies, and fungus separated by dilution on an agar plate.

Pure Cultures Can Be Obtained by Dilution Streaking or by Spread Plate Technique

Solid media are basically liquid media to which a solidifying agent has been added. The most versatile and widely used solidifying agent is agar (for the development of agar medium, see Section 1.5). Derived from seaweed, agar forms an unusual gel that liquefies at 100°C but does not solidify until cooled to about 40°C. Liquefied agar medium poured into shallow, covered petri dishes cools and hardens to provide a large, flat surface on which a mixture of microorganisms can be streaked to separate individual cells. Each cell will divide and grow to form a distinct, visible colony of cells (**Fig. 4.10**). As shown in **Figure 4.11**, a drop of liquid culture is collected using an inoculating loop and streaked across the agar plate surface in a pattern called **dilution streaking**. Organisms fall off the loop as it moves along the agar surface. Toward the end of the streak, few bacteria remain on the loop, so at that point, individual cells will land and stick to different places on the agar surface. If the medium, whether artificial (for example, laboratory medium) or natural (for example, crab carapace) contains the proper nutrients and growth factors, a single cell will multiply into many millions of offspring, forming a **microcolony**. At first visible only under a microscope, the microcolony grows into a visible droplet called a **colony** (**Figs. 4.11B** and **4.12**). A pure culture of the species, or one strain of a species, can be obtained by touching a single colony with a sterile inoculating loop and inserting that loop into fresh liquid medium.

It is important to note that the "one cell equals one colony" paradigm does not hold for all bacteria. Organisms such as *Streptococci* or

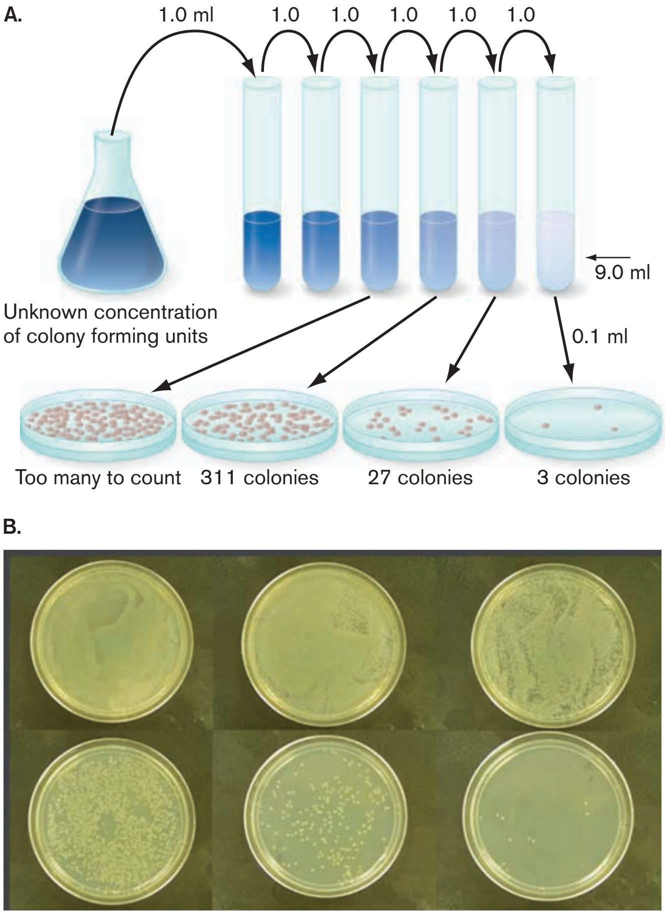
Figure 4.12 **Bacterial colonies.** **A.** A three-day-old microcolony (biofilm) on the surface of a membrane used to treat municipal wastewater in Fountain Valley, California (SEM). **B.** Bacterial colony attacking a crab carapace.

Staphylococci usually do not exist as single cells, but occur as chains or clusters of several cells. Thus, a cluster of 10 *Staphyloccocus* cells will only form one colony on an agar medium and is called a colony-forming unit (CFU).

Another way to isolate pure colonies is the **spread plate** technique. Starting from a liquid culture of bacteria, a series of tenfold dilutions is made, and a small amount of each dilution is placed directly on the surface of separate agar plates (**Fig. 4.13**). The sample is spread over the surface of the plate using a heat-sterilized, bent glass rod. The early dilutions, those containing the most bacteria, will produce **confluent** growth that covers the entire agar surface. The later dilutions, containing fewer and fewer organisms, yield individual colonies. As we shall see later, spread plates not only enable us to isolate pure cultures but also can be used to enumerate the number of **viable** bacteria in the original growth tube. A viable organism is one that successfully replicates to form a colony. Thus, each colony on an agar plate represents one viable organism present in the original liquid culture.



John Foster, U. of South Alabama

Figure 4.13 **Tenfold dilutions, plating, and viable counts.** **A.** A culture containing an unknown concentration of cells is serially diluted. One milliliter (ml) of culture is added to 9.0 ml of diluent broth and mixed, and then 1 ml of this $\frac{1}{10}$ dilution is added to another 9.0 ml of diluent (10^{-2} dilution). These steps are repeated for further dilution, each of which lowers the cell number tenfold. After dilution, 1 ml of each dilution is spread onto an agar plate. **B.** Plates prepared as in (A) are incubated at 37°C to yield colonies. By multiplying the number of countable colonies (11 colonies on the 10^{-6} plate) by the reciprocal of the dilution factor you can calculate the number of cells (colony-forming units; CFUs) per milliliter in the original broth tube ($11 \times 10^6 = 1.1 \times 10^7$ CFUs per ml).

There is some disagreement about the use of the term *viable cell*. Is an organism that does not replicate but continues to metabolize viable? Consider, for instance, that human beings who have undergone sterilization are incapable of producing offspring, but they are certainly alive. Nevertheless, based on a tradition dating back to the time of Koch, it remains convention within the scientific community that a "viable" cell reproduces to form a colony on a plate. Organisms that appear to metabolize but for some reason cannot replicate have been referred to as dormant or "**viable but nonculturable**." Increasingly, it seems probable that all viable but nonculturable organisms simply appear that way to us because we have not yet discovered the culture conditions necessary for them to reproduce.

Growth in Complex Media or in Synthetic Media

Bacteria can be grown in nutrient-rich but poorly defined **complex media** or in precisely defined **synthetic media**.

Recipes for complex media usually contain several poorly defined ingredients, such as yeast extract or beef extract, whose exact composition is not known. These additives include a rich variety of amino acids, peptides, nucleosides, vitamins, and some sugars. Some organisms are particularly fastidious, requiring that components of blood be added to a basic complex medium. The complex medium is now called an **enriched medium**.

Complex, or rich, media provide many of the chemical building blocks that a cell would otherwise have to synthesize on its own. For example, instead of making proteins that synthesize tryptophan, all the cell needs is a membrane transport system to harvest prefabricated tryptophan from the medium. Likewise, fastidious organisms that require blood in their media may reclaim the heme released from red blood cells as their own, using it as an enzyme prosthetic group, a group critical to enzyme function (for example, the heme group in cytochromes). All of this saves the scavenging cell a tremendous amount of energy, and as a result, bacteria tend to grow fastest in complex media.

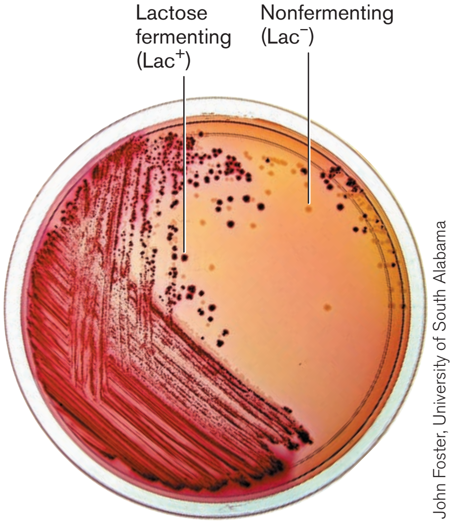
An argument can be made that complex media mimics the rich environment that pathogens encounter in an animal host. However, the metabolism of a microbe growing in a complex medium is hard to characterize. How would you know whether *E. coli* possesses the ability to make tryptophan if the bacterium grows only in complex media? Fortunately, some organisms grow in fully defined synthetic media. In preparing a synthetic medium, one starts with water, then adds various salts, carbon, nitrogen, and energy sources in precise amounts. For self-reliant organisms like *E. coli* or *Bacillus subtilis*, that is all that is needed. Other organisms, such as *Shigella* species or mutant strains of *E. coli* or *B. subtilis*, require additional ingredients to satisfy requirements imposed by the absence of specific metabolic pathways.

THOUGHT QUESTION 4.4 What would be the phenotype (growth characteristic) of a cell that lacks the *trp* genes (genes required for the synthesis of tryptophan)? What would be the phenotype of a cell missing the *lac* genes (genes whose products catabolize the carbohydrate lactose)?

Selective and Differential Media Reveal Differences in Metabolism

Microorganisms are remarkably diverse with respect to their metabolic capabilities and resistance to certain toxic agents. These differences are exploited in **selective media**, which favor the growth of one organism over another, and in **differential media**, which expose biochemical differences between two species that grow equally well. For example, gram-negative bacteria, with their outer membrane, are much more resistant than gram-positive microbes to detergents like bile salts and certain dyes, such as crystal violet. A solid medium containing bile salts and crystal violet is considered selective because it favors the growth of gram-negative organisms over gram-positive ones. On the other hand, *E. coli* and *S. enterica* are both gram-negative, but only *E. coli* can ferment lactose. Colonies of each can be distinguished on solid media containing lactose, the dye neutral red, and a nonfermentable carbon source like peptone. Both organisms grow in the medium, but *E. coli* ferments the lactose and produces acidic end products. The lower pH surrounding an *E. coli* colony causes the dye to enter the cells, turning the colony red. In stark contrast, *S. enterica*, a major cause of diarrhea, will grow on nonfermentable peptides, but, because it cannot ferment lactose, acidic end products are not produced and the colonies remain white, the natural color of the colony. In this example, growth in differential media easily distinguishes colonies of lactose fermenters from nonfermenters.

Several media used in clinical microbiology are both selective and differential. **MacConkey medium**, for example, selects for growth of gram-negative bacte-



John Foster, University of South Alabama

Figure 4.14 MacConkey medium, a culture medium both selective and differential. Dilution streak of a mixture of Lac$^+$ and Lac$^-$ bacteria. Only gram-negative bacteria grow on lactose MacConkey (selective). Only a species capable of fermenting lactose produces pink colonies (differential).

ria because it contains bile salts and crystal violet, which prevent the growth of gram-positives. The medium also includes lactose, neutral red, and peptones to differentiate lactose fermenters from nonfermenters. Thus, a culture grown in MacConkey medium will consist of gram-negative organisms that can be identified as lactose fermenters (red colonies) or nonfermenters (uncolored colonies; **Fig. 4.14**). This medium is of particular benefit when diagnosing the etiology (cause) of diarrheal disease because most normal flora are lactose fermenters, whereas two important pathogens, *Salmonella* and *Shigella*, are lactose nonfermenters.

THOUGHT QUESTION 4.5 The addition of sheep blood to agar produces a very rich medium called blood agar. Do you think blood agar can be considered a selective medium? A differential medium? *Hint*: Some bacteria can lyse red blood cells.

TO SUMMARIZE:

- **Microbes in nature** usually exist in complex, multispecies communities, but for detailed studies they must be grown separately in pure culture.
- **Bacteria can be cultured** on solid or liquid media.
- **Minimal defined media** contain only those nutrients essential for growth.
- **Complex, or rich, media** contain many nutrients. Other media exploit specific differences between organisms and can be defined as selective or differential.

4.4 Counting Bacteria

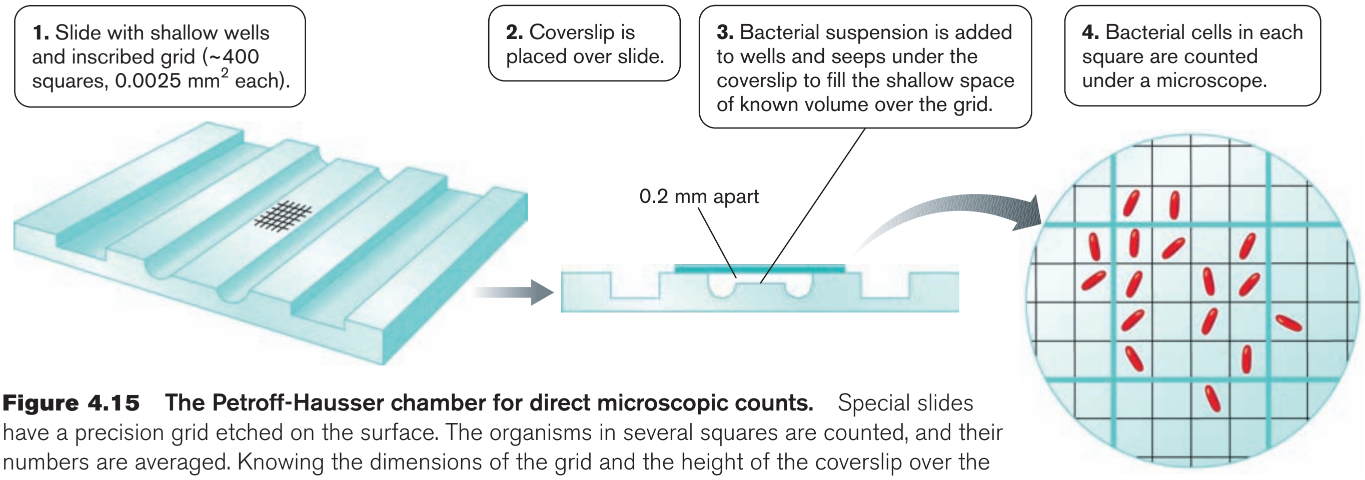
Counting or quantifying organisms invisible to the naked eye is surprisingly difficult because each of the available techniques measures a different physical or biochemical aspect of growth. Thus, a cell density value (given as cells per milliliter) derived from one technique will not necessarily agree with the value obtained by a different method.

Direct Counting Enumerates Both Living and Dead Cells

Microorganisms can be counted directly using a microscope. A dilution of a bacterial culture is placed on a special microscope slide called a hemocytometer (or, more specifically for bacteria, a Petroff-Hausser counting chamber, **Fig. 4.15**). Etched on the surface of the slide is a grid of precise dimensions, and placing a coverslip over the grid creates a space of precise volume. The number of organisms counted within that volume is used to calculate the concentration of cells in the original culture.

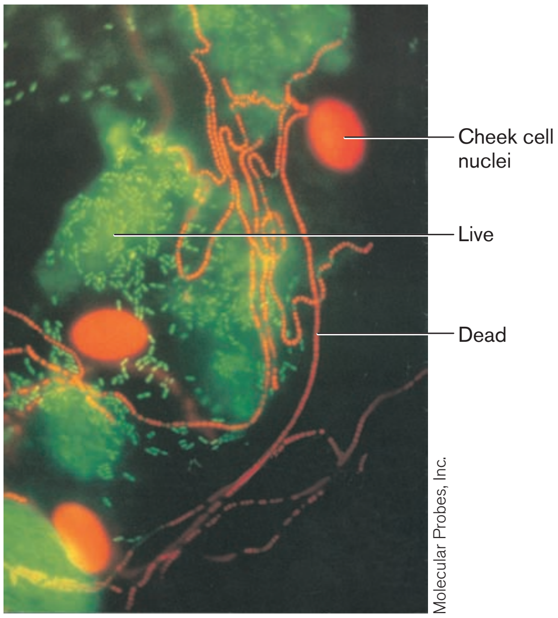
However, "seeing" an organism under the microscope does not mean that the organism is alive. Living and dead cells are indistinguishable by this basic approach. Living cells may be distinguished from dead cells by fluorescence microscopy using fluorescent chemical dyes, as discussed in Chapter 2. For example, propidium iodide, a red dye, intercalates between DNA bases but cannot freely penetrate the energized membranes of living cells. Thus, only *dead* cells stain red under a fluorescence scope. Another dye, Syto-9, enters both living and dead cells, staining them both green. By combining Syto-9 with propidium iodide, living and dead cells can be distinguished: Living cells will stain green, whereas dead cells appear orange or yellow because both dyes enter, and Syto-9 (green) plus propidium (red) appears yellow (**Fig. 4.16**).

Direct counting without microscopy can be accomplished by a **Coulter counter**. In the Coulter counter, a microbial culture is forced through a small orifice, through which flows an electrical current. Electrodes placed on both sides measure resistance. Every time



1. Slide with shallow wells and inscribed grid (~400 squares, 0.0025 mm² each).
2. Coverslip is placed over slide.
3. Bacterial suspension is added to wells and seeps under the coverslip to fill the shallow space of known volume over the grid.
4. Bacterial cells in each square are counted under a microscope.
0.2 mm apart

Figure 4.15 The Petroff-Hausser chamber for direct microscopic counts. Special slides have a precision grid etched on the surface. The organisms in several squares are counted, and their numbers are averaged. Knowing the dimensions of the grid and the height of the coverslip over the slide enables one to calculate the number of organisms in a milliliter.



Molecular Probes, Inc.

Figure 4.16 **Live-dead stain.** Live and dead bacteria visualized on freshly isolated human cheek epithelial cells using LIVE/DEAD BacLight Bacterial Viability Kit. Dead bacterial cells fluoresce orange or yellow because propidium (red) can enter the cells and intercalate the base pairs of DNA. Live cells fluoresce green because Syto-9 (green) enters the cell. The faint green smears are the outlines of cheek cells.

a cell passes through the orifice, electrical resistance increases, and the cell is counted. The Coulter counter, however, works best with larger eukaryotic cells, such as red blood cells; the instrument is not generally sensitive enough to detect individual bacteria.

An electronic technique more suited to counting and separating bacterial cells requires an instrument called a **fluorescence-activated cell sorter (FACS)**. In the FACS technique, bacterial cells that synthesize a fluorescent protein (see cyan fluorescent protein, Section 3.6) or that have been labeled with a fluorescent antibody or chemical are passed through a small orifice, as in the Coulter counter, and then past a laser (**Fig. 4.17A**). Detectors measure light scatter in the forward direction, a measure of particle size, and to the side, which indicates shape or granularity. In addition, the laser activates the fluorophore in the fluorescent antibody, and a detector measures fluorescence intensity.

The FACS technique can be used to identify and count different populations of cells within a single culture based on cell size and level of fluorescence (that is, one subpopulation may fluoresce more than or less than another). For example, by placing the green fluorescent protein gene (*gfp*) under the control of the regulatory DNA sequences of a bacterial gene (creating a gene fusion), researchers can count the cells expressing that gene using FACS analysis; this, in turn, makes it possible to determine under what conditions that gene is expressed and whether all cells in the population express that gene at the same time and to the same extent (**Fig. 4.17B**).

Viable Counts Estimate the Number of Cells That Can Form Colonies

Viable cells, as noted previously, are those that can replicate and form colonies on a plate. To obtain a viable cell count, dilutions of a liquid culture can be plated directly on an agar surface or added to liquid agar cooled to about 42–45°C. The agar is subsequently poured into an empty Petri plate (**pour plate**), where the agar cools further and solidifies. Because many bacteria resist short exposures to that temperature, individual cells retain the ability to form colonies on, and in, the pour plate. After colonies form, they are counted, and the original cell number is calculated. For example, if 100 colonies are observed in a pour plate made with 100 microliters (μl) of a 10^{-3} dilution of a culture, there are 10^{6} organisms per milliliter of the original culture.

Although viable counts are widely used in research, there are problems using this method to measure cell number and determine cultural characteristics. One issue is that colony counting does not reflect cell size or growth stage. Even more problematic is that colony counts usually underestimate the number of living cells in a culture. As noted earlier, metabolically active cells that do not form colonies on agar plates will typically not be counted as alive. Cells damaged for one reason or another, while still alive, may be too compromised to divide. Comparing a viable count with a direct count obtained from a live-dead stain can expose the presence of damaged cells. Organisms such as *Streptococci* pose another problem. These organisms grow in chains. If individual cells in a chain are not separated prior to plating, each colony seen will have formed from a group of cells. This will cause actual cell numbers to be underestimated and is why the results of this counting technique are reported as colony-forming units (CFUs) rather than cells.

Biochemical Assays Measure Overall Population Size

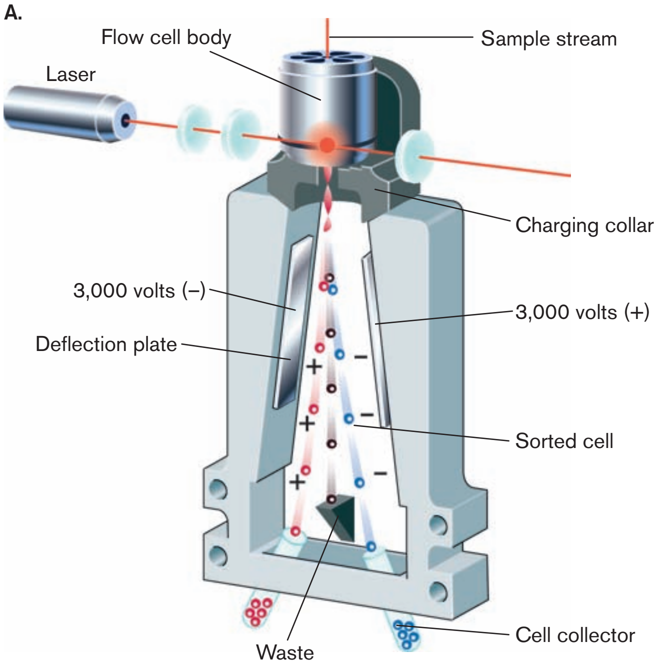
In contrast to methods that visualize individual cells, assays of cell mass, protein content, or metabolic rate measure the overall size of a population of cells. The most straightforward but time-consuming biochemical approach to monitoring population growth is to measure the dry weight of a culture. Cells are collected by centrifugation, washed, dried in an oven, and weighed. Because bacterial cells weigh very little, a large volume of culture must be harvested to obtain measurements, which makes this technique quite insensitive. A more accurate alternative is to measure increases in protein levels, which correlate with increases in cell number. Protein levels are more easily measured and use relatively sensitive assays.

Optical Density: A Rapid Measure of Population Growth

The phenomenon of light scattering was introduced in Chapter 2. We noted that although individual bacteria could not be resolved based on the detection of scattered light by the unaided human eye, the presence of numerous bacteria in a tube of medium could be detected as a cloudy appearance. The decrease in intensity of a light beam due to the scattering of light by a suspension of particles is measured as **optical density**. Note that only particles in suspension, such as cells and macromolecules, can scatter light. True solutions, such as a solution of salt or of glucose, are clear even at high concentration.

The optical density of light scattered by bacteria is a very useful tool for estimating population size. The method is quick and easy, but because light scattering is a complex function of cell number and volume, optical density provides only an approximate result that must be corrected using a standard curve. Typically, a standard curve is obtained that plots viable counts for cultures versus optical densities as measured by a spectrophotometer. Thereafter, the optical density of a growing culture is measured, and the standard curve is used to estimate cell number at any given point during growth.

One inherent problem in estimating cell numbers based on optical density is that a cell's volume can vary, depending on its growth stage, altering its light-scattering properties. Thus, the cell number estimated by the standard curve may deviate from the true number. Another problem is that dead cells also scatter light. Clearly, using optical density to estimate viable count can be misleading, especially when measuring populations in stationary phase.



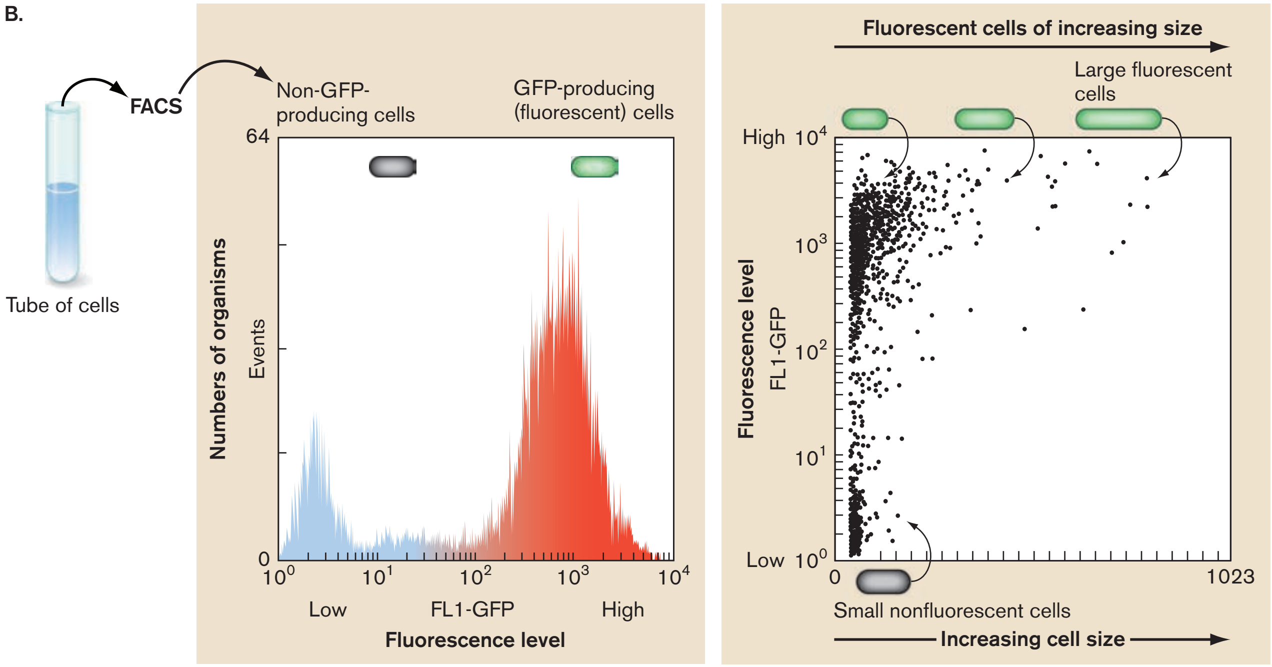


Figure 4.17 Fluorescence-activated cell sorter. **A.** Schematic diagram of a FACS apparatus (bidirectional sorting). **B.** Separation of GFP-producing *E. coli* from non-GFP-producing *E. coli.* The low-level fluorescence in the cells on the left is baseline fluorescence (autofluorescence). The scatterplot displays the same FACS data, showing the size distribution of cells (*x*-axis) with respect to level of fluorescence (*y*-axis). The larger cells may be ones that are about to divide.

TO SUMMARIZE:

- **Microorganisms in culture may be counted directly** under a microscope, with or without staining, or by using a fluorescence-activated cell sorter.
- **Microorganisms can be counted indirectly**, as in viable counts and measurement of dry weight, protein levels, or optical density.
- **A viable bacterial organism** is defined as being capable of replicating and forming a colony on a solid-medium surface.

4.5 The Growth Cycle

How do microbes grow? What determines their rate of growth? And when does growth start in a nongrowing population? In nature, the answers to these questions are extremely complex. Most microbes in nature do not exist alone, but in complex communities of microbes and multicellular organisms. Studying the growth of multicellular forms requires considering them as a unit. Yet these same multicellular forms can send off **planktonic cells**, free-living organisms that grow and multiply on their own.

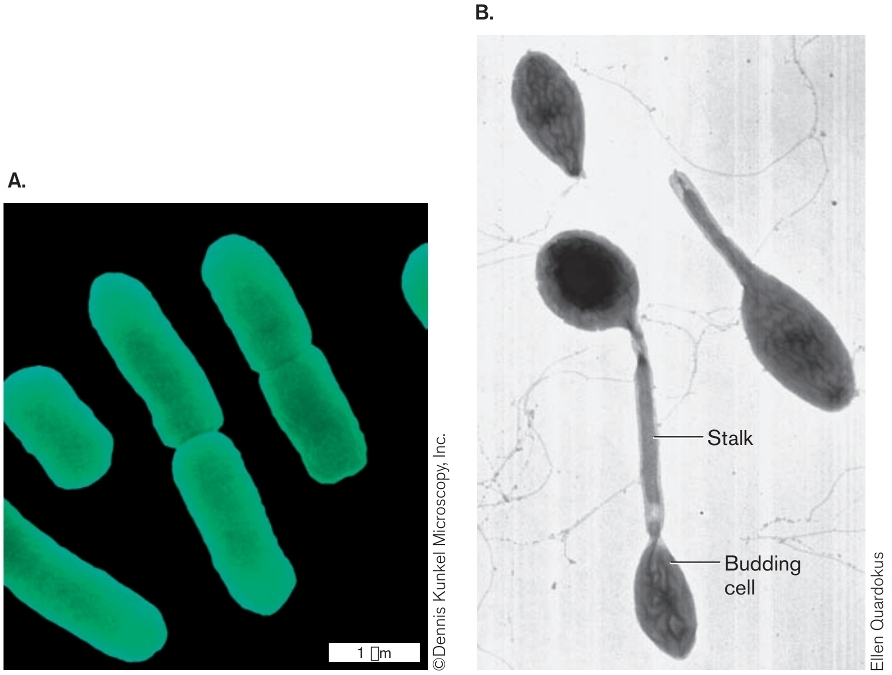
Nevertheless, all species at one time or another exhibit both rapid growth and nongrowth, as well as many phases in between. For clarity, we present here the principles of rapid growth, while bearing in mind the actual diversity of growth situations in nature.

The ultimate goal of any species is to make more of its own kind. This fundamental law ensures survival of the species. A typical bacterium (at least the typical bacterium that can be cultured in the laboratory) grows by increasing in length and mass, which facilitates expansion of its nucleoid as its DNA replicates (see Section 3.3). As DNA replication nears completion, the cell, in response to complex genetic signals, begins to synthesize an equatorial septum that ultimately separates the two daughter cells. In this overall process called **binary fission**, one parent cell splits into two equal daughter cells (**Fig. 4.18A**). Note, however, that although a majority of culturable bacteria divide symmetrically in two equal halves, some species divide asymmetrically. For example, the bacterium *Caulobacter* forms a stalked cell that remains fixed to a solid surface but reproduces by budding from one end to produce small, unstalked motile cells. The marine organism *Hyphomicrobium* also replicates asymmetrically by budding, releasing a smaller cell from a stalked parent (**Fig. 4.18B**).

Eukaryotic microbes divide by a special form of cell fission involving **mitosis**, the segregation of pairs of chromosomes within the nucleus (see Section 20.2 and Appendix 2). Some eukaryotes also undergo more complex life cycles involving budding and diverse morphological forms. Nevertheless, a large population of eukaryotic microbes will exhibit the same mathematical functions of growth seen in bacteria; indeed, these same growth patterns are seen in large populations of multicellular organisms, including ourselves.

Unlimited Population Growth Is Exponential

The process of reproduction has implications for growth not only of the individual, but also of populations. If we assume that growth occurs without limits, what happens to the population? The unlimited growth of any population obeys a simple law: The **growth rate**, or rate of increase in population numbers or biomass, is *proportional* to the population size at a given time. Such a growth rate is called exponential because it generates an exponential curve, a curve whose slope increases continually.



©Dennis Kunkel Microscopy, Inc.

Ellen Quardokus

Figure 4.18 Symmetrical and asymmetrical cell division. A. Symmetrical cell division, or binary fission, in *Lactobacillus* sp. (SEM). **B.** Budding of the marine bacterium *Hyphomicrobium* (approx. 4 μm long).

How does binary fission of cells generate an exponential curve? If each cell produces two cells per generation, then the population size at any given time is proportional to 2^n, where the exponent n represents the number of generations (replacement of parents by offspring) that have taken place between two time points. Thus, cell number rises exponentially. Many microbes, however, have replication cycles based on numbers other than two. For example, some cyanobacteria form cell aggregates that divide by multiple fission, releasing dozens of daughter cells. The cyanobacterium enlarges without dividing, and then suddenly divides many times without separating. The cell mass breaks open to release hundreds of progeny cells.

It is important to note that simple binary fission is not the only kind of reproduction that would generate an exponential curve. Any generation size will yield exponential growth. For example, the imaginary, softball-sized, fuzzy creatures called "tribbles" created in an episode of the television series *Star Trek* supposedly produced 11 offspring per generation and soon overran the starship. The rate of increase of the tribble population is proportional to 11^n, where n is the number of tribble generations (**Fig. 4.19A**). In comparison with bacterial reproduction, which produces only 2 cells per generation, we might expect the growth *rate* of tribbles to be dramatically faster. In fact, this is the case for the first few generations. But after a few more generations, the bacterial growth curve eventually achieves the same steep slope (that is, rate) as the tribble curve (**Fig. 4.19B**); the two curves are, in fact, graphical representations of the same kind of exponential function.

THOUGHT QUESTION 4.6 A virus such as influenza virus might produce 800 progeny virus particles from one infected host cell. How would you mathematically represent the exponential growth of the virus? What practical factors might limit such growth?

A Constant Generation Time Results in Logarithmic Growth

A variable not accounted for in Figure 4.19B is the length of time from one generation to the next. In an environment with unlimited resources, bacteria divide at a constant interval called the **generation time**. The length of that interval varies with respect to many parameters, including the bacterial species, type of medium, temperature, and pH. The generation time for cells in culture is also known as the **doubling time**, because the population of cells doubles over one generation. For example, one cell of *E. coli* placed into a complex medium will divide every 20 minutes. After 1 hour of growth (three generations), that one cell will have become eight (1 to 2, 2 to 4, 4 to 8). Because cell number (N) *doubles* with each division, the increase in cell number over time is exponential, not linear. A linear increase would occur if cell number rose by a *fixed* amount after every generation (for example, 1 to 2, 2 to 3, 3 to 4).

Starting with any number of organisms (N_0), the number of organisms after n generations will be $N_0 \times 2^n$. For example, a single cell after three generations ($n = 3$) will produce

$$1 \text{ cell} \times 2^3 = 8 \text{ cells}$$

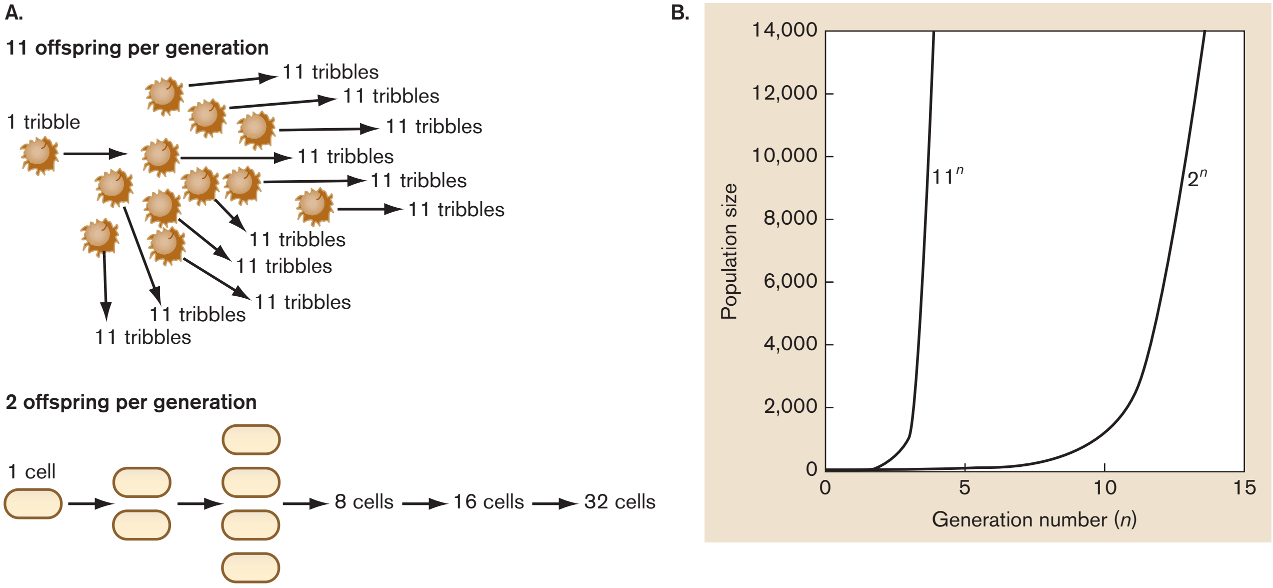


Figure 4.19 Reproduction: from one to many. A. Exponential growth of a hypothetical organism (tribbles from the *Star Trek* series) that produces 11 progeny per generation, compared with an organism that produces 2 offspring per generation. **B.** Growth curves for a population that increases 11-fold per generation and for a population that increases twofold per generation.

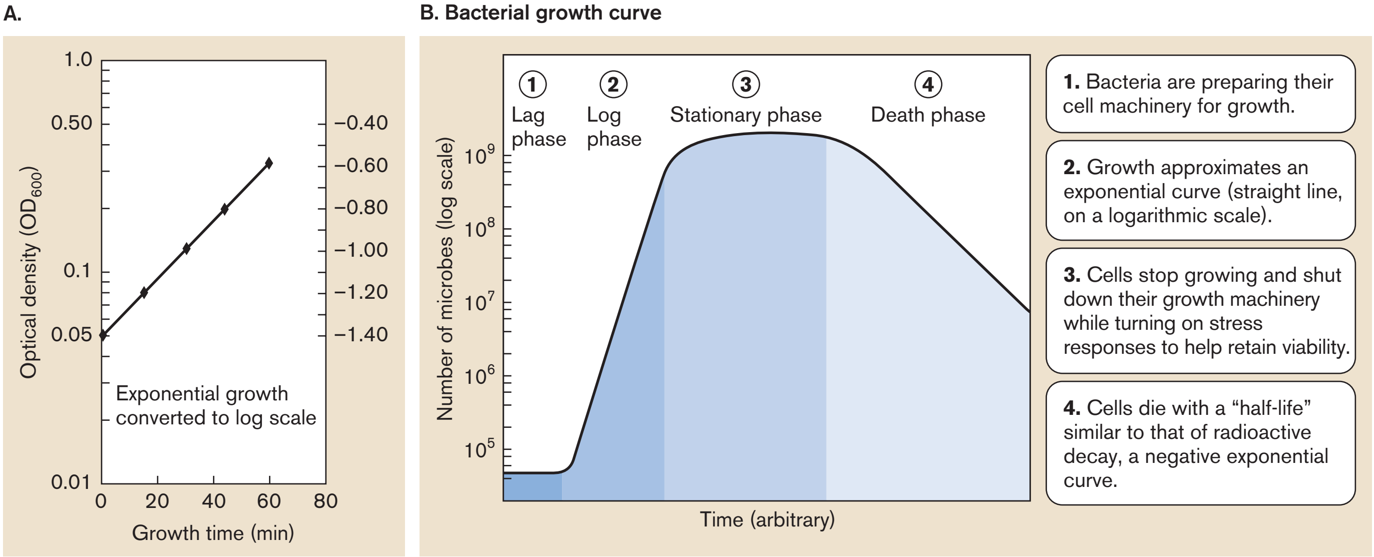
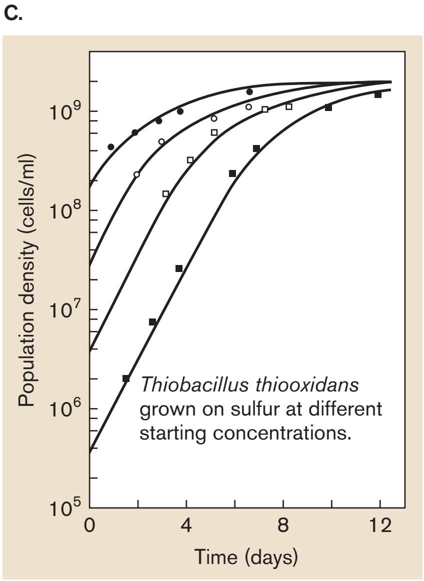


1. Bacteria are preparing their cell machinery for growth.

2. Growth approximates an exponential curve (straight line, on a logarithmic scale).

3. Cells stop growing and shut down their growth machinery while turning on stress responses to help retain viability.

4. Cells die with a "half-life" similar to that of radioactive decay, a negative exponential curve.



Thiobacillus thiooxidans grown on sulfur at different starting concentrations.

Figure 4.20 Bacterial growth curves. A. Theoretical growth curve of a bacterial suspension measured by optical density at a wavelength of 600 nm. **B.** Phases of bacterial growth in a typical batch culture. **C.** Published growth curves of *Thiobacillus thiooxidans*, an acidophile that oxidizes sulfur to sulfuric acid. Whatever the starting cell density, the culture grows exponentially until it runs out of sulfur; then it enters the stationary phase.
Source: C. Yasuhiro Konishi, et al. 1995. *Applied and Environmental Biology* 61:3617.

The number of generations that an exponential culture undergoes in a given time period can be calculated if the number of cells at the start of the period (N_0) and the number of cells at the end of the period (N_t) are known. Methods such as viable count are used to make those determinations. To simplify calculations, instead of using base 2 logarithms, the $\log_2$ expressions are converted to base 10 through division by a factor of $\log_{10} 2$, which is approximately 0.301. Thus:

$$N_t = N_0 \times 2^n$$

becomes

$$\log_{10} N_t = \log_{10} N_0 + n \log_{10} 2$$
$$n \log_{10} 2 = \log_{10} N_t - \log_{10} N_0$$
$$n = (\log_{10} N_t - \log_{10} N_0) \div \log_{10} 2$$
$$n = \log_{10} (N_t/N_0) \div \log_{10} 2$$
$$n = \log_{10} (N_t/N_0) \div 0.301$$

In practice, exponential growth occurs only for a short period when all nutrients are in full supply and the concentration of waste products has not become a limiting factor.

The rate of exponential growth can be expressed as the **mean growth rate constant** (k), which is the number of generations (n) per unit time (usually generations per hour). Even if we do not know the generation time, we can calculate k if we know the number of organisms at time zero (N_0) and the number of organisms after incubation time t (N_t) as follows:

$$k = n/t = (\log_{10} N_t - \log_{10} N_0) \div 0.301t$$

Thus, a culture with a generation time of 20 minutes (0.33 hour) will have a mean growth rate constant of 3 generations per hour ($k = 3$). For a culture doubling every 120 minutes (2 hours), k is 0.5. Note from these examples that the mean generation time (g) in hours is the reciprocal of the mean growth rate constant:

$$g = 1/k$$

The growth rate constant can also be calculated from the slope of $\log_{10} N$ over time, where N is a relative measure of culture density, such as the optical density measured in a spectrophotometer (**Fig. 4.20A**). The units of N do not matter because we are always looking at ratios of cell numbers relative to an earlier level. For example, we can use the following series of optical density (OD) measurements to measure N:

Time (min)	OD_{600}	$\log_{10} OD_{600}$
0	0.05	−1.30
15	0.08	−1.10
30	0.13	−0.89
45	0.20	−0.69
60	0.33	−0.48

If we plot $\log_{10} OD_{600}$ versus time, we obtain a line with a slope of 0.0136/min. Substituting in equation 4.1, we obtain k, the growth rate constant (doubling time):

$$
\begin{aligned}
k &= (0.0136/\text{min})(60\ \text{min/h}) \div 0.301\\
&= 2.7\ \text{doublings per hour}
\end{aligned}
$$

The steeper the slope, the faster the organisms are dividing.

THOUGHT QUESTION 4.7 Suppose 1,000 bacteria are inoculated in a tube of minimal salts medium, where they double once an hour; and 10 bacteria are inoculated into rich medium, where they double in 20 minutes. Which tube will have more bacteria after 2 hours? After 4 hours?

THOUGHT QUESTION 4.8 An exponentially growing culture has an optical density at 600 nm (OD_{600}) of 0.2 after 30 minutes and an OD_{600} of 0.8 after 80 minutes. What is the doubling time?

THOUGHT QUESTION 4.9 **Figure 4.20C** shows growth curves for different population densities of *Thiobacillus thiooxidans* when the concentration of sulfur in the medium is constant. Draw the growth curves you would expect to see if the initial population density was constant but the concentration of sulfur varied.

The mathematics of exponential growth is relatively straightforward, but remember that microbes grow differently in pure culture (very rare in nature) than they do in mixed communities, where neighboring cells produce all kinds of substances that may feed or poison other microbes. In mixed communities, the microbes may grow planktonically (floating in liquid), as in the open ocean, or as a biofilm on solid matter suspended in that ocean. In each instance, the mathematics of exponential growth apply at least until the community reaches a density at which different species begin to compete.

THOUGHT QUESTION 4.10 It takes 40 minutes for a typical *E. coli* cell to completely replicate its chromosome and about 20 minutes to prepare for another round of replication. Yet the organism enjoys a 20-minute generation time growing at 37°C in complex medium. How is this possible?

Stages of Growth in Batch Culture

Exponential growth never lasts indefinitely because nutrient consumption and toxic by-products eventually slow the growth rate until it halts altogether. The simplest way to model the effects of changing conditions is to culture bacteria in liquid medium within a closed system, such as a flask or test tube. This is called **batch culture**. In batch culture, no fresh medium is added during incubation; thus, nutrient concentrations decline and waste products accumulate during growth.

These changing conditions profoundly affect bacterial physiology and growth and illustrate the remarkable ability of bacteria to adapt to their environment. As medium conditions deteriorate, alterations occur in membrane composition, cell size, and metabolic pathways, all of which impact generation time. Microbes possess intricate, self-preserving genetic and metabolic mechanisms that slow growth before their cells lose viability. Because many bacteria replicate by binary fission, the plotting of culture growth (as represented by the logarithm of the cell number) versus incubation time allows us to see the effect of changing conditions on generation time and reveals several stages of growth (**Fig. 4.20B**).

Lag phase. Cells transferred from an old culture to fresh growth media need time to detect their environment, express specific genes, and synthesize components needed to institute rapid growth. As a result, bacteria inoculated into fresh media typically experience a lag period, or **lag phase**, where cells do not divide. There are several reasons for this. Cells taken from an aged culture may be damaged and require time for repair. Carbon, nitrogen, or energy sources different from those originally used by the seed culture must be sensed, and the appropriate enzyme systems must be synthesized. The length of lag phase varies, depending on the age of the culture, changes in temperature, and the differences between the new and old media (for example, changes in nutrient levels, pH, and salt concentrations). For example, transferring cells from a complex medium to a fresh complex medium results in a very short lag phase, whereas cells grown in a complex medium and then plunged into a minimal defined medium experience a protracted lag phase, during which time they readjust to synthesize all the amino acids, nucleotides, and other metabolites originally supplied by the complex medium.

Early log, or exponential, phase. Once cells have retooled their physiology to accommodate the new environment, they begin to grow exponentially and enter what is called **exponential**, or **logarithmic (log) phase**. Exponential growth is balanced growth, where all cell components are synthesized at constant rates relative to each other. At this stage, cells are growing and dividing at the maximum rate possible based on the medium and growth conditions provided (such as, temperature, pH, and osmolarity). Cells are largest at this stage of growth. This is the linear part of the growth curve. If cell division were synchronized and all cells divided at the same time, the growth curve during this period would appear as a series of steps with cell numbers doubling instantly after every generation time. But batch cultures are not synchronous. Every cell has an equal generation time, but each cell divides at a slightly different moment, making the cell number rise smoothly.

Cells enjoying balanced, exponential growth are temporarily thrown into metabolic chaos (unbalanced growth) when their medium is abruptly changed. Nutritional downshift (moving cells from a good carbon source such as glucose to a poorer carbon source such as succinate) or nutritional upshift (moving cells to a better carbon source) casts cells into unbalanced growth. Downshift to a carbon source with a lower energy yield not only means that a different set of enzymes must be made and employed to use the carbon source, but also means that the previous high rate of macromolecular synthesis (such as ribosome synthesis) used to support a fast generation time is now too rapid relative to the lower energy yield. Failure to adjust will lead to increased mistakes in RNA, protein, and DNA synthesis, depletion of key energy stores, and ultimately death.

Microbes, however, possess molecular fail-safe systems that immediately dampen rates of macromolecular synthesis until they come into balance with the rest of metabolism. In contrast, nutritional upshift means that the cell will start making more energy (ATP) than it can use at its current rate of macromolecular synthesis. The same fail-safe mechanisms used during downshift will, during upshift, kick macromolecular synthesis into a higher gear, once again establishing balanced growth. Nutritional upshift causes cells to reenter log phase but with a shorter generation time.

Late log phase. As cell density (number of cells per milliliter) rises during log phase, the rate of doubling eventually slows, and a new set of growth-phase–dependent genes are expressed. At this point, some species can also begin to detect the presence of others by sending and receiving chemical signals in a process known as quorum sensing (discussed in Chapter 10).

Stationary phase. Eventually, cell numbers stop rising owing to lack of a key nutrient or buildup of waste products. This occurs for bacteria grown in a complex medium when cell density rises above 10^9 cells per milliliter, but it can occur at lower cell densities if nutrients are limiting. At this point, the growth curve levels off and the culture enters what is called **stationary phase**. In contrast to bacteria, eukaryotic microorganisms, such as protozoa, enter stationary phase at much lower cell numbers, usually around 10^6 organisms per milliliter. The reason for this is simply that eukaryotic cells are bigger than bacteria. Bigger cells use more nutrient and run out of it sooner.

If they did not change their physiology, microbes would be very vulnerable once entering stationary phase. Because cells in stationary phase are not as metabolically nimble as cells in exponential phase, damage from oxygen radicals and toxic by-products of metabolism would readily kill them. As an avoidance strategy, some bacteria differentiate into very resistant spores in response to nutrient depletion (see Section 4.7), while other bacteria undergo less dramatic but very effective molecular reprogramming. The microbial model organism *E. coli*, for example, adjusts to stationary phase by decreasing its size, minimizing the volume of its cytoplasm compared with the volume of its nucleoid. Less nutrient is required to sustain the smaller cell. New stress resistance enzymes are also synthesized to handle oxygen radicals, protect DNA and proteins, and increase cell wall strength through increased peptidoglycan cross-linking. As a result, *E. coli* cells in stationary phase become more resistant to heat, osmotic pressure, pH changes, and other stresses that they might encounter while waiting for a new supply of nutrients.

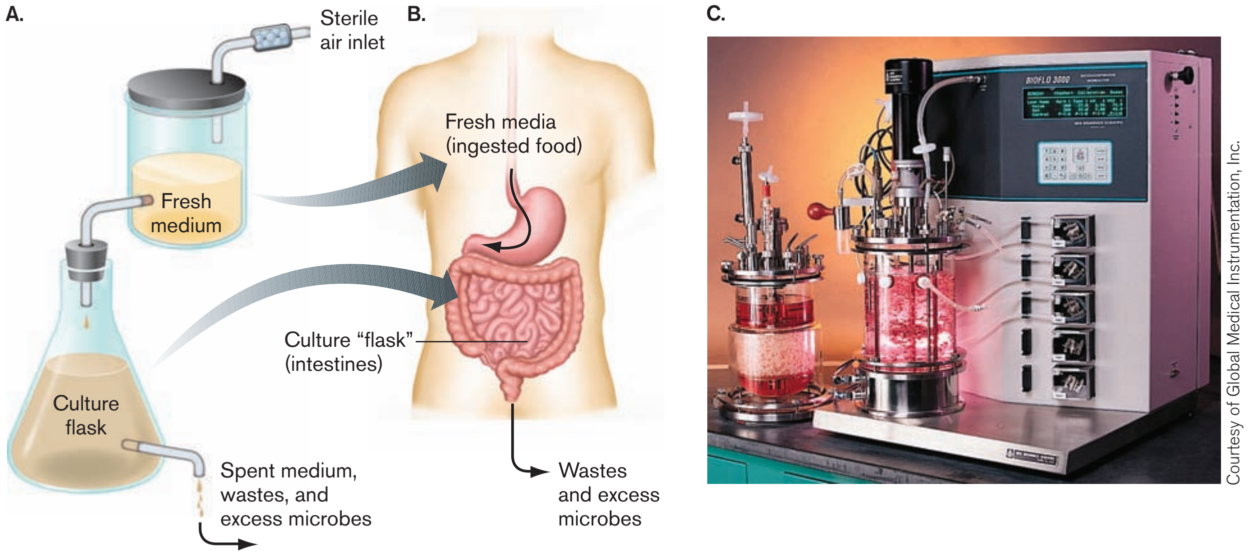
Death phase. Without reprieve in the way of new nutrients, cells in stationary phase will eventually succumb to toxic chemicals present in the environment. Like the growth rate, the **death rate**, the rate at which cells die, is logarithmic. The death rate, however, is a negative exponential function. Recall that the increase in cell number during exponential phase is a positive exponential function of time. In **death phase**, the number of cells that die in a given time period is proportional to the number that existed at the beginning of the time period. Determining microbial death rates is critical to the study of food preservation and to antibiotic development (further discussed in Chapters 5, 16, and 27). Although death curves are basically logarithmic, exact death rates are difficult to define because mutations arise that promote survival, and some cells grow by cannibalizing others. Consequently, the death phase is extremely prolonged. A portion of the cells will often survive for months, years, or even decades.

In **Figure 4.20C**, we see an actual bacterial growth curve from a study of *T. thiooxidans*, an organism that oxidizes sulfur to sulfuric acid and grows below pH 1. Growth curves are shown for several different starting concentrations of bacteria. In each case, the bacteria grow exponentially for several days, until they have exhausted the sulfur in their growth medium. Their growth then slows until they enter stationary phase.

THOUGHT QUESTION 4.11 What can happen to the growth curve when a culture medium contains two carbon sources, one a preferred carbon source of growth-limiting concentration and a second, nonpreferred source? (See Section 10.3.)

THOUGHT QUESTION 4.12 How would you modify the equations describing microbial growth rate to describe the rate of death?

THOUGHT QUESTION 4.13 Why are cells in log phase larger than cells in stationary phase?



Courtesy of Global Medical Instrumentation, Inc.

Figure 4.21 Chemostats and continuous culture. A. The basic chemostat ensures logarithmic growth by constantly adding and removing equal amounts of culture media. **B.** Note that the human gastrointestinal tract is engineered much like a chemostat in that new nutrients are always arriving from the throat while equal amounts of bacterial culture exit in fecal waste. **C.** A modern chemostat.

Continuous Culture Maintains Constant Cell Mass during Exponential Growth

In the classic growth curve that develops in closed systems, the exponential phase spans only a few generations. In open systems, however, where fresh medium is continually added to a culture and an equal amount of culture is constantly siphoned off, bacterial populations can be maintained in exponential phase at a constant cell mass for extended periods of time. In this type of growth pattern, known as **continuous culture**, all cells in a population achieve a steady state, which permits detailed analysis of microbial physiology at different growth rates. The **chemostat** is a continuous culture system in which the diluting medium contains a limiting amount of an essential nutrient (**Fig. 4.21**). Increasing the flow rate increases the amount of nutrient available to the microbe. The more nutrient available, the faster a cell's mass will increase. Because cell division is triggered at a defined cell mass, it follows that the growth rate in a chemostat is directly related to the dilution rate, or flow rate (milliliters per hour divided by the vessel volume). The more nutrient a culture receives as a result of increasing flow rate, the faster those cells can replicate (that is, the shorter the generation time).

The complex relationships among dilution rate, cell mass, and generation time in a chemostat are illustrated in **Figure 4.22**. The curves in this figure represent a typical experimental result, which can vary with organism, limiting nutrient, temperature, and so on. Depending on the experimental conditions, the shapes of the curves may change, but the general relationships will remain similar. Note that at moderate dilution rates (defined differently for each species), an increased flow rate of medium through the system increases division rate (thus, generation time decreases as the cells divide faster). A constant cell mass, or density, is maintained over a range of flow rates because the amount of culture (and cells) removed from the vessel exactly compensates for the increased rate of cell division.

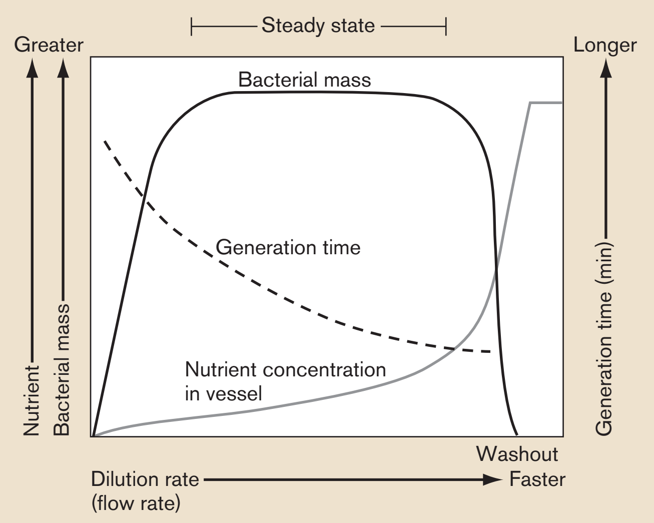


Figure 4.22 Relationships between dilution rate, cell mass, and generation time. As the dilution rate increases in a chemostat (meaning more nutrient is fed to the culture), the generation time decreases (the cells divide more quickly) and the cell mass of the culture increases. This continues until the rate of dilution exceeds the division rate, at which point cells are washed from the vessel faster than they can be replaced by division and the cell mass decreases. The *y*-axis varies, depending on the curve, as labeled in figure.

At faster and faster flow rates, cells are eventually removed more quickly than they can be replenished by division, so cell density (cell mass) *decreases* in the vessel. This is called washout. Notice, in contrast, that at very *low* dilution (flow) rates, an increase in rate will actually *increase* cell density. This is because at extremely low dilution rates, the nutrient is so limiting that cell mass cannot increase to the point necessary for division. If more nutrient becomes available, the system can maintain a higher cell mass and cell density because the cells are able to divide faster than they are removed. With slow flow rates, the removal of fluid is not a significant factor in determining cell density.

The **turbidostat** is essentially a chemostat in which a photoelectric cell constantly monitors the optical density (turbidity) of the culture. The flow of medium through the vessel is then regulated to maintain a constant turbidity and thus cell density. The turbidostat is most suited to high dilution rates, where the numbers of cells can change quickly and overwhelm a less responsive system; the chemostat, which must be adjusted manually, is better suited at low dilution rates.

Continuous cultures are used to study large numbers of cells at constant growth rate and cell mass for both research and industrial applications. Most bacteria in nature grow at very slow rates, a situation that can be mimicked in a chemostat. The physiology of these cells is quite different from what is typically observed using batch culture.

TO SUMMARIZE:

- **The growth cycle** of organisms grown in liquid batch culture consists of lag phase, log phase, stationary phase, and death phase.
- **The physiology of a bacterial population** changes with growth phase.
- **Continuous culture** can be used to sustain a population of bacteria at a specified growth rate and cell density.

4.6 Biofilms

Bacteria are typically thought of as unicellular; but in nature, many, if not most, bacteria form specialized, surface-attached communities called **biofilms**. Indeed, within aquatic environments, bacteria are found mainly associated with surfaces, a fact that underscores the importance of biofilms in nature. Biofilms also play critical roles in microbial pathogenesis and environmental quality, and cost the nation billions of dollars each year in equipment damage, product contamination, and medical infections. For example, pseudomonad or staphylococcal biofilms can damage ventilators used to assist respiration and can act as direct sources of infection.

Biofilms: A Multicellular Microbe?

Biofilms can be constructed by a single species or by multiple, collaborating species and can form on a range of organic or inorganic surfaces (**Fig. 4.23**). The gram-negative bacterium *Pseudomonas aeruginosa*, for example, can form a single-species biofilm on the lungs of patients with cystic fibrosis or on medical implants (**Special Topic 4.1**). Distinct stages in biofilm development include initiation, maturation, maintenance, and dissolution. Bacterial biofilms form when nutrients are plentiful. The goal is to stay where food is plentiful. Why should a microbe travel off to hunt for food when it is already available? Once nutrients become scarce, however, individuals detach from the community to forage for new sources of nutrient.

Biofilms in nature can take many different forms and serve different functions for different species. In addition, formation of biofilms can be cued by different environmental signals in different species. Such signals include pH, iron concentration, temperature, oxygen availability, and the presence of certain amino acids.

The biofilm that forms on teeth is called plaque.

Special Topic 4.1 Biofilms, Disease, and Antibiotic Resistance

When causing diseases of plants, animals, or humans, bacteria preferentially exist in surface-attached biofilms. Attachment to host tissues and multicellular growth are important in many situations, from simple wound infections caused by *Staphylococcus aureus* to colonization of the lungs of cystic fibrosis patients by *Pseudomonas aeruginosa.* One characteristic of bacterial biofilms is a marked increase in antibiotic tolerance. The failure to cure infections that stem from bacterial-pathogen biofilm formation is well documented, but the basis of persistence remains unclear. The literature offers different explanations for increased tolerance of antibiotics by microcolonies, including reduced penetration of drug into the microcolony and an altered stress-resistant physiology by the cells in the interior of the colony.

A study of *P. aeruginosa* biofilms clearly demonstrated the importance of multicellular cooperativity of cells within the biofilm. It appears that quorum sensing induces the drug-tolerant state. Cells in the biofilm release a chemical signal molecule called an acyl homoserine lactone (AHL). The population of cells respond to these molecules by increasing resistance to certain antimicrobial agents. As shown in **Figure 1**, cells within a typical biofilm are resistant to the antibiotic tobramycin. The fluorescent stain used in this experiment will stain live cells green and dead cells red. However, simultaneous treatment of *P. aeruginosa* biofilms with a specific quorum-sensing blocker *and* the antibiotic tobramycin led to the effective killing of the cells by the antibiotic. The quorum-sensing blocker, a novel, synthetically produced brominated furanone, did not reduce the viability of the *P. aeruginosa* cells. This result is consistent with the furanone specifically interfering with the AHL quorum-sensing system as seen by a microarray analysis. Hence, the shutdown of the AHL quorum-sensing system in the biofilm cells made them sensitive to the antibiotic.

B. 10 μg/ml furanone; 100 μg/ml tobramycin

Hentzer, et al. 2003. European Molecular Biology Organization

Hentzer, et al. 2003. European Molecular Biology Organization

Figure 1 Resistance of *Pseudomonas aeruginosa* biofilms to the antibiotic tobramycin is mediated by cell-cell signaling. Tobramycin sensitivity was tested in the presence and absence of the furanone compound C-30, which specifically inhibits cell-cell signaling. *P. aeruginosa* biofilms were grown in the absence (left panel) and presence (right panel) of 10 mM C-30. After three days, the biofilms were exposed to 100 μg/ml tobramycin for 24 hours. Bacterial viability was assayed by staining using the LIVE/DEAD BacLight BacterialViability Kit. Red areas are dead bacteria and green areas are live bacteria. Views are top and cross-sectional. Panels show top and side views of the biofilms.

Nevertheless, a common pattern emerges in the formation of many kinds of biofilms (**Fig. 4.24**).

First, the specific environmental signal induces a genetic program in planktonic cells. The planktonic cells then start to attach to nearby inanimate surfaces by means of flagella, pili, lipopolysaccharides, or other cell surface appendages, and begin to coat that surface with an organic monolayer of polysaccharides or glycoproteins to which more planktonic cells can attach. At this point, cells may move along surfaces using a **twitching motility** that involves the extension and retraction of a specific type of pilus. Ultimately, they stop moving and

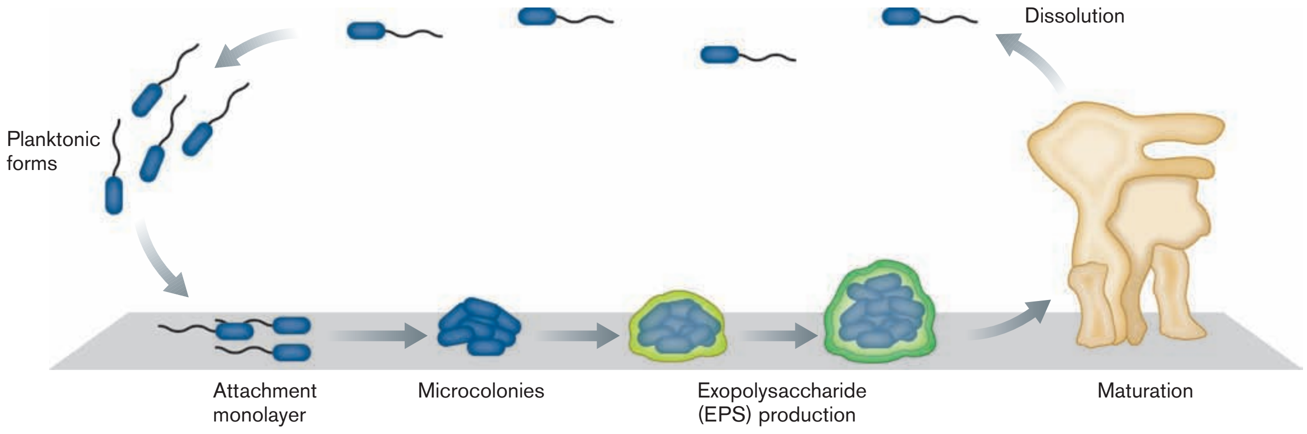

Figure 4.24 **Biofilm development.** Biofilm development in *Pseudomonas.*

firmly attach to the surface. As more and more cells bind to the surface, they can begin to communicate with each other by sending and receiving chemical signals in a process called **quorum sensing**. These chemical signal molecules are continually made by individual cells. Once the population reaches a certain number (analogous to an organizational "quorum"), the chemical signal reaches a specific concentration that the cells can sense. This triggers genetically regulated changes that cause cells to bind tenaciously to the substrate and to each other.

Next, the cells form a thick extracellular matrix of polysaccharide polymers and entrapped organic and inorganic materials. These **exopolysaccharides (EPSs)**, such as alginate produced by *P. aeruginosa* and colanic acid produced by *E. coli*, increase the antibiotic resistance of residents within the biofilm. As the biofilm matures, the amalgam of adherent bacteria and matrix takes on complex three-dimensional forms such as columns and streamers, creating channels through which nutrients flow. Sessile cells in a biofilm chemically "talk" to each other in order to build microcolonies and keep water channels open. Little is known about how a biofilm dissolves, although the process is thought to be triggered by starvation. *P. aeruginosa* produces an alginate lyase that can strip away the EPSs, but the regulatory pathways involved in releasing cells from biofilms are not clear.

It is important to keep in mind that most biofilms in nature are consortia of several species. Multispecies biofilms certainly demand interspecies communication, and individual species may perform specialized tasks in the community.

Organisms adapted to life in extreme environments also form biofilms. Members of Archaea form biofilms in acid mine drainage (pH 0), where they contribute to the recycling of sulfur, and cyanobacterial biofilms are common in thermal springs. Suspended particles called "marine snow" are found in ocean environments and appear to be floating biofilms comprising many organisms that have not yet been identified. The particles appear capable of methanogenesis, nitrogen fixation, and sulfide production, indicating that biofilm architecture can allow anaerobic metabolism to occur in an otherwise aerobic environment.

WWW | Biofilms

TO SUMMARIZE:

- **Biofilms** are complex multicellular surface-attached microbial communities.
- **Chemical signals** enable bacteria to communicate (quorum sensing) and in some cases to form biofilms.
- **Biofilm development** involves adherence of cells to a substrate, formation of microcolonies, and, ultimately, formation of complex channeled communities that generate new planktonic cells.

4.7 Cell Differentiation

Many bacteria faced with environmental stress undergo complex molecular reprogramming that includes changes in cell structure. Some species, like *E. coli*, experience relatively simple changes in cell structure, such as the formation of smaller cells or thicker cell surfaces. However, select species undergo elaborate cell differentiation processes. An example is *Caulobacter crescentus*, whose cells convert from the swimming form to the holdfast form before cell division. Each cell cycle then produces one sessile cell attached to its substrate by a holdfast, while its sister cell swims off in search of another habitat.

Other species undergo far more elaborate transformations. The endospore formers generate heat-resistant capsules (spores) that can remain in suspended animation for thousands of years. Yet another group, the actinomycetes, form complex multicellular structures analogous to those of eukaryotes. In this case, cell structure can change radically; and individual, freewheeling members of a species can relinquish their independence and band together, forming multicellular "organisms." The actinomycete that produces streptomycin is one example. These differentiation programs illustrate the distinction between the presence of genes in a bacterial genome and their activation. Genes for differentiation are expressed only when the cell needs to survive stress. We will discuss gene activation in more detail in Chapter 10.

Eukaryotic microbes also undergo highly complex life cycles. For example, *Dictyostelium discoideum* is a seemingly unremarkable ameba that grows as separate, independent cells. However, when challenged by adverse conditions such as starvation, the microbe secretes chemical signal molecules that choreograph a massive interaction of individuals to form complex multicellular structures. The developmental cycle of this organism may be compared to other eukaryotic microbes that are human parasites (discussed in Chapter 20).

Endospores Are Bacteria in Suspended Animation

Certain gram-positive genera, including important pathogens such as *Clostridium tetani* (tetanus), *Clostridium botulinum* (botulism), and *Bacillus anthracis* (anthrax) have the remarkable ability to develop dormant spores that are heat- and desiccation-resistant. Dessication and heat resistance are properties that make *B. anthracis* spores a potential bioweapon.

Most of our knowledge of bacterial sporulation comes from the gram-positive soil bacterium *B. subtilis*. When growing in rich media, this microbe undergoes normal vegetative growth and can replicate every 30–60 minutes. However, starvation initiates an elaborate 8-hour genetic program that directs an asymmetrical cell division process and ultimately yields a spore (see Section 10.4).

As shown in **Figure 4.25**, sporulation can be divided into discrete stages primarily based on morphological

appearance. Stage 0 (not shown) represents the point at which the vegetative cell decides to use one of two potential polar division sites to begin septum formation instead of the central division site used for vegetative growth. Stage I involves replicating and stretching the DNA into a long axial filament that spans the length of the cell. Ultimately, one of the polar division sites wins out, and in stage II, septation occurs, dividing the cell into two unequal compartments, the **forespore**, which will ultimately become the spore, and the larger **mother cell**, from which it is derived. Each compartment contains a chromosome.

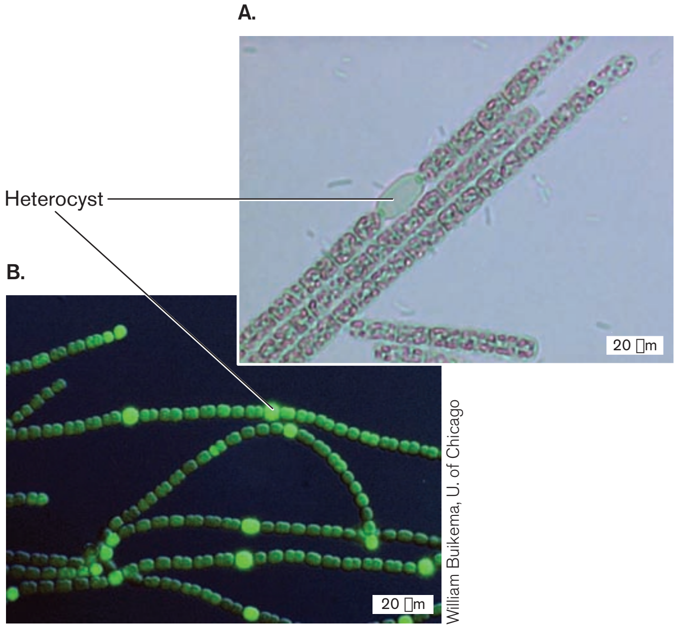
In stage III of sporulation, the mother cell membrane engulfs the forespore. Next, the mother cell chromosome is destroyed and a thick peptidoglycan layer (cortex) is placed between the two membranes surrounding the forespore protoplast (stage IV). Layers of coat proteins are then deposited on the outer membrane in stage V. Stage VI completes development of spore resistance to heat and chemical insults. This last process includes the synthesis of dipicolinic acid and the uptake of calcium into the core of the spore. Finally, the mother cell, now called a sporangium, releases the mature spore (stage VII).

Spores are resistant to many environmental stresses that would kill vegetative cells. The nature of this resistance is due, in part, to desiccation of the spore (they have only 10–30% of a vegetative cell's water content). But, as discovered by Peter Setlow and colleagues, spores are also packed with small acid-soluble proteins (SASPs) that bind to and protect DNA. The SASP coat protects the spore's DNA from damage by ultraviolet light and various toxic chemicals.

A fully mature spore can exist in soil for at least 50–100 years and spores have been known to last thousands of years. Once proper nutrient conditions arise, another genetic program, called **germination**, is triggered to wake the dormant cell, dissolve the spore coat, and release a viable vegetative cell.

Cyanobacteria Differentiate into Nitrogen-Fixing Heterocysts

Some of the autotrophic cyanobacteria, such as *Anabaena*, not only make oxygen through photosynthesis but "fix" atmospheric nitrogen to make ammonia. This is surprising because nitrogenase, the enzyme required to fix nitrogen, is very sensitive to oxygen, so one might expect that photosynthesis and nitrogen fixation would be two mutually exclusive physiological activities. *Anabaena* have solved this dilemma by developing specialized cells, called heterocysts, that function in nitrogen fixation (**Fig. 4.26**). A tightly regulated genetic program converts every tenth photosynthetic cell to a heterocyst, which loses the capacity to fix CO_2 and forms a specialized envelope to limit O_2 access. How this organism produces such a precise spacing of heterocysts is currently the subject of intensive research.



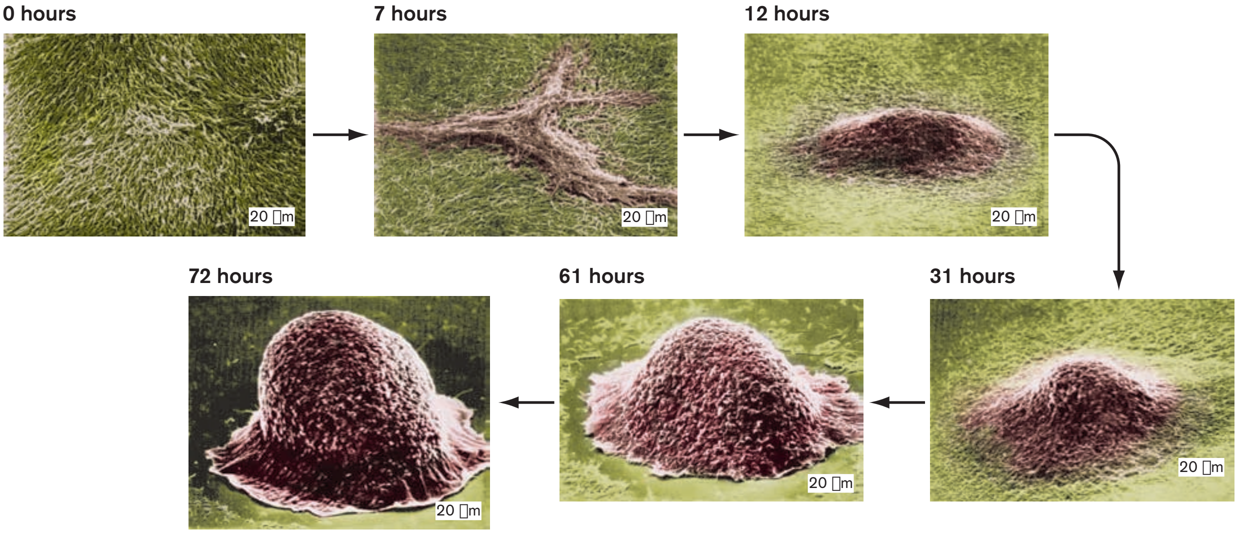
Biodidac

William Buikema, U. of Chicago

Figure 4.26 Cyanobacteria and heterocyst formation. **A.** Light microscope image of cyanobacteria *Phanizomenon.* **B.** The cyanobacterial genus *Anabaena*. The expression of genes in heterocysts is different from their expression in other cells. All cells in the figure contain a cyanobacter gene to which the gene for green fluorescent protein (GFP) has been spliced. Only cells that have formed heterocysts are expressing the fused gene, which makes the cell fluoresce bright green.

Starvation Induces Differentiation into Fruiting Bodies

Certain species of bacteria, in the microbial equivalent of barn raising, produce architectural marvels called fruiting bodies. The gram-negative species *Myxococcus xanthus* uses a **gliding motility** (involving a type of pilus, not a flagellum) to travel on surfaces as individuals or to move together as a mob (**Fig. 4.27**). Starvation triggers a developmental cycle in which 100,000 or more individuals aggregate, rising into a mound called a fruiting body. At this point, the system resembles a stage in *P. aeruginosa* biofilm formation. However, myxococci within the interior of the fruiting body differentiate into thick-walled, spherical spores that are released into the surroundings. The changes involved in this differentiation process require many cell-cell interactions and a complex genetic program that we do not fully understand.



J. M. Kuner and D. Kaiser

Figure 4.27 ***Myxococcus* swarm erecting a fruiting body.** Approximately 100,000 cells begin to aggregate, and over the course of 72 hours they erect a fruiting body.

Some Bacteria Differentiate to Form Eukaryotic-like Structures

The actinomycetes (see Chapter 19) such as *Streptomyces* are bacteria that form mycelia and sporangia analogous to the filamentous structures of eukaryotic fungi (**Fig. 4.28**). Several developmental programs tied to nutrient availability are at work in this process (**Fig. 4.29**). Under favorable nutrient conditions, a germ tube emerges from a germinating spore, grows from its tip (tip extension), and forms branches that grow along the surface of its food source. This type of growth produces an intertwined network of long multinucleate filaments (hyphae) collectively called substrate **mycelia**. After a few days, new genes are activated that cause the hyphae to grow upward, rising above the surface to form aerial mycelia. Compartments at the tips of these aerial hyphae contain 20–30 copies of the genome. Aerial hyphae stop growing as nutrients decline, triggering a developmental program that synthesizes antibiotics and produces spores (arthrospores) that are fundamentally different from endospores. This program lays down multiple septa that subdivide the compartment into single-genome prespores. The shape of the prespore then changes, its cell wall thickens, and deposits

are made in the spore that increase resistance to desiccation. These organisms are of tremendous interest, both for their ability to make antibiotics and for their fascinating developmental programs.

TO SUMMARIZE:

- **Microbial development** involves complex changes in cell forms.
- **Endospore development** in *Bacillus* and *Clostridium* involves production of dormant, stress-resistant endospores.
- **Heterocyst development** enables cyanobacteria to fix nitrogen anaerobically while maintaining oxygenic photosynthesis.
- **Multicellular fruiting bodies** in *Myxococcus* and *Dictyostelium* and **mycelia** in actinomycetes develop in response to starvation, dispersing dormant cells to new environments.

THOUGHT QUESTION 4.14 How might *Streptomyces* and *Actinomyces* species avoid committing suicide when they make their antibiotics?

Concluding Thoughts

All systems of microbial development share a common theme. They are all triggered in response to a change in their environment, such as depletion of resources, desiccation, or changes in temperature. Microbial responses to the environment have major implications for the function of ecosystems and for the microbial communities that inhabit the human body for good or ill. In Chapter 5, we survey the mechanisms of some of the major environmental responses of microbes.

CHAPTER REVIEW

Review Questions

1. What nutrients do microbes need to grow?
2. Explain the differences between autotrophy, heterotrophy, phototrophy, and chemotrophy.
3. Explain the basics of the carbon and nitrogen cycles.
4. Describe the various mechanisms of transporting nutrients in prokaryotes and eukaryotes. What are facilitated diffusion, coupled transport, ABC transporters, group translocation, and endocytosis?
5. Why is it important to grow bacteria in pure culture?
6. Under what circumstances would you use a selective medium? A differential medium?
7. What are the factors that define the growth phases of bacteria grown in batch culture?
8. Describe the important features of biofilms.
9. Name three kinds of bacteria that undergo differentiation, and give highlights of the differentiation processes.

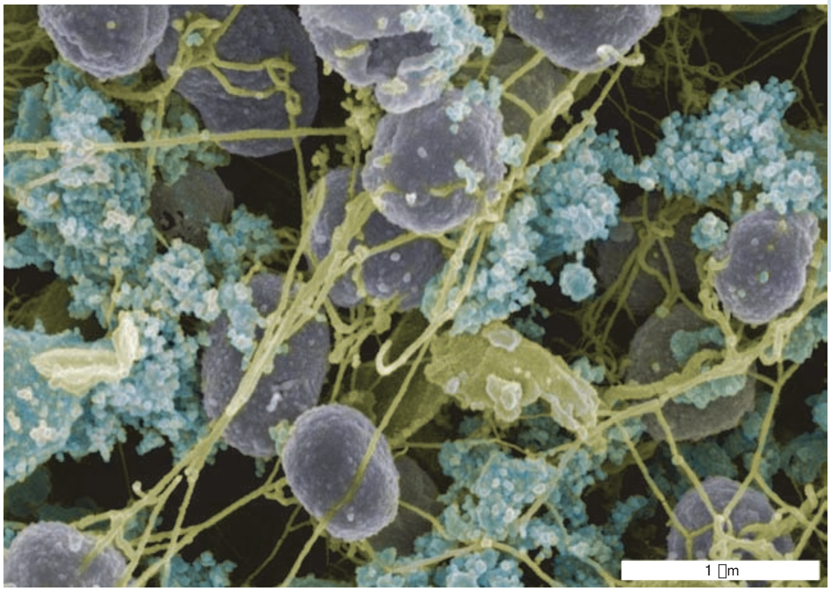
Chapter 5

Environmental Influences and Control of Microbial Growth

5.1 Environmental Limits on Microbial Growth
5.2 Microbial Responses to Changes in Temperature
5.3 Microbial Adaptation to Variations in Pressure
5.4 Microbial Responses to Changes in Water Activity and Salt Concentration
5.5 Microbial Responses to Changes in pH
5.6 Microbial Responses to Oxygen and Other Electron Acceptors
5.7 Microbial Responses to Nutrient Deprivation and Starvation
5.8 Physical and Chemical Methods of Controlling Microbial Growth
5.9 Biological Control of Microbes

Microbes have both the fastest and the slowest growth rates of any known organism. Some hot-springs bacteria can double in as little as 10 minutes, whereas deep-sea sediment microbes may take as long as 100 years. And while the rapid growth of pathogens underlies the rapid spread of disease, Earth's crust is shaped by microbes that grow very slowly in soil and rock. What determines these differences in growth rate? Nutrition is one factor, but niche-specific physical parameters like temperature, pH, and osmolarity are equally important.

A microbe's physiology is geared to work only within a narrow range of physical parameters. But in nature, the environment can quickly change. Many marine microbes, for instance, can move from deep-sea cold to the searing heat of a thermal vent. How do these organisms survive? Stop-gap measures called stress survival responses help, but a more permanent solution is when a species slowly evolves to thrive, not just survive, in extreme environments. How does the biology of these so-called extremophiles permit growth under conditions that seem uninhabitable? In this chapter, we explore the limits of microbial growth and show how this knowledge has helped us control the microbial world.



The extremophile *Halorubrum lacusprofundi*, an Antarctic haloarchaeon that forms biofilms at subzero temperatures in 5 M NaCl. Extremophiles are considered model systems for astrobiology.
Source: Shiladitya DasSarma. 2006. *Microbe* 1:120.

In 1998, apple and pear growers in Washington and northern Oregon lost crops worth an estimated $68 million owing to outbreaks of fire blight, a devastating bacterial disease; the causative agent, *Erwinia amylovora*, destroys apple and pear trees, making them appear as if they were torched by fire. As with human disease, we try to control microbial plant infections by controlling the growth of microbes. It should not be surprising, then, that antibiotics are often utilized for this purpose. But while many antibiotics are used to protect humans, only two are currently approved for use on plants: streptomycin and oxytetracycline. The fact that resistance to streptomycin has already been demonstrated in *Erwinia amylovora* underscores the importance of studying all aspects of bacterial growth in the effort to control pathogens of plants, animals, and humans.

We begin this chapter by discussing how physical and chemical changes in the environment modify the growth of different groups of microbes. We will also explore how microorganisms adapt to different environments in ways both transient (involving temporary expression of inactive genes) and permanent (modifications of the gene pool). The permanent genetic changes have led to biological diversity. Finally, we will examine the different ways humans try to limit the growth of microorganisms to protect plants, animals, and ourselves.

As you proceed through this chapter, you will encounter two recurring themes: that different groups of microbes live in vastly different environments and that microbes can respond in diverse ways when confronted by conditions outside their niche, or comfort zone.

5.1 Environmental Limits on Microbial Growth

With our human frame of reference, we tend to think that "normal" growth conditions are those found at sea level with a temperature between 20°C and 40°C, a near-neutral pH, a salt concentration of 0.9%, and ample nutrients. Any ecological niche outside this window is called *extreme* and the organisms inhabiting them **extremophiles** (R. MacElroy first used the term *extremophile* in 1974). Extremophiles are prokaryotes (bacteria and archaea) that are able to grow in extreme environments. For example, one group of organisms can grow at temperatures above boiling, while another group requires a pH 2 acidic environment to grow. Based on our definition of *normal* conditions, conditions on Earth when life began were certainly extreme. Consequently, the earliest microbes likely grew in these extreme environments. Organisms that grow under conditions that seem "normal" to humans likely evolved from an ancient extremophile that gradually adapted as the environment evolved to that of our present-day Earth.

Be aware that multiple extremes in the environment can be encountered simultaneously. For instance, in Yellowstone National Park, one can find an extreme acid pool next to an extreme alkali pool, both at extremely high temperatures. Thus, extremophiles typically evolve to survive multiple extreme environments.

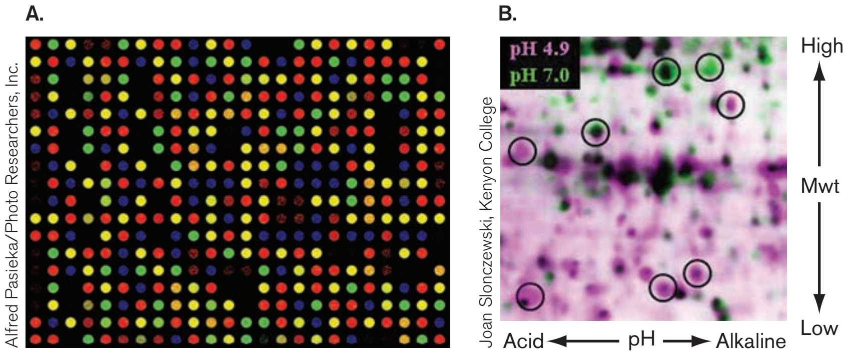
Extremophiles may provide insight into the workings of extraterrestrial microbes we may one day encounter, since outer space certainly qualifies as an extreme environment. Our experiences with extremophiles should alert us to the dangers of underestimating the precautions necessary in handling extraterrestrial samples. For example, we should not assume that irradiation would be sufficient to sterilize samples from future planetary or interstellar missions. Such treatments do not even kill the extremophile *Deinococcus radiodurans* found on Earth.

WWW | Pyrodictium

How do we even begin to study organisms that grow in boiling water or sulfuric acid solutions or organisms that we cannot even culture in the laboratory? How do we dissect the molecular response of organisms to changes in an environment such as acid rain or to changes in the human body? Genome sequences present new opportunities for investigating these questions.

Bioinformatic analysis allows us to study the biology of organisms that we cannot culture. First, genome sequences from novel organisms are amplified by polymerase chain reaction, or PCR (a technique that multiplies a small sample of DNA; see Section 7.6). PCR amplification can be done directly from the natural environment in which the organisms are found, and the sequences are compared with those of model systems, such as *E. coli*, whose biochemistry is well known. Genomic comparison quickly reveals whether an organism under study may possess specific metabolic pathways and regulatory responses.

Global arrays of DNA and proteins allow us to study the response of an organism to changing environments. Global approaches can reveal in a single experiment the response of all an organism's genes to a single environmental change, such as change in temperature or pH (**Fig. 5.1**). **DNA microarrays** (see Section 10.8) consist of slides with a grid containing DNA probes for every gene in an organism's genome. They are used to assess which genes are expressed to make RNA in a given organism at a given time or under a given condition. **Two-dimensional protein gels** (see Section 3.5) achieve two-dimensional separation of proteins based on differences in each protein's isoelectric point (first dimension) and molecular weight (second dimension). They show which proteins the cell produces when cultured in different environments. Knowing what genes and proteins are expressed in a given situation helps elucidate the molecular strategies that microbes use to grow under different conditions and to defend themselves against environmental stresses.



Alfred Pasieka/Photo Researchers, Inc.

Joan Slonczewski, Kenyon College

Figure 5.1 **Response to environmental stress: global analysis of genes and proteins.** **A.** This microarray contains DNA probes (small pieces of DNA sequence) representing each gene in the genome. The DNA probes hybridize to preparations of fluorescent-labeled cDNA (complementary DNA) made from whole-cell RNA of cultures grown under different conditions. Each colored disk represents one gene. Red fluorescence indicates RNA expressed under one condition; green indicates expression under the second condition; yellow indicates expression under both conditions. **B.** Two-dimensional gels separate the proteins expressed in the cell. Proteins are separated in one dimension by their charge (isoelectric pH point) and in the second dimension by their molecular weights. Gel images are obtained from cultures grown under two different conditions (in this case, *Escherichia coli* K-12 grown at pH 4.9 versus pH 7.0). Pink spots denote proteins expressed only at pH 4.9; green indicates expression only at pH 7.0. Circled spots were chosen for additional studies.

These techniques of molecular analysis are discussed further in Chapters 8 and 10.

We have already mentioned the fundamental physical conditions (temperature, pH, osmolarity) that define an environment and select for (favor) the growth of specific groups of organisms. And within a given microbial community, each species is further localized to a specific niche defined by a narrower range of environmental factors. The reason for this is that every protein and macromolecular structure within a cell is affected profoundly by changes in environmental conditions and through reaction with the by-products of oxygen consumption. For example, a single enzyme works best under a unique set of temperature, pH, and salt conditions because those conditions allow it to fold into its optimum shape, or conformation. Deviations from these optimal conditions cause the protein to fold a little differently and become less active. While all enzymes within a cell do not boast the same physical optima, these optima must at least be similar and matched to the organism's environment for the organism to function effectively.

As may be apparent from the preceding discussion, there are many different classes of microbes based on their environmental niche. **Table 5.1** summarizes these environmental classes.

Table 5.1 **Basic environmental classification of microorganisms.**

Environmental parameter	Classification			
Temperature	Hyperthermophile* (growth above 80°C)	Thermophile* (growth between 50°C and 80°C)	Mesophile (growth between 15°C and 45°C)	Psychrophile* (growth below 15°C)
pH	Alkaliphile* (growth above pH 9)	Neutralophile (growth between pH 5–8)	Acidophile* (growth below pH 3)	
Osmolarity	Halophile* (growth in high salt > 2M NaCl)			
Oxygen	Aerobe (growth only in oxygen)	Facultative (growth with or without oxygen)	Microaerophile (growth only in small amounts of oxygen)	Anaerobe (growth only without oxygen)
Pressure	Barophile* (growth at high pressure, greater than 380 atm)		Barotolerant (grown between 10–495 atm)	

*considered extremophiles

TO SUMMARIZE:

- **Extremophiles** inhabit fringe environmental conditions that do not support human life.
- **The environmental niche** (such as high salt or acidic pH) inhabited by a particular species is defined by the tolerance of that organism's proteins and other macromolecular structures to the physical conditions within that niche.

5.2 Microbial Responses to Changes in Temperature

Unlike humans (and mammals in general), microbes cannot control their temperature; thus, bacterial cell temperature matches that of the immediate environment. Because temperature affects the average rate of molecular motion, changes in temperature impact every aspect of microbial physiology, including membrane fluidity, nutrient transport, DNA stability, RNA stability, and enzyme structure and function. Every organism has an *optimum* temperature at which it grows most quickly, as well as minimum and maximum temperatures that define the limits of growth. These limits are imposed, in part, by the thousands of proteins in a cell, all of which must function within the same temperature range. The fastest growth rate for a species occurs at temperatures where all of the cell's proteins work most efficiently as a group to produce energy and synthesize cell components. Growth stops when rising temperatures cause critical enzymes or cell structures (such as the cell membrane) to fail. At cold temperatures, growth ceases because enzymatic processes become too sluggish and the cell membrane less fluid. The membrane needs to remain fluid so that it can expand as cells grow larger and so that proteins needed for solute transport can be inserted into the membrane.

Maximum Growth Rate Increases with Temperature

In general, microbes that grow at higher temperatures can achieve higher rates of growth. Remarkably, the relationship between the maximum growth temperature and the growth rate constant k (number of generations per hour; see Section 4.5) obeys the Arrhenius equation for simple chemical reactions:

$$\log k = C/T \qquad (5.1)$$

T is the absolute temperature in degrees Kelvin, and C is a second constant that combines the gas constant and the average activation energy of cellular reactions. Over a defined temperature range, which differs for each species, growth rate increases (that is, cells divide faster) as temperature increases. If we plot the logarithm of the growth rate versus temperature, we get a straight line whose slope (C) can be obtained by substituting in equation 5.1:

$$\log (k_2/k_1) = C/(T_1 - T_2)$$

The general result of the Arrhenius equation is that growth rate roughly doubles for every 10°C rise in temperature (**Fig. 5.2**). This is the same relationship observed for any chemical reaction.

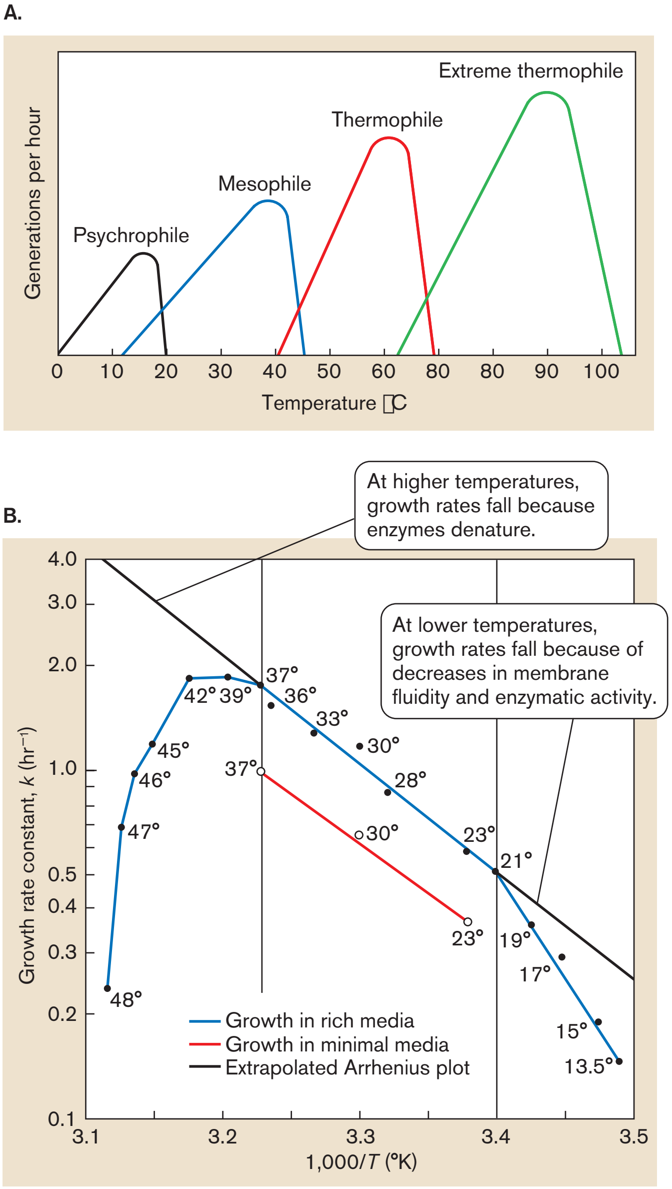


Figure 5.2 Relationship between temperature and growth rate. A. Relationship between temperature and growth rates of different groups of microbes. Note that the growth rate increases linearly with temperature and obeys the Arrhenius equation. **B.** Growth rate constant (k) of the enteric organism *Escherichia coli* is plotted against the inverse of growth temperature on the Kelvin scale (1,000/T is used to give a convenient scale on the x-axis). This is a more detailed view of a mesophilic growth temperature curve. As temperature rises above or falls below the optimum range, growth rate decreases faster than predicted by the Arrhenius equation.

Source: B. Sherrie L. Herendeen, et al. 1979. *Journal of Bacteriology* 139:185.

At the upper and lower limits of the growth range, however, the Arrhenius effect breaks down. At high temperatures, critical proteins denature. Lower temperatures decrease membrane fluidity and limit the conformational mobility of enzymes, thereby lowering their activities. As a result, growth fails to occur. The typical growth temperature range spans about 30–40°C, but some organisms have a much narrower range. Within a species, we can identify mutants that are more sensitive to one extreme or the other (heat sensitive or cold sensitive). These mutations often define key molecular components of stress responses, such as the heat-shock proteins (discussed in Chapter 10).

Thermodynamic principles limit a cell's growth to a narrow temperature range. For example, heat increases molecular movement within proteins. Too much or too little movement will interfere with enzymatic reactions. As a result, there is a great biological diversity among microbes as different groups have evolved to grow within very different thermal niches. A species grows within a specific thermal range because its proteins have evolved to tolerate that range. Outside that range, proteins will denature or function too slowly for growth. The upper limit for protists is around 50°C, while some fungi can grow at temperatures as high as 60°C. Prokaryotes, however, have been found to grow at temperatures ranging from below 0°C to above 100°C. Temperatures over 100°C are usually found around thermal vents deep in the ocean, where water temperature can rise to 350°C but the pressure is sufficient to keep water liquid.

THOUGHT QUESTION 5.1 Why haven't cells evolved so that all their enzymes have the same temperature optimum? If they did, wouldn't they grow even faster?

Microorganisms Are Classified by Growth Temperature

Based on their ranges of growth temperature, microorganisms can be classified as mesophiles, psychrophiles, or thermophiles (**Fig. 5.2A**).

Mesophiles include the typical "lab rat" microbes, such as *Escherichia coli* and *Bacillus subtilis.* Their growth optima range between 20°C and 40°C, with a minimum of 15°C and a maximum of 45°C. Because they are easy to grow and because human pathogens are mesophiles, much of what we know about protein, membrane, and DNA structure came from studying this group of organisms. Current advances, particularly in obtaining detailed three-dimensional (3-D) views of protein structures, are frequently based on studies of two other classes of organisms whose optimum growth temperature ranges flank that of the mesophiles, namely **psychrophiles** (on the low temperature side) and **thermophiles** (on the high temperature side; **Fig. 5.3**). Because of their more stable folding structures, proteins from the thermophilic extremophiles are generally easier to crystallize than those of mesophiles or psychrophiles, so it is possible to determine their structures by X-ray crystallography (see Section 2.7).

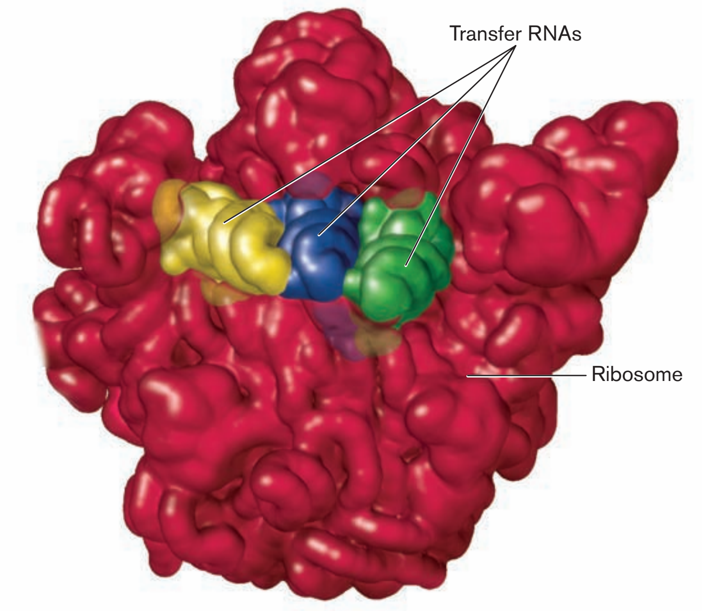

Figure 5.3 Thermophilic proteins. Special properties of thermophilic proteins facilitate 3-D structure analysis, as shown here. The structure of the *Thermus thermophilus* 70S ribosome is shown here at 7.8 Å (or 0.78 nm) resolution. Transfer RNAs (green, blue, and yellow) occupy a cavity between two ribosomal subunits. (PDB codes: 1GIX, 1GIY)

Psychrophiles are microbes that grow at temperatures as low as 0°C, but their optimum growth temperature is usually around 15°C. Psychrophiles are prominent flora beneath icebergs in the Arctic and Antarctic (**Fig. 5.4**). In addition to true psychrophiles, whose growth optima are below 20°C, there are mesophiles that are cold resistant. For instance, the modern practice of refrigeration has selected for cold-resistant, yet mesophilic, pathogens such as *Listeria monocytogenes* (one cause of food poisoning and septic abortions). Why do these organisms grow so well in the cold? One reason psychrophilic microbes prefer cold is that their proteins are more flexible than those of mesophiles and require less energy (heat) to function. Of course, the downside to the increased flexibility of psychrophilic proteins is that they denature at lower temperatures than their mesophilic counterparts. As a result, psychrophiles grow poorly, if at all, when temperatures rise above 20°C. Another reason psychrophiles favor cold is that their membranes are more fluid at low temperature owing to the high proportion of

unsaturated fatty acids present; at higher temperatures, their membranes are *too* flexible and fail to maintain cell integrity.

Psychrophilic enzymes are of commercial interest because their ability to carry out reactions at low temperature has potential utility in food processing and bioremediation. Many food products require enzymatic processing. Enzymes help brew beer more quickly, break down lactose in milk, and can remove cholesterol from various foods. Production of foods at lower temperatures would be beneficial, since lower processing temperatures would minimize the growth of typical mesophiles that degrade and spoil food. Another goal is to find organisms that can safely degrade toxic organic contaminants (for example, petroleum) in the cold. Arctic environments are particularly sensitive to pollution because contaminants are slow to degrade in the freezing temperatures. Consequently, the ability to seed Arctic oil spills with psychrophilic organisms armed with petroleum-degrading enzymes could rapidly restore contaminated environments.

Thermophiles (**Fig. 5.5**) are species adapted to growth at high temperature, typically 55°C and higher. **Hyperthermophiles** grow at temperatures as high as

Cell length varies from 3 to 10 μm. **C.** Thermophile *Methanocaldococcus jannaschii* grown at 78°C and 30 psi. **D.** A "smoker," a hydrothermal vent 2 miles deep in the Pacific Ocean. *M. jannaschii* was isolated in 1983 in the area of this vent.

110°C, which occur under extreme pressure (for example, at the ocean floor). These organisms flourish in hot environments such as composts or near thermal vents that penetrate Earth's crust on the ocean floor and on land (for example, hot springs). The thermophile *Thermus aquaticus* was the first source of a DNA polymerase used for PCR amplification of DNA. *T. aquaticus* was discovered in a hot spring at Yellowstone National Park by microbiologist Thomas Brock, a pioneer in the study of thermophilic organisms. Its application to the polymerase chain reaction has revolutionized molecular biology (discussed in Chapter 7).

Extreme thermophiles often have specially adapted membranes and protein sequences. The thermal limits of these structures determine the specific high-temperature ranges in which various species can grow. Because enzymes in thermophiles (thermozymes) do not unfold as easily as mesophilic enzymes, they more easily hold their shape at higher temperatures. Thermophilic enzymes are stable, in part, because they contain relatively low amounts of glycine, a small amino acid that contributes to an enzyme's flexibility. In addition, the amino-termini of proteins in these organisms often are "tied down" by hydrogen bonding to other parts of the protein, making them harder to denature.

Like all microbes, thermophiles have chaperone proteins that help refold other proteins as they undergo thermal denaturation. Thermophile genomes are packed with numerous DNA-binding proteins that stabilize DNA. In addition, these organisms possess special enzymes that function to tightly coil DNA in a way that makes it more thermostable and less likely to denature (think of a coiled phone cord that has twisted and bunched up on itself). Special membranes also help give cells additional stability at high temperatures. Unlike the typical lipid bilayers of mesophiles, the membranes of thermophiles manage to "glue" together parts of the two hydrocarbon layers that point toward each other, making them more stable. They do this by incorporating more saturated linear lipids into their membranes. Saturated lipids form straight hydrocarbon tails that align well with neighboring lipids and form a highly organized structure stable to heat. The membranes of mesophiles are composed mostly of unsaturated lipids that bend against each other and align poorly. This property makes the membranes of mesophiles more fluid at lower temperatures.

High Temperatures Induce the Heat Shock Response

As insurance against extinction, most microorganisms possess elegant genetic programs that remodel their physiology to one that can temporarily survive inhospitable conditions. Rapid temperature changes experienced during growth activate batches of stress response genes, resulting in the **heat shock response** (discussed in Chapter 10). The protein products of these heat-activated genes include chaperones that maintain protein shape and enzymes that change membrane lipid composition. The heat-shock response, first identified in *E. coli* by Yamamori and Yura in 1982, has since been documented in all living organisms examined thus far.

THOUGHT QUESTION 5.2 If microbes lack a nervous system, how can they sense a temperature change?

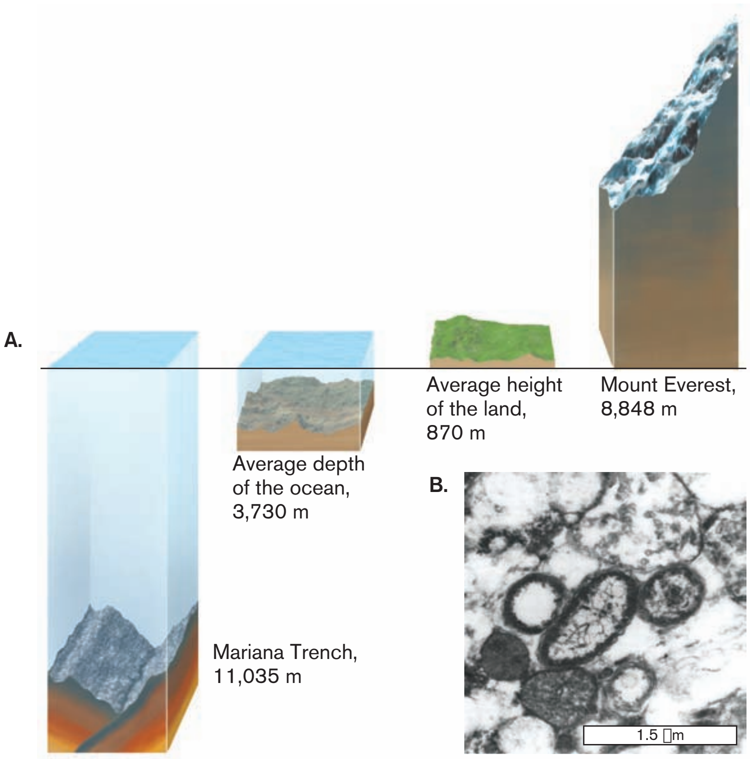
The appearance of different branches of life in the course of evolution reflects, in some ways, the narrowing of tolerance to heat. Different archaeal species, for example, can grow in extremely hot or extremely cold temperatures and some can grow in the middle range. Bacteria, for the most part, tolerate a temperature range that bridges the archaeal extremes. Eukaryotes are less temperature tolerant than bacteria, with individual species capable of growth between 10°C and 65°C. Archaeal species have been found to grow at greater extremes than bacterial species, and bacteria at greater extremes than eukaryotes. As we will see, this evolutionary relationship holds for other environmental conditions.

TO SUMMARIZE:

- **Different species** exhibit different optimal growth values of temperature, pH, and osmolarity.
- **The Arrhenius equation** applies to growth of microorganisms: Growth rate doubles for every 10°C rise in temperature.
- **Membrane fluidity** varies with the composition of lipids in a membrane, which in turn dictates at what temperature an organism can grow.
- **Mesophiles, psychrophiles, and thermophiles** are groups of organisms that grow at moderate, low, and high temperatures, respectively.
- **The heat shock response** produces a series of protective proteins in organisms exposed to temperatures near the upper edge of their growth range.

5.3 Microbial Adaptation to Variations in Pressure

Living creatures at Earth's surface (sea level) are subjected to a pressure of 1 atmosphere (atm), which is equal to 0.101 megapascal (Mpa) or 14 pounds per square inch (psi). At the bottom of the ocean, however, thousands of meters deep, hydrostatic pressure averages a crushing 400 atm and can go as high as 1,000 atm (101 Mpa, or 14,000 psi) in ocean trenches (**Fig. 5.6**). Organisms adapted to



A.
Average height of the land, 870 m
Mount Everest, 8,848 m
Average depth of the ocean, 3,730 m
Mariana Trench, 11,035 m
B.
1.5 μm

J. W. Deming & R. Colwell, *Applied Environmental Microbiology*, 44.

Figure 5.6 Barophilic environments and barophiles. A. Ocean depths. The deepest part of the ocean is at the bottom of the Mariana Trench, a depression in the floor of the western Pacific Ocean, just east of the Mariana Islands. The Mariana Trench is 1,554 miles long and 44 miles wide. Near its southwestern extremity, 210 miles southwest of Guam, lies the deepest point on Earth. This point, referred to as the "Challenger Deep," plunges to a depth of nearly 7 miles. **B.** Barophile *Shewanella violacea*. Length is approx. 1.5 μm.

grow at overwhelmingly high pressures are called **barophiles** or **piezophiles**. From the curves in **Figure 5.7**, we can see that barophiles actually *require* elevated pressure to grow, while barotolerant organisms grow well over the range of 1–50 Mpa, but their growth falls off thereafter.

Many barophiles are also psychrophilic because the average temperature at the ocean's floor is 2°C. However, barophilic hyperthermophiles form the basis of thermal vent communities that support symbiotic worms and giant clams (see Chapter 21).

How bacteria can survive pressures of 12,000 psi is still a mystery. It is known that increased hydrostatic pressure and cold temperatures similarly reduce membrane fluidity. Because fluidity of the cell membrane is critical to survival, the phospholipids of deep-sea bacteria commonly have high levels of polyunsaturated fatty acids to increase membrane fluidity. It is thought that in addition to these membrane changes, internal structures must also be pressure adapted. For example, ribosomes in the barosensitive organism *E. coli* dissociate at pressures above 60 Mpa, so barophiles must contain uniquely designed ribosome structures that can withstand pressures even higher than that.

Specific applications for barotolerant proteins and pressure-regulated genes have not yet been developed. However, many food processes are carried out at high pressure to minimize bacterial contamination (destructive bacteria will not tolerate the pressure), so it is expected that barophiles will ultimately offer useful biotechnology products, such as enzymes that will carry out food processing at high pressure. High-pressure processing has been used on cheeses, yogurt, luncheon meats, and oysters to kill contaminating bacteria without destroying the flavor or texture of the food.

TO SUMMARIZE:

- **Barophiles** can grow at pressures up to 1,000 atm but fail to grow at low pressures.
- **Membrane fluidity** can be compromised at high pressures and cold temperatures. Specially designed membranes and protein structures are thought to enable the growth of barophiles.

THOUGHT QUESTION 5.3 What could be a relatively simple way to grow barophiles in the laboratory?

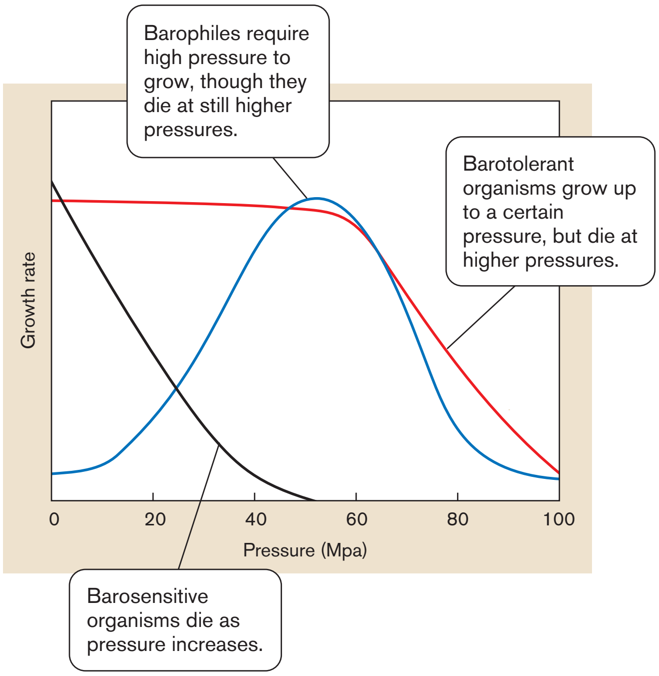


Figure 5.7 Relationship between growth rate and pressure.

5.4 Microbial Responses to Changes in Water Activity and Salt Concentration

Water is critical to life, but environments differ in terms of how much water is actually available to growing organisms; microbes can only use water that is not bound to ions or other solutes in solution. Water availability is measured as **water activity** (a_w), a quantity approximated by concentration. Because interactions with solutes lower water activity, the more solutes there are in a solution, the less water is available for microbes to use for growth. Water activity is typically measured as the ratio of the solution's vapor pressure relative to that of pure water. A solution is placed in a sealed chamber and the amount of water vapor determined at equilibrium. If the air above the sample is 97% saturated relative to the moisture present over pure water, the relative humidity is 97% and the water activity is 0.97. Most bacteria require water activity to be greater than 0.91 for growth (the water activity of seawater). Fungi can tolerate water activity levels as low as 0.86.

Osmotic Stress

Osmolarity is a measure of the number of solute molecules in a solution and is inversely related to a_w. The more particles there are in a solution, the greater the osmolarity and the lower the water activity (see Appendix 1). Osmolarity is important for the cell because it is related to water activity and also because a semipermeable membrane surrounds microbial cells, so osmolarity inside the cell can be, and often is, different from the osmolarity outside. The principles of physical chemistry dictate that solute concentrations in two chambers separated by a semipermeable membrane will tend to equilibrate. Equilibrating osmolarity across a semipermeable cell membrane, which does not allow the movement of solutes, requires the movement of water. In hypertonic medium, where the external osmolarity is higher than the internal, water will try to *leave* the cell in an attempt to equalize osmolarity across the membrane. In contrast, suspension of a cell in a hypotonic medium (one of lower osmolarity than the cell) will cause an *influx* of water (see Fig. A2.6). This movement of water across cell membranes does not occur primarily by simple diffusion. Special membrane water channels formed by proteins called aquaporins enable water to traverse the membrane much faster than by diffusion and help protect cells against osmotic stress (**Fig. 5.8**). However, too much water moving in or out of a cell is detrimental. Cells may ultimately explode or implode, depending on the direction in which the water moves. Even bacteria with a rigid cell wall suffer. They may not explode like a human cell, but the forces placed on the cell wall are great.

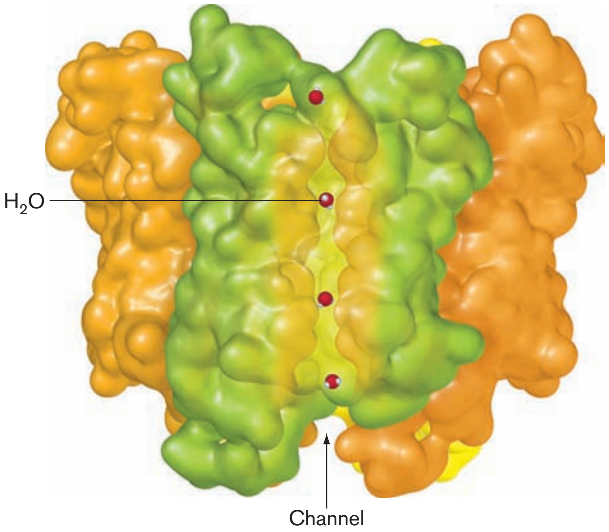

Figure 5.8 **Aquaporin.** Transverse view of the channel. Complementary halves of the channel are formed by adjacent protein monomers. The curvilinear, size-selective (~4 × 0.5 nm) core of the channel (~18 nm) is primarily lined by hydrophobic residues. (PDB code: 1J4N)

Cells Minimize Osmotic Stress across Membranes

In addition to moving water, microbes have at least two other mechanisms to minimize osmotic stress across membranes. When stranded in a hypertonic medium (higher osmolarity than the cell), bacteria try to protect their internal water by synthesizing or importing compatible solutes that increase intracellular osmolarity. Compatible solutes are small molecules that do not disrupt normal cell metabolism, even when present at high intracellular concentrations. Increasing intracellular levels of these compounds (for example, proline, glutamic acid, potassium, or betaine) elevates cytoplasmic osmolarity without any detrimental effects, making it unnecessary for water to leave the cell.

Cells also contain pressure-sensitive (mechanosensitive) channels that can be used to leak solutes out of the cell. It is believed that these channels are activated by rising internal pressures in cells immersed in a *hypo*tonic medium. When activated, the channels allow solutes to escape, which lowers internal osmolarity.

Outside their osmotic comfort range—that is, where the aforementioned housekeeping strategies become ineffective at controlling internal osmolarity—microbes launch a global response in which cellular physiology is transformed to tolerate brief encounters with potentially lethal salt concentrations. Some changes are similar to those provoked by heat shock, such as the increased synthesis of chaperones that protect critical cell proteins from denaturation. Other changes include alterations in outer membrane pore composition (for gram-negative organisms).

Halophiles Require High Salt Concentration

Some species of archaea have evolved to require high salt (NaCl) concentration. These are called **halophiles** (**Fig. 5.9**). In striking contrast to most bacteria, which prefer salt concentrations from 0.1 to 1 M (0.2–5% NaCl), the extremely halophilic archaea can grow at an a_w of 0.75 and actually require 2–4 M NaCl (10–20% NaCl) to grow. For comparison, seawater is about 3.5% NaCl. All cells, even halophiles, prefer to keep a relatively low intracellular Na^+ concentration. One reason for this is that some solutes are moved into the cell by symport with Na^+. To achieve a low internal Na^+ concentration, halophilic microbes use special ion pumps to excrete sodium and replace it with other cations, such as potassium, which is a compatible solute. In fact, the proteins and cell components (for example, ribosomes) of halophiles require remarkably high intracellular potassium levels to maintain their structure.

Halophilic algae use a different strategy for dealing with hypertonic media. They redirect photosynthesis to make glycerol (a compatible solute) instead of starch. Increasing glycerol production raises internal osmolarity, which stops water from leaving the cell and prevents dehydration. Although halophilic bacteria appear to have lost ecological flexibility by adapting to such an extreme environment, they have gained access to environments that other organisms are not equipped to use.

THOUGHT QUESTION 5.4 How might the concept of water availability be used by the food industry to control spoilage?

TO SUMMARIZE:

- **Water activity** (a_w) is a measure of how much water in a solution is available for a microbe to use.
- **Osmolarity** is a measure of the number of solute molecules in a solution and is inversely related to a_w.
- **Aquaporins** are membrane channel proteins that allow water to move quickly across membranes to equalize internal and external pressures.
- **Compatible solutes** are used to minimize pressure differences across the cell membrane.
- **Mechanosensitive channels** can leak solutes out of the cell when internal pressure rises.
- **Halophilic organisms** grow best at high salt concentration.

5.5 Microbial Responses to Changes in pH

As with salt and temperature, the concentration of hydrogen ions (H^+)—actually, hydronium (H_3O^+)—also has a direct effect on the cell's macromolecular structures. Extreme concentrations of either hydronium or hydroxyl ions (OH^-) in a solution will limit growth. In other words, too much acid or base is harmful to cells. Despite this sensitivity to pH extremes, living cells tolerate a greater range in environmental concentration of H^+ than of virtually any other chemical substance. *E. coli*, for example, tolerates a pH range of 2–9, a 10,000,000-fold difference. For a brief review of pH, refer to Section A1.7.

Enzymes Show pH Optima, Minima, and Maxima

The charges on various amino or carboxyl groups within a protein help forge the intramolecular bonds that dictate protein shape and thus protein activity. Because H^+ concentration affects the protonation of these ionizable groups, altering pH can alter the charges on these groups, which in turn changes protein structure and activity. The result is that all enzyme activities exhibit optima, minima, and maxima with regard to pH, much as they do for temperature. As we saw with temperature, groups of microbes have evolved to inhabit diverse niches, for which pH values can range from pH 0 to pH 11.5 (**Fig. 5.10**). However, species differences in optimum growth pH are *not* dictated by the pH limits at which critical cell proteins function.

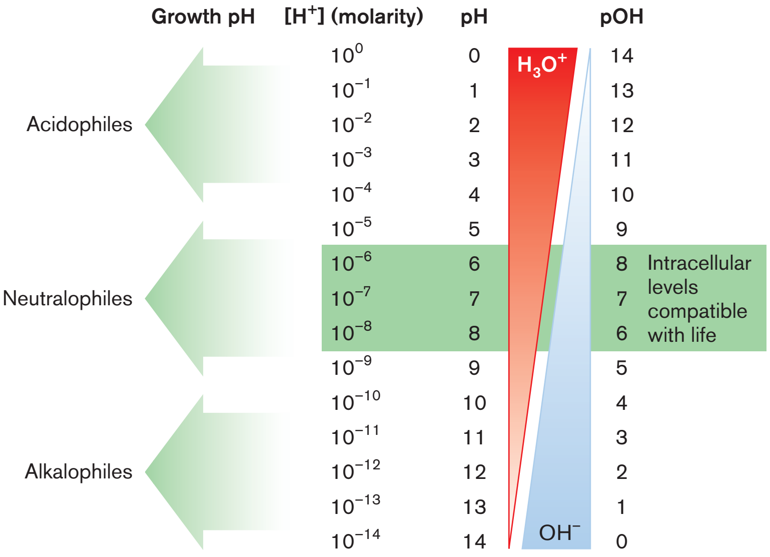

Figure 5.10 Classification of organisms grouped by optimal growth pH.

Generally speaking, the majority of enzymes, regardless of the pH at which their source organism thrives, tend to operate best between pH 5 and 8.5 (which, if you think about it, is still a range in which the hydrogen ion concentration varies more than 1,000-fold), yet many microbes grow in even more acidic or alkaline environments.

Unlike its temperature, the intracellular pH of a microbe, as well as its osmolarity, is not necessarily the same as that of its environment. Biological membranes are relatively impermeable to protons, a fact that allows the cell to maintain an internal pH compatible with protein function when growing in extremely acidic or alkaline environments. When the difference between the intracellular and extracellular pH (□pH) is very high, protons can leak through either directly or via proteins that thread the membrane. Excessive influx or efflux of protons can cause problems by altering internal pH.

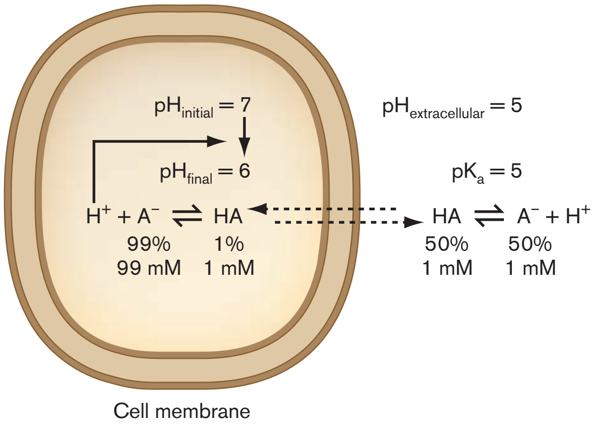

Figure 5.11 Effect of organic acids on internal pH. In this contrived example, the organic acid (HA) has an extracellular concentration of 2 mM and has a dissociation constant of pH 5. Because the medium is also pH 5, half of the acid is protonated (undissociated, or un-ionized) and half is dissociated (ionized). The un-ionized form, because it is uncharged, diffuses across the membrane to establish equilibrium between the inside and outside of the cell. However, because the inside of the cell is pH 7 (2 units above the external pH), 99% of the acid will dissociate. This lowers the internal HA concentration, so more HA enters the cell in search of equilibrium. Because neither the ionized form of the acid nor the released proton can diffuse out of the cell, both accumulate. At equilibrium, the concentrations of HA inside and outside the cell are equal, but for every HA that enters the cell, ionization of HA has yielded 99 A^- molecules and an equal number of protons, which lower the internal pH to an extent that depends on the buffering capacity of cellular proteins.

Membrane-permeant organic acids, also called weak acids (discussed in Chapter 3), can accelerate the leakage of H^+. Unlike H^+, the uncharged form of an organic acid (HA) can freely permeate cell membranes and dissociate intracellularly, releasing a proton that then acidifies internal pH (**Fig. 5.11**). The extent of the pH drop depends on the buffering capacity of the cell's proteins. This shuttling of protons can turn a relatively mild external pH level (say, pH 6) into a deadly acid stress. A naturally occurring example of organic acid stress is the lactic acid produced by lactobacilli during the formation of yogurt. The buildup of lactic acid limits the bacterial growth, leaving yogurt with plenty of food value. The food industry has taken advantage of this phenomenon by preemptively adding citric acid or sorbic acid to certain foods. This allows manufacturers to control microbial growth under pH conditions that do not destroy the

flavor or quality of the food. **Figure 5.12** illustrates the pH values of various everyday items. Food microbiology is further discussed in Chapter 16.

Neutralophiles, Acidophiles, and Alkaliphiles Grow in Different pH Ranges

Cells have evolved to live under different pH conditions not by drastically changing the pH optima of their enzymes but by using novel pH homeostasis strategies that maintain intracellular pH above pH 5 and below pH 8, even when the cell is immersed in pH environments well above or below that range.

There are three classes of organisms marked by the pH of their growth range.

Neutralophiles generally grow between pH 5 and pH 8, and include most human pathogens. Many neutralophiles, including *E. coli* and *Salmonella enterica*, adjust their metabolism to maintain an internal pH slightly above neutrality, which is where their enzymes work best. They maintain this pH even in the presence of moderately acidic or basic external environments (**Fig. 5.13**). Others allow their internal pH to fluctuate with external pH but usually maintain a pH difference (ΔpH) of about 0.5 pH units across the membrane at the upper and lower limits of growth pH. The ΔpH value is an important component of the transmembrane proton potential, a source of energy for the cell (see Chapter 13).

NOTE: The older term *neutrophile* used for this group of organisms is also similar to the descriptor for a specific type of white blood cell (*neutrophil*). To avoid confusion, the term *neutrophil* should be reserved for the white blood cell and the term *neutralophile* used to designate microbes with growth optima near neutral pH.

Acidophiles are bacteria and archaea that live in acidic environments. They are often chemoautotrophs (lithotrophs) that oxidize reduced metals and generate strong acids such as sulfuric acid. Consequently, they grow between pH 0 and pH 5. The ability to grow at this pH is due partly to altered membrane lipid profiles (high levels of tetraether lipids) that decrease proton permeability as well as to ill-defined proton extrusion mecha-

nisms. Often, an organism that is an extremophile with respect to one environmental factor is an extremophile with respect to others. *Sulfolobus acidocaldarius*, for example, is a thermophile and an acidophile (**Fig. 5.14**). It uses sulfur as an energy source and grows in acidic hot springs rich in sulfur.

Alkaliphiles occupy the opposite end of the pH spectrum, growing best at values ranging from pH 9 to pH 11. They are commonly found in saline soda lakes, which have high salt concentrations and pH values (as high as pH 11). Soda lakes, like Lake Magadi in Africa (**Fig. 5.15A**), are steeped in carbonates, which explains their extraordinarily alkaline pH. An alkaliphilic organism first identified in Lake Magadi is *Halobacter salinarum* (also known as a *Natronobacterium gregoryi*), a halophilic archaeon (**Fig. 5.15B**).

The cyanobacterium *Spirulina* is another alkaliphile that grows in soda lakes. Its high concentration of carotene gives the organism a distinctive pink color (note the color of the lake in **Fig. 5.15A**). *Spirulina* is also a major food for the famous pink flamingos indigenous to these African lakes and is, in fact, the reason pink flamingos are pink. After the birds ingest these organisms, digestive

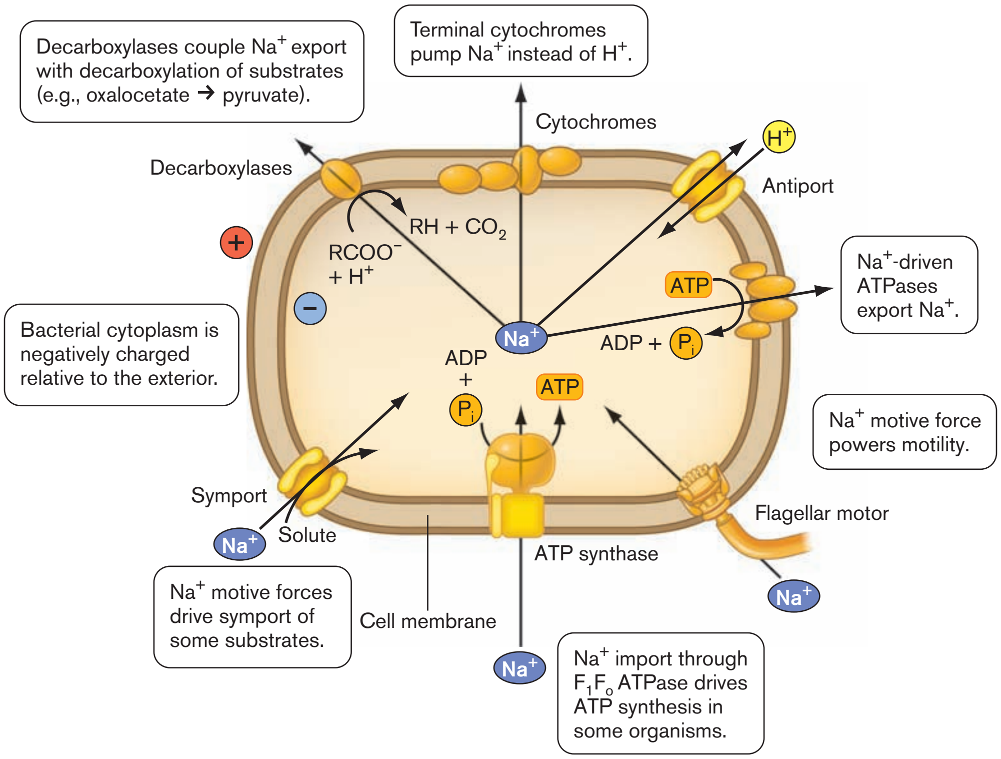
processes release the carotene pigment to the circulation, which then deposits it in the birds' feathers, turning them pink (**Fig. 5.15C**).

NOTE: Humans also consume *Spirulina* as a health food supplement, but do not turn pink because the cyanobacteria are only a small component of the diet.

The internal enzymes of alkaliphiles, like those of acidophiles, exhibit rather ordinary pH optima (around pH 8). The key to the survival of alkaliphiles is the cell surface barrier that sequesters fragile cytoplasmic enzymes away from harsh extracellular pH. Key structural features of the cell wall, such as the presence of acidic polymers and an excess of hexosamines in the peptidoglycan, appear to be essential. The reason for this is not clear. At the membrane, some alkaliphiles also possess a high level of diether lipids, which are more stable than ester-linked phospholipids, that prevent protons from leaking out of the cell (see Section 3.4).

Because external protons are in such short supply at alkaline pH, most alkaliphiles use a sodium motive force in addition to a proton motive force to do much of the work of the cell (see Section 14.3). They also rely heavily on Na^+/H^+ antiporters (see Section 4.2) to bring protons into the cell, and this keeps the internal pH well below the extremely alkaline external pH. This is partly why many alkaliphiles are resistant to high salt (NaCl) concentrations; sodium ions are expelled while protons are sucked in. Important aspects of sodium circulation in alkaliphiles are depicted in **Figure 5.16**.

In contrast to proteins *within* the cytoplasm, enzymes *secreted* from alkaliphiles are able to work in very alkaline environments. The inclusion of base-resistant enzymes like lipases and cellulases in laundry detergents helps get our "whites whiter and our brights brighter." Other commercially useful alkaliphilic enzymes produce cyclodextrins from starch. The cyclodextrins are complex cyclic carbohydrates whose structure resembles a hollow truncated cone with a hydrophobic (water-hating) core and hydrophilic (water-loving) exterior (**Fig. 5.17**). It is a superb vehicle for drug delivery. For example, cyclodextrins have been used in eyedrops to deliver the antibiotic chloramphenicol. The hydrophobic cavity of cyclodextrin can harbor a poorly soluble drug, while the hydrophilic exterior increases its apparent water solubility. The drug goes into solution more easily, permitting smoother absorption into the body.



Decarboxylases couple Na^+ export with decarboxylation of substrates (e.g., oxalocetate → pyruvate).

Terminal cytochromes pump Na^+ instead of H^+.

Na^+-driven ATPases export Na^+.

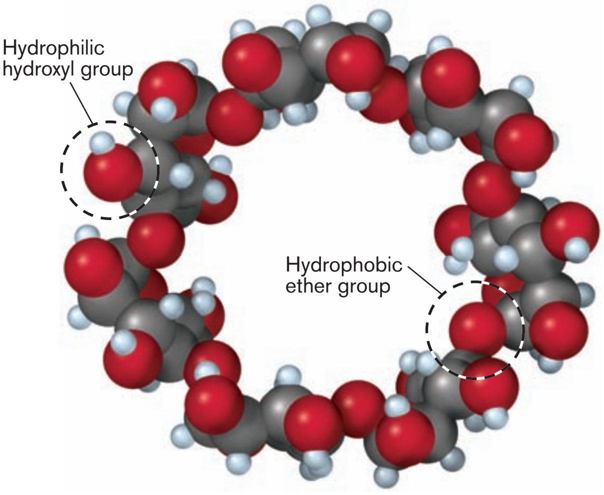
Bacterial cytoplasm is negatively charged relative to the exterior.

Na^+ motive force powers motility.

Na^+ motive forces drive symport of some substrates.

Na^+ import through F_1F_o ATPase drives ATP synthesis in some organisms.

Figure 5.16 **Na^+ circulation in alkaliphiles.** Cells of alkaliphiles are designed to use Na^+ in place of H^+ to do the work of the cell. They require an inwardly directed sodium gradient that can be used to rotate flagella, transport nutrient solutes, and generate energy. The Na^+/H^+ antiporter is used to keep internal pH lower than exterior pH. Sodium homeostasis inside the cell is maintained by the net effects of efflux and influx mechanisms.



Hydrophilic hydroxyl group
Hydrophobic ether group

Figure 5.17 A cyclodextrin. View down the channel in the hydrophobic core lined by C-O-C ether groups, which is surrounded by a hydrophilic exterior covered in -OH hydroxyl groups. The hydrophobic core can harbor drugs that are poorly soluble in water.

THOUGHT QUESTION 5.5 In Chapter 4, we stated that an antiporter couples movement of one ion down its concentration gradient with movement of another molecule uphill, against its gradient. If this is true, how could a Na$^+$/H$^+$ antiporter work to bring protons into a haloalkiliphile growing in high salt at pH 10? Since the Na$^+$ concentration is lower inside the cell than outside and H$^+$ concentration is higher inside than outside (see Fig. 5.16), both ions are moving against their gradients.

pH Homeostasis and Acid Tolerance Mechanisms Enable Cells to Live in Different pH Environments

When cells are placed in pH conditions below their optimum, protons can enter the cell and lower internal pH to lethal levels. Microbes can prevent the unwanted influx of protons by exchanging extracellular K$^+$ for intracellular protons when internal pH becomes too low. At the other extreme, under extremely alkaline conditions, the cells can use the Na$^+$/H$^+$ antiporters mentioned previously (and in Section 4.2) to recruit protons into the cell in exchange for expelling Na$^+$ (**Fig. 5.18**). Some organisms can also change the pH of the medium using various amino acid decarboxylases and deaminases. *Helicobacter pylori*, the causative agent of gastric ulcers, employs an exquisitely potent urease to generate massive amounts of ammonia, which neutralizes the acid pH environment. These acid stress and alkaline stress protection systems are usually not made or at least do not become active until the cell encounters an extreme pH.

Many, if not all, microbes also possess an emergency global response system referred to as acid tolerance or acid resistance. In a process analogous to the heat-shock response, bacterial physiology undergoes a major molecular reprogramming in response to hydrogen ion stress. The levels of a large number of proteins increase, while the levels of others decrease. Many of the genes and proteins involved in the acid stress response overlap with other stress response systems, including the heat-shock response. These physiological responses include modifications in membrane lipid composition, enhanced pH homeostasis,

Figure 5.18 Proton circulation and pH homeostasis. A typical *E. coli* cell uses various proton transport strategies to maintain an internal pH near pH 7.8 in the face of different external pH stresses. Proton pumping through cytochromes also establishes a proton gradient, which drives flagellar rotation and solute transport.

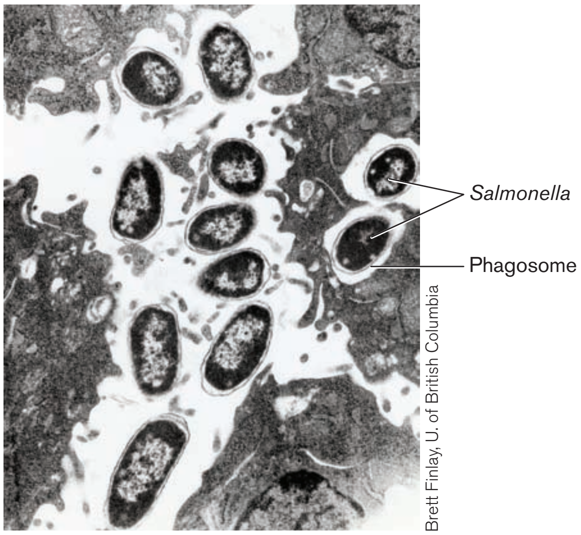
Special Topic 5.1 Signaling Virulence

One of the burning questions in the study of infectious disease is, “How does a microbe know when it has entered a suitable host?” Most, if not all, pathogens express certain genes only *after* infection, so they must sense that something in their environment has changed. A change in environment that causes increased virulence is called a virulence signal. One of these virulence signals is pH. On their way to causing disease, many pathogens travel through acidic host compartments. The most obvious are the stomach, which is extremely acidic (pH 1–3), and infected host cell phagosomes and phagolysosomes, which are mildly acidic (pH 4.5–6). *Salmonella enterica*, a major causative agent of diarrheal disease, provides an intriguing example of virulence that is triggered by low pH. After gaining entrance to the intestine via the mouth and subsequently penetrating intestinal epithelia, this pathogen tricks certain white blood cells, called macrophages, into engulfing the bacterium, placing it within a phagosome (**Fig. 1**). The microbe then waits for the phagosome (initially pH 6) to partially fuse with a lysosome and form a phagolysosome, after which the pH of the compartment drops to about pH 4.5. Numerous bacterial proteins are then expressed, many of which enable *Salmonella* to survive in the macrophage. Drugs that prevent phagolysosome acidification, however, render *Salmonella* extremely susceptible to the various antimicrobial weapons wielded by the macrophage. *Salmonella* “knows” it is in a macrophage phagolysosome in part because the pH drops. Recent studies have started to map the complex bacterial regulatory circuits involved in sensing acid pH signals and translating them into defensive actions by the pathogen.



Brett Finlay, U. of British Columbia

Figure 1 *Salmonella* **(1 µm in length) within human epithelial cell phagosomes.**

and numerous other changes with unclear purpose. Some pathogens, such as *Salmonella*, sense a change in external pH as part of the signal indicating the bacterium has entered a host cell environment (**Special Topic 5.1**).

TO SUMMARIZE:

- **Hydrogen ion concentration** affects protein structure and function. Thus, enzymes have pH optima, minima, and maxima.
- **Microbes use pH homeostasis mechanisms** to keep their internal pH near neutral when in acidic or alkaline media.
- **The addition of weak acids** to certain foods undermines bacterial pH homeostasis mechanisms, which prevents food spoilage and kills potential pathogens.
- **Neutralophiles, acidophiles, and alkaliphiles** prefer growth under neutral, low, and high pH conditions, respectively.
- **Acid and alkaline stress responses** occur when placing a given species under pH conditions that slow its growth. The cell increases the levels of proteins designed to mediate pH homeostasis and protect cell constituents.

5.6 Microbial Responses to Oxygen and Other Electron Acceptors

Many microorganisms can grow in the presence of molecular oxygen (O_2). Some even use oxygen as a terminal electron acceptor in the **electron transport chain**, a group of membrane proteins (cytochromes) that convert energy trapped in nutrients to a biologically useful form. The use of O_2 as the terminal electron acceptor is called **aerobic respiration** (see Chapter 14).

Oxygen Has Benefits and Risks

Electrons pulled from various energy sources (for example, glucose) possess intrinsic energy, an energy that cytochrome proteins can harness. They do this by extracting the energy in incremental stages and using it to move protons out of the cell. This unequal distribution of H^+ across the membrane produces a transmembrane electrochemical gradient, a sort of biobattery called proton motive force (discussed in Section 14.2). Once the cell has drained as much energy as possible from an electron,

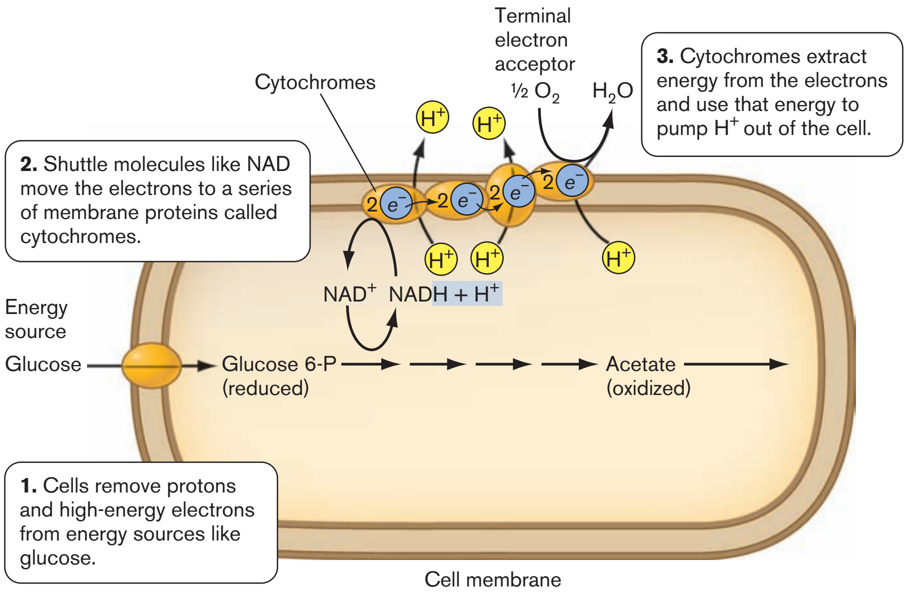


Figure 5.19 Role of oxygen as a terminal electron acceptor in respiration. This pumping of protons out of the cell by cytochromes produces more positive charges outside the cell than inside, creating an electrochemical gradient (also called proton motive force). An electron from a high-energy source is passed from one member of the chain to the next. With each transfer of an electron to the next member of the chain, more energy is extracted and converted to proton motive force. At the end of the chain, the electron must be passed to a final or terminal electron acceptor, clearing the path for the next electron. This net process is called respiration.

1. Cells remove protons and high-energy electrons from energy sources like glucose.

2. Shuttle molecules like NAD move the electrons to a series of membrane proteins called cytochromes.

3. Cytochromes extract energy from the electrons and use that energy to pump H^+ out of the cell.

that electron must be passed to a diffusible, final electron acceptor molecule floating in the medium. This clears the way for another electron to be passed down the cytochrome chain (**Fig. 5.19**).

One such terminal electron acceptor is dissolved oxygen. However, oxygen and its breakdown products are dangerously reactive, a serious problem for all cells. As a result, different species have evolved to either tolerate or avoid oxygen all together. **Table 5.2** gives examples of microbes that grow at different levels of oxygen.

Microbes Are Classified by Their Relationship with Oxygen

The relationships between microbes and oxygen are varied. **Figure 5.20** illustrates a test tube with growth medium. The top of the tube, closest to air, is oxygenated; the bottom of the tube has much lower levels of oxygen. Some microbes grow only at the top of the tube, while others prefer to grow at the bottom, the distributions based on each organism's relationship with oxygen. A

Figure 5.20 Oxygen-related growth zones in a standing test tube.

strict aerobe is an organism that not only exists in oxygen but also uses oxygen as a terminal electron acceptor. In fact, a strict aerobe can *only* grow with oxygen present and possesses an aerobic metabolism (aerobic respiration). An aerobe will grow at the top of the tube shown in Figure 5.20. In contrast, a **strict anaerobe** dies in the least bit of oxygen. Strict anaerobes do not use oxygen as an electron acceptor, but this is not why they die in air. They die because this type of microbe is vulnerable to reactive oxygen molecules (also called **reactive oxygen species**; ROS) produced by its own metabolism when it is exposed to oxygen. Anaerobes will grow at the bottom of the tube shown in Figure 5.20.

Do not confuse the ability of an organism to *exist* in the presence of oxygen with its ability to *use* oxygen as a terminal electron acceptor. Some aerobes can survive in oxygen but do not have the ability to use oxygen. Any organism that possesses NADH dehydrogenase II, aerobe or anaerobe, will, in the presence of oxygen, inadvertently autooxidize the FAD cofactor within the enzyme and produce dangerous amounts of superoxide radicals ($^{\bullet}O_2^-$; **Fig. 5.21**). Superoxide will degrade to hydrogen peroxide (H_2O_2), another reactive molecule. Iron, present as a cofactor in several enzymes, can then catalyze a reaction with hydrogen peroxide to produce the highly toxic hydroxyl radical ($^{\bullet}OH$). All of these molecules seriously damage DNA, RNA, proteins, and lipids. Consequently, oxygen is actually an extreme environment in which survival requires special talents. Aerobes, but not anaerobes, destroy reactive oxygen species with the aid of enzymes such as superoxide dismutase (to remove superoxide) and peroxidase and catalase (to remove hydrogen peroxide). Aerobes also have resourceful enzyme systems that detect and repair macromolecules damaged by oxidation.

Anaerobes Ferment and Respire without Oxygen

Anaerobic microbes fall into several categories. Some anaerobes actually do respire using cytochrome systems, but instead of using oxygen, they rely on alternative terminal electron acceptors like nitrate to conduct **anaerobic respiration** and produce energy. Anaerobes of another ilk do not possess cytochromes, cannot respire, and so must rely on carbohydrate **fermentation** for energy (that is, they conduct **fermentative metabolism**). Fermentation involves the production of ATP energy through substrate-level phosphorylation in a process that does not involve cytochromes. **Facultative** organisms are

FAD is a cofactor for a number of enzymes (for example, NADH dehydrogenase II). Catalase and peroxidase do not produce ROS but detoxify hydrogen peroxide.

microbes that can live with or without oxygen. They will grow throughout the tube shown in Figure 5.20. **Facultative anaerobes** (sometimes called aerotolerant) only use fermentation to provide energy but contain superoxide dismutase and catalase (or peroxidase) to protect them from reactive oxygen species. This allows them to grow in oxygen while retaining a fermentation-based metabolism. **Facultative aerobes** (such as *E. coli*) also possess enzymes that destroy toxic oxygen by-products, but have both fermentative *and* aerobic respiratory potential. Whether a member of this group uses aerobic respiration, anaerobic respiration, or fermentation depends on the availability of oxygen and the amount of carbohydrate present. Microorganisms that possess *decreased* levels of superoxide dismutase and/or catalase will be **microaerophilic**, meaning they will grow only at low oxygen concentrations.

The fundamental composition of all cells reflects their evolutionary origin as anaerobes. Lipids, nucleic acids, and amino acids are all highly reduced—which is why our bodies are combustible. We never would have evolved that way if molecular oxygen were present from the beginning. Even today, the majority of all microbes are anaerobic, growing buried in the soil, within our anaerobic digestive tract, or within biofilms on our teeth.

THOUGHT QUESTION 5.6 If anaerobes cannot live in oxygen, how do they incorporate oxygen into their cellular components?

THOUGHT QUESTION 5.7 How can anaerobes grow in the human mouth when there is so much oxygen there?

Culturing Anaerobes in the Laboratory

Many anaerobic bacteria cause horrific human diseases, such as tetanus, botulism, and gangrene. Some of these organisms or their secreted toxins are even potential weapons of terror (for example, *Clostridium botulinum*). Because of their ability to wreak havoc on humans, culturing these microorganisms was an early goal of microbiologists. Despite the difficulties involved, conditions were eventually contrived in which all, or at least most, of the oxygen could be removed from a culture environment.

Three techniques are used today. Special reducing agents (for example, thioglycolate) or enzyme systems (Oxyrase®) that eliminate dissolved oxygen can be added to ordinary liquid media. Anaerobes can then grow beneath the culture surface. A second, very popular, way to culture anaerobes, especially on agar plates, is to use an anaerobe jar (**Fig. 5.22A**). Agar plates streaked with the organism are placed into a sealed jar with a foil packet that releases H_2 and CO_2 gases. A palladium packet hanging from the jar lid catalyzes a reaction between the H_2 and O_2 in the jar to form H_2O and effectively removes O_2 from the chamber. The CO_2 released is required by some reactions to produce key metabolic intermediates. Some microaerophilic microbes, like the pathogens *H. pylori* (the major cause of stomach ulcers) and *Campylobacter jejuni* (a major cause of diarrhea), require low levels of O_2 but elevated amounts of CO_2. These conditions are obtained by using similar gas-generating packets.

For strict anaerobes exquisitely sensitive to oxygen, even more heroic efforts are required to establish an oxygen-free environment. A special anaerobic glove box must be used in which the atmosphere is removed by

vacuum and replaced with a precise mixture of N_2 and CO_2 gases (**Fig. 5.22B**).

THOUGHT QUESTION 5.8 What evidence led people to think about looking for anaerobes? *Hint*: Look up Spallanzani, Pasteur, and spontaneous generation on the Web.

TO SUMMARIZE:

- **Oxygen is a benefit** to organisms (aerobes) that can use it as a terminal electron acceptor to extract energy from nutrients.
- **Oxygen is toxic** to all cells (anaerobes) that do not have enzymes capable of efficiently destroying the reactive oxygen species.
- **Anaerobic metabolism** can either be **fermentative** or **respiratory**. Anaerobic respiration requires the organism to possess cytochromes that can use compounds other than oxygen as terminal electron acceptors.
- **Facultative anaerobes** grow either in the presence or in the absence of oxygen, but use fermentation as their primary, if not only, means of gathering energy. These microbes also have enzymes that destroy reactive oxygen species, allowing them to grow in oxygen.
- **Facultative aerobes**, like facultative anaerobes, grow with or without oxygen and have enzymes that destroy reactive oxygen species. In addition, they possess both the ability for fermentative metabolism and the ability to use oxygen as a terminal electron acceptor.

5.7 Microbial Responses to Nutrient Deprivation and Starvation

It is intuitively obvious that limiting the availability of a carbon source or other essential nutrient will limit growth. Not so obvious are the dramatic molecular events that cascade through a cell undergoing nutrient limitation and ultimately starvation. Optimizing growth rate at suboptimal nutrient levels is an important aim of free-living bacteria, given that intestinal, soil, and marine environments rarely offer nutrient excess.

Starvation Slows Cell Metabolism but Activates Key Survival Genes

Numerous gene systems are affected when nutrients decline (see Section 10.3 for details). Growth rate slows, and daughter cells become smaller and begin to experience what is termed a **"starvation" response**, where the microbe senses a dire situation developing but still strives to find new nourishment. The resulting metabolic slowdown generates increased concentrations of critically important small signal molecules such as cyclic AMP and guanosine tetraphosphate (ppGpp) that globally transform gene expression. During this metabolic retooling, transport systems for potential nutrients are produced even if the matching substrates are unavailable. Cells begin to make and store glycogen, presumably as an internal emergency store in case no other nutrient is found. Some organisms growing on nutrient-limited agar plates can even form colonies with intricate geometrical shapes that help the population cope, in some unknown way, with nutrient stress (**Fig. 5.23**). As a cultural environment progressively worsens, the organism must prepare for famine, and many different stress survival genes become active. The products of these genes afford protection against stressors such as reactive oxygen radicals or temperature and pH extremes. No cell can predict the precise stresses it might encounter while incapacitated, so it is advantageous to be prepared for as many as possible. As described in Chapter 4, some species undergo elaborate developmental processes that ultimately produce dormant spores.

The colony consists of branches with chiral twists (colored green), all with the same handedness. The added coloration indicates time of growth (yellow = oldest; red = most recent).

Some Organisms Only Grow in Nutrient-Poor Media

Most well-studied organisms thrive on organically rich media (more than 2 g of carbon per liter) but struggle to grow at very low nutrient concentration (1–5 mg of carbon per liter). In natural ecosystems, however, the majority of existing microbes appear to be **oligotrophs**, organisms with a high rate of growth at extremely low organic substrate concentrations. Oligotrophs are well suited for growth in the nutrient-poor, or oligotrophic, environments found in certain lakes and streams. Some oligotrophs are actually poisoned by concentrated organics or commit suicide in rich media by overproducing excess toxic hydrogen peroxide. Consequently, they *require* low nutrient levels to survive. In soil, for example, there exist a variety of uncharacterized oligotrophic bacteria that are very sensitive to NaCl and various L-amino acids. How do oligotrophs manage to grow in such impoverished conditions? Some oligotrophic bacteria have thin extensions of their membrane and cell wall called prothecae (stalks) that essentially *expand* the surface area of the cell and increase capacity to transport nutrients. How other oligotrophs grow remains a mystery.

Microbes Encounter Multiple Stresses in Real Life

In keeping with the reductionist approach to science, bacterial stress responses have traditionally been studied in terms of *individual* stresses. *Escherichia coli*, for example, increases synthesis of a specific set of proteins when exposed to high temperature and a different set of proteins when exposed to high salt. There are overlapping members of the two sets; that is, several proteins may be highly expressed under both conditions, but each stress response also includes proteins unique to each stress.

Environmental situations in the world outside of the laboratory, however, can be quite complex, involving multiple, not just single, stresses. An organism could simultaneously undergo carbon starvation in a high salt, low pH environment. A classic study by Kelly Abshire and Frederich Neidhardt examined this situation using the pathogen *Salmonella enterica*, a cause of diarrhea. *S. enterica* invades human macrophage cells and survives in phagocytic vacuoles, where numerous stresses, such as low pH, oxidative stress, and nutrient limitations, are simultaneously imposed on the bacteria. Comparing the proteins synthesized by *Salmonella* growing in this compartment with the proteins synthesized under single stresses in the laboratory revealed an unexpected response pattern. Although many stress-related proteins were induced in the intracellular environment, no one set of stress-induced proteins was induced in its entirety. Furthermore, several bacterial proteins were induced by growth *only* within the macrophage phagolysosome, suggesting the presence of unknown intracellular stresses. Thus caution is advised when trying to predict cell responses to real-world situations based solely on controlled laboratory studies that alter only single parameters.

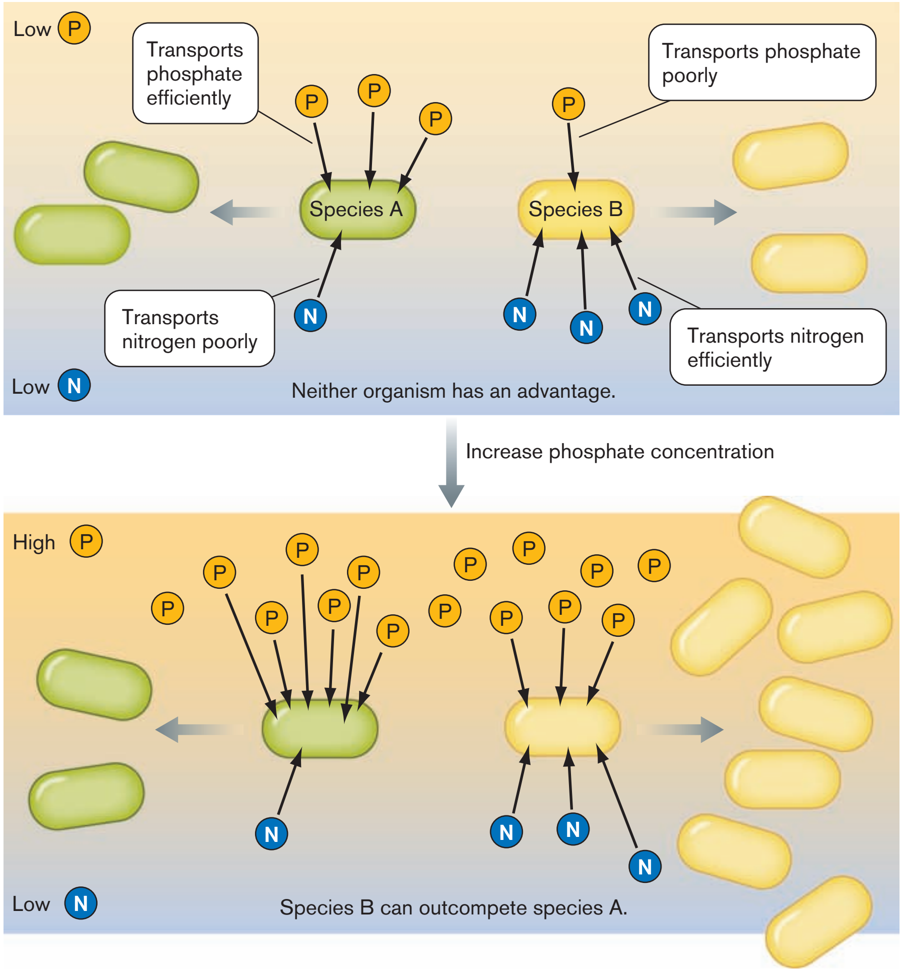
Humans Influence Microbial Ecosystems

Natural ecosystems are typically low in nutrients (oligotrophic) but teem with diversity, so that numerous species compete for the same limiting nutrients. Maximum diversity in a given ecosystem is maintained, in part, by the different nutrient-gathering profiles of competing microbes. Take a scenario in which microbe A is better than microbe B at gathering phosphate when phosphate levels are low, but microbe B is superior to A at culling limited quantities of nitrogen (**Fig. 5.24**). Neither organism dominates when both phosphate *and* nitrogen are in short supply. So even though B can harvest more nitrogen than A, it cannot outgrow A, since the phosphate concentration is low. However, if phosphate is suddenly increased so that it is no longer limiting for either organism, the one better adapted to low nitrogen (microbe B) will outgrow and overwhelm the other. The sudden infusion of large quantities of a formerly limiting nutrient, a process called **eutrophication**, can lead to a "bloom" of microbes. Organisms initially held in check by the limiting nutrient now exhibit unrestricted growth, consuming other nutrients to a degree that threatens the existence of competing species.

Humans have caused nutrient pollution in several ways. Runoff from agricultural fields, urban lawns, and golf courses is one source. Untreated or partially treated domestic sewage is another. Sewage was a primary source of phosphorus eutrophication of lakes in the 1960s and 1970s, when detergents contained large amounts of phosphates. The phosphates acted as water softeners to improve cleaning action, but when washed into lakes, they also proved to be powerful stimulants to algal growth (**Fig. 5.25**). The resulting algal "blooms" in many lakes led to oxygen depletion and resultant fish kills. Many native fish species disappeared, to be replaced by species more tolerant of the new conditions.

TO SUMMARIZE:

- **Starvation** is a stress that can elicit a starvation response in many microbes. Enzymes are produced to increase the efficiency of nutrient gathering and to protect cell macromolecules from damage.
- **The starvation response** is usually triggered by the accumulation of small signal molecules such as cyclic AMP or ppGpp.



Low P

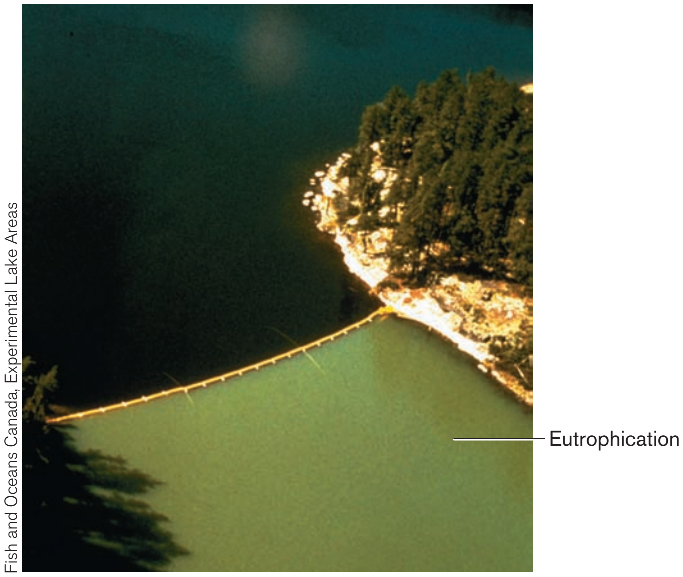
Transports phosphate poorly
Species A
Species B
Transports nitrogen poorly
Transports nitrogen efficiently
Low N
Neither organism has an advantage.
Increase phosphate concentration
High P
Low N
Species B can outcompete species A.

Figure 5.24 Maintaining microbial diversity through nutrient limitation. Species A and species B require both nitrogen and phosphate to grow. *Top*: Neither species dominates because each has a limiting nutrient (N = nitrogen; P = phosphate). *Bottom*: Following phosphate eutrophication, species B will outgrow species A because while both species have enough phosphate, B is better able to assimilate the limited quantity of nitrogen.



Eutrophication

Fish and Oceans Canada, Experimental Lake Areas

Figure 5.25 Eutrophication. Algal bloom in an experimental lake resulting from phosphate eutrophication. A divider curtain separates the lake and prevents mixing of water. The bright green color results from cyanobacteria growing on phosphorus added to the near side of the curtain.

- **Oligotrophs** are organisms that thrive in nutrient-poor conditions.
- **Human activities can cause eutrophication**, which damages delicately balanced ecosystems by introducing nutrients that can allow one member of the ecosystem to flourish at the expense of other species.

5.8 Physical and Chemical Methods of Controlling Microbial Growth

Prevention, control, or elimination of microbes that are potentially harmful to humans is one of the primary goals of our health care system. Within the recent past, infectious disease was an imminent and constant threat to most of the human population. The average family in the United States prior to 1900 had four or five children, in part because parents could expect half of them to succumb to deadly infectious diseases. What today would be a simple infected cut in years past held a serious risk of death, and a trip to the surgeon was tantamount to playing Russian roulette with an unsterilized scalpel. Improvements in sanitation procedures and antiseptics and the advent of antibiotics have, to a large degree, curtailed the incidence and lethal effects of many infectious diseases. Success in this endeavor has played a major role in extending life expectancy and in contributing to the population explosion.

A variety of terms are used to describe antimicrobial control measures. The terms convey subtle, yet vitally important, differences in various control strategies and outcomes.

- **Sterilization** is the process by which *all* living cells, spores, and viruses are destroyed on an object.
- **Disinfection** is the killing, or removal, of *disease-producing* organisms from inanimate surfaces; it does not necessarily result in sterilization. Pathogens are killed, but other microbes may survive.
- **Antisepsis** is similar to disinfection, but it applies to removing pathogens from the surface of living tissues, like the skin. Antiseptic chemicals are usually not as toxic as disinfectants, which frequently damage living tissues.
- **Sanitation**, closely related to disinfection, consists of reducing the microbial population to safe levels and usually involves cleaning an object as well as disinfection.

Antimicrobials can also be classified on the basis of the specific groups of microbes destroyed, leading to the terms *bactericide*, *algicide*, *fungicide*, and *virucide*. Furthermore, these agents can be classified either as *-static* (inhibiting growth) or *-cidal* (killing cells). For example, antibacterial agents are called **bacteriostatic** or **bactericidal**. Chemical substances that kill microbes are **germicidal** if they kill pathogens (and many nonpathogens). Germicidal agents do not necessarily kill spores. Although these descriptions place emphasis on killing pathogens, it is also important to note that antimicrobial agents can also kill or prevent the growth of nonpathogens. Many public health standards are based on *total* numbers of microorganisms on an object, regardless of pathogenic potential. For example, to gain public health certification, the restaurants we frequent must demonstrate low numbers of bacteria in their food preparation areas.

Cells Treated with Antimicrobials Die at a Logarithmic Rate

Exposure of microbes to lethal chemicals or conditions does not instantly kill all microorganisms. Microbes die according to a negative exponential curve, where cell numbers are reduced in equal fractions at constant intervals. The efficacy of a given agent or condition is measured as **decimal reduction time (D-value)**, which is the length of time it takes that agent (or condition) to kill 90% of the population (a drop of 1 log unit, or a drop to 10% of the original value). **Figure 5.26** illustrates the exponential death profile of a bacterial culture heated to 100°C. The D-value is a little over 1 minute.

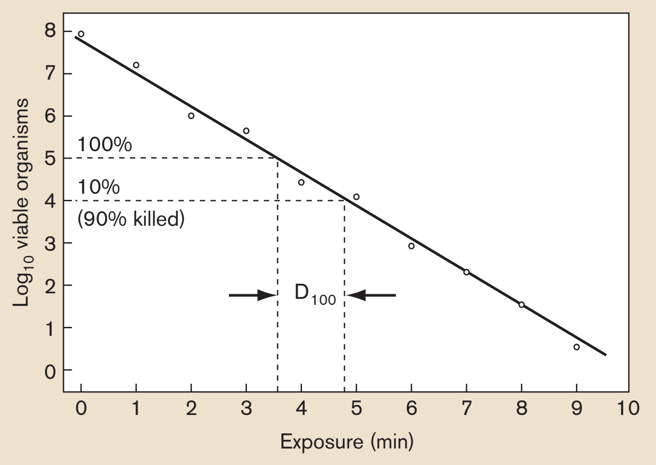


Figure 5.26 The death curve and the determination of D-values. Bacteria were exposed to a temperature of 100°C, and survivors were measured by viable count. The D-value is the time required to kill 90% of cells (that is, for the viable cell count to drop by one $\log_{10}$ unit). In this example, the D-value at 100°C (D_{100}) is approximately 1 minute.

Several factors influence the D-value—that is, the ability of an antimicrobial agent to kill microbes. These include the initial population size (the larger the population, the longer it takes to decrease it to a specific number), population composition (are spores involved?), agent concentration, and duration of exposure. Although the effect of concentration seems intuitively obvious, only over a narrow range is an increase in concentration matched by an increase in death rate. Increases above a certain level might not accelerate killing at all. For example, 70% ethanol is actually better than pure ethanol at killing organisms. This is because some water is needed to help ethanol penetrate cells. The ethanol then dehydrates cell proteins.

So, why is death a logarithmic function? Why don't all cells in a population die instantly when treated with lethal heat or chemicals? The reason is based, in part, on the random probability of the agent causing a lethal "hit" in a given cell. Cells contain thousands of different proteins and thousands of molecules of each. Not all proteins and not all genes in a chromosome are damaged by an agent at the same time. Damage accumulates. Only when enough molecules of an *essential* protein or a gene encoding that protein are damaged will the cell die. Cells that die first are those that accumulate lethal hits early. Members of the population that die later have, by random chance, absorbed more hits on nonessential proteins or genes, sparing the essential ones.

Why, if 90% of a population is killed in 1 minute, aren't the remaining 10% killed in the next minute? It seems logical that all should have perished. Yet after the second minute, 1% of the original population remains alive. This can also be explained by the random hit concept. Although there are fewer viable cells after 1 minute, each has the same random chance of having a lethal hit as when the treatment began. Thus, death rate is an exponential function, much like radioactive decay is an exponential function.

A final consideration involves the overall fitness of individual cells. It is mistaken to assume that all cells in a population are identical. For example, at any given time, one cell may express a protein that another cell has just stopped expressing (for example, superoxide dismutase). In that instant, the first cell might contain a bit more of that protein. If the protein is essential or confers a level of stress protection (such as against superoxide), the cell can absorb more punishment before it is dispatched. The presence of lucky individuals expressing the right repertoire of proteins might also explain why death curves commonly level off after a certain point.

Physical Agents That Kill Microbes

Physical agents are often used to kill microbes or control their growth. Commonly used physical control measures are temperature extremes, pressure (usually combined with temperature), filtration, and irradiation.

High temperature and pressure. Even though microbes were discovered less than 400 years ago, thermal treatment of food products to render them safe has been practiced for over 5,000 years. Moist heat is a much more effective killer than dry heat, thanks to the ability of water to penetrate cells. Many bacteria, for instance, easily withstand 100°C dry heat but not 100°C in boiling water. We humans are not so different, finding it easier to endure a temperature of 32°C (90°F) in dry Arizona than in humid Louisiana.

While boiling water (100°C) can kill most vegetative (actively growing) organisms, spores are built to withstand this abuse, and thermophiles prefer it. Killing spores and thermophiles usually requires combining high pressure and temperature. At high pressure, the boiling point of water rises to a temperature rarely experienced by microbes living at sea level. Even endospores quickly die under these conditions. This combination of pressure and temperature is the principle behind sterilization using the **steam autoclave** (**Fig. 5.27**). Standard conditions for steam sterilization are 121°C (250°F) at 15 psi for 20 minutes, a set of conditions that experience has taught us will kill all spores. These are also the conditions produced in pressure cookers used for home canning of vegetables.

Figure 5.27 Steam autoclave.

Failure to adhere to these heat and pressure parameters can have deadly consequences, even in your own home. For instance, *Clostridium botulinum* is a spore-forming soil microbe that commonly contaminates fruits and vegetables used in home canning. The improper use of a pressure cooker while canning these goods will allow spores of this pathogen to survive. Once the can or jar is cool, the spores will germinate and begin producing their deadly toxin. All of this happens while the canned goods sit on a shelf waiting to be opened and consumed. Once ingested, the toxin makes its way to the nervous system and paralyzes the victim. Several incidents of this disease, called botulism, occur each year in the United States. (For more on food poisoning, see Chapter 16.)

THOUGHT QUESTION 5.9 How would you test the killing efficacy of an autoclave?

The food industry uses several parameters to evaluate the efficiency of heat killing. The D-value has already been described. Two additional measures are **12D**, the amount of time required to kill 10^{12} spores (or reduce a population 12 logs); and the **z-value**, the increase in temperature needed to lower the D-value to $1/10$ its previous value. If, for example, D_{100} (the D-value at 100°C) and D_{110} (the D-value at 110°C) for a given organism are 20 minutes and 2 minutes, respectively, then $12D_{100}$ equals 240 minutes (that is, 20 minutes × 12), and the z-value is 10°C (because a 10°C increase in temperature reduced the D-value to $^{1}/_{10}$, from 20 minutes to 2 minutes). These measurements are extremely important to the canning industry, which must ensure that canned goods do not contain spores of *Clostridium botulinum*, the previously described anaerobic soil microbe that causes the paralyzing food-borne disease botulism.

Because the tastes of certain foods suffer if they are overheated, z-values and 12D-values are used to adjust heating times and temperatures to achieve the same sterilizing result. Take the following example, where D_{121} is 10 minutes and $12D_{121}$ is 120 minutes. Sterilizing food at 121°C for 120 minutes might result in food with a repulsive taste, whereas reducing the temperature and extending the heating time may yield a more palatable product. The D- and z-values are used to adjust conditions for sterilization at a lower temperature. If D_{121} is 15 minutes and the z-value is known to be 10°C, then reducing temperature by 10°C to 110°C will mean D_{111} is 150 minutes (10 times D_{121}). As a result, $12D_{111}$ is 1,800 minutes. Sterilization may take longer, but food quality is likely to remain high, because the sterilizing temperature is lower.

Pasteurization. Originally devised by Louis Pasteur to save products of the French wine industry from devastating bacterial spoilage, **pasteurization** today involves heating a particular food (such as milk) to a specific temperature long enough to kill *Mycobacterium tuberculosis* and *Coxiella burnetii*. These two organisms, the causative agents of tuberculosis and Q fever, respectively, are the most heat-resistant nonspore-forming pathogens known. Many different time and temperature combinations can be used for pasteurization. The LTLT (low-temperature/long-time) process involves bringing milk to a temperature of 63°C (145°F) for 30 minutes. In contrast, the HTST (high-temperature/short-time, also called flash pasteurization) method brings the milk to a temperature of 72°C (161°F) for only 15 seconds. Both processes accomplish the same thing: the destruction of *M. tuberculosis* and *C. burnetii*.

Cold. Low temperatures have two basic purposes in microbiology: to temper growth and to preserve strains. Bacteria not only grow more slowly in cold, but also die more slowly. Refrigeration temperatures (4–8°C, or 39–43°F) are used for food preservation because most pathogens are mesophilic and grow poorly, if at all, at those temperatures. One exception is the gram-positive bacillus *Listeria monocytogenes*, which can grow reasonably well in the cold and causes disease when ingested.

Long-term storage of bacteria usually requires placing solutions in glycerol at very low temperatures (–70°C). Glycerol prevents the production of razor-sharp ice crystals that can pierce cells from without or within. This deep-freezing suspends growth altogether and keeps cells from dying. Another technique called **lyophilization** freeze-dries microbial cultures for long-term storage. In this technique, cultures are quickly frozen at very low temperatures (quick-freezing also limits ice crystal formation) and placed under vacuum, where the resulting sublimation process removes all water from the media and cells, leaving just the cells in the form of a powder. These freeze-dried organisms remain viable for years. Finally, viruses and mammalian cells must be kept at extremely low temperatures (–196°C), submerged in liquid nitrogen. Liquid nitrogen freezes cells so quickly that ice crystals do not have time to form.

Filtration. Filtration through micropore filters with pore sizes of 0.2 μm can remove microbial cells, but not viruses, from solutions. Samples from 1 ml to several liters can be drawn through a membrane filter by vacuum or can be forced through it using a syringe (**Fig. 5.28**). Filter sterilization has the advantage of avoiding heat, which can damage the material sterilized. Of course, since these filters do not trap viruses, the solutions are not really sterile.

Air can also be sterilized by filtration. This forms the basis of several personal protective devices. A surgical mask is a crude example, while **laminar flow biological safety cabinets** are more elaborate (and more effective). These cabinets force air through high-efficiency particulate air (HEPA) filters and remove over 99.9% of airborne particulate material 0.3 μm in size or larger. Biosafety cabinets are critical to protect individuals working with highly pathogenic material (**Fig. 5.29**). Newer technologies have been developed that embed antimicrobial agents or enzymes directly into the fibers of the filter

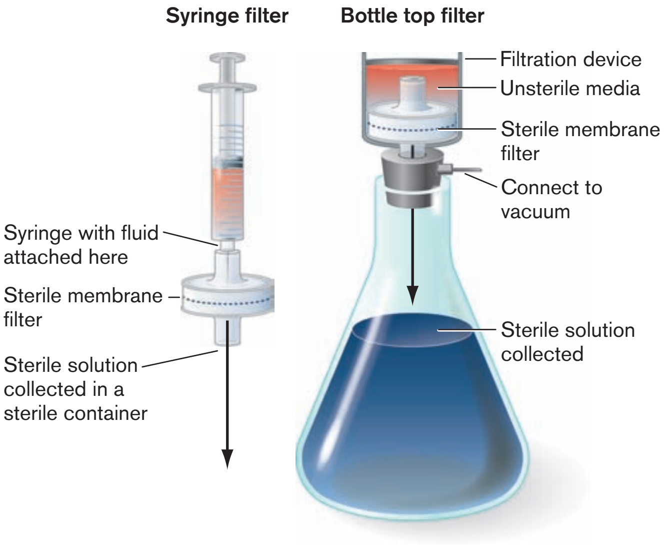

Figure 5.28 **Membrane filtration apparatus.**

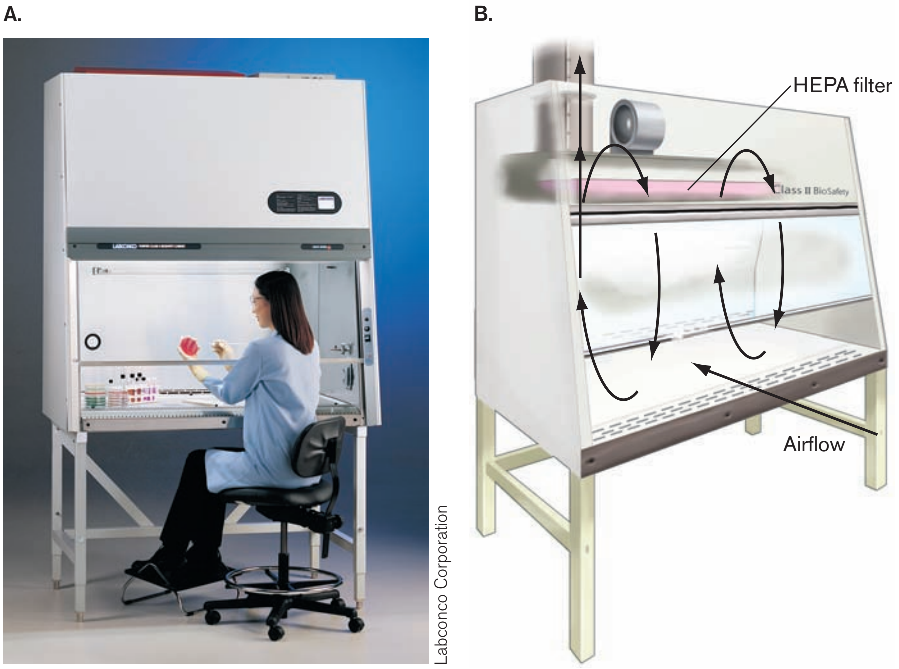


Labconco Corporation

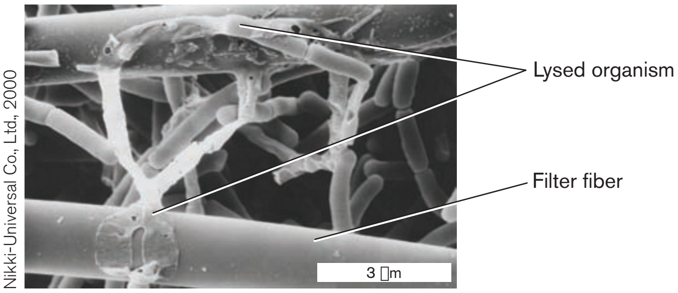
Figure 5.29 Biological safety cabinet. Air is drawn into the chamber and continually passed through the HEPA filter to remove hazardous agents. This prevents the escape of aerosolized infectious agents.

(**Fig. 5.30**). Organisms entangled in these fibers are not just trapped; they are attacked by the antimicrobials and lyse.

Irradiation. Public health authorities worldwide are increasingly concerned about food contaminated with pathogenic microorganisms such as *Salmonella* species, *E. coli* O157:H7, *L. monocytogenes*, and *Yersinia enterocolitica*. Irradiation, the bombardment of foods with high-energy electromagnetic radiation, has long been a potent, if politically sensitive, strategy for sterilizing food after harvesting. The food consumed by NASA astronauts, for example, has for some time been sterilized by irradiation as a safeguard against food-borne illness in space. Until recently, public pressure severely limited the use of this technology because of concerns about product safety and exposure of workers. However, the recent use of the U.S. mail service by a bioterrorist to disseminate anthrax spores across the eastern United States has renewed interest in sterilization by irradiation. Foods do not become radioactive when irradiated, but there are concerns that reactive molecules potentially dangerous to humans are produced when high-energy particles are absorbed by the natural chemicals in the food and react to produce toxic substances.

Aside from ultraviolet light, which, owing to its poor penetrating ability, is only useful for surface sterilization, there are three other sources of irradiation: gamma rays, electron beams, and X-rays. Radiation dosage is usually measured in a unit called the gray (Gy), which is the amount of energy transferred to food, microbe, or other substance being irradiated. A single chest X-ray delivers roughly half a milligray (1 mGy = 0.001 Gy). To kill *Salmonella*, freshly slaughtered chicken can be irradiated at up to 4.5 kilograys (kGy), about 7 million times the energy of a single chest X-ray.

When microbes present in food are irradiated, water and other intracellular molecules absorb the energy and create transient reactive chemicals that damage DNA and scramble genetic information. Unless the organism repairs this damage, it will die while trying to replicate. Microbes differ greatly in their sensitivity to irradiation, depending on the size of their DNA, the rate at which they can repair damaged DNA, and other factors. It also matters if the irradiated food is frozen or fresh, as it takes a higher dose of radiation to kill microbes in frozen foods.



Nikki-Universal Co., Ltd., 2000

Figure 5.30 Immobilized enzyme filter. The primary function of this enzyme filter is to kill airborne microorganisms caught on the surface of the filter to protect against secondary contamination from microorganisms in air filtration systems. The photo shows lysed bacteria (*Bacillus subtilis*). The cell walls have been hydrolyzed by enzymatic action, and cell membranes are broken as a result of osmotic pressure pushing outward against the membrane.

The size of the DNA "target" is a major factor in radiation efficacy. Parasites and insect pests, which have large amounts of DNA, are rapidly killed by extremely low doses of radiation, typically with D-values of less than 0.1 kGy (in this instance, the D-value is the *dose* of radiation needed to kill 90% of the organisms). It takes more radiation to kill bacteria (D-values in the range of 0.3–0.7 kGy) because they have less DNA per cell unit (less target per cell). It takes even more radiation to kill a bacterial spore (D-values on the order of 2.8 kGy) because they contain little water, the source of most ionizing damage to DNA. Viral pathogens have the smallest amount of nucleic acid, making them resistant to irradiation doses approved for foods (viruses have D-values of 10 kGy or higher). Prion particles associated with bovine spongiform encephalopathy (BSE, also known as mad cow disease) do not contain nucleic acid and are only inactivated by irradiation at extremely high doses. Thus, irradiation of food is effective in eliminating parasites and bacteria, but is woefully inadequate for eliminating viruses or prions.

Some Bacteria Are Highly Resistant to Physical Control Measures

Deinococcus radiodurans could be nicknamed "Conan the bacterium" and designated as a poster microbe for extremophiles (**Fig. 5.31**). It was discovered in 1956 in a can of meat that spoiled despite having been sterilized by radiation. The microbe has the greatest ability to survive radiation of any known organism. Based on the amount of radiation it can handle, it has been estimated that it could even survive the amount of radiation released in an atomic blast. The bacterium's ability to withstand radiation may have evolved as a side effect of developing resistance to extreme drought, since dehydration and radiation produce similar types of DNA damage.

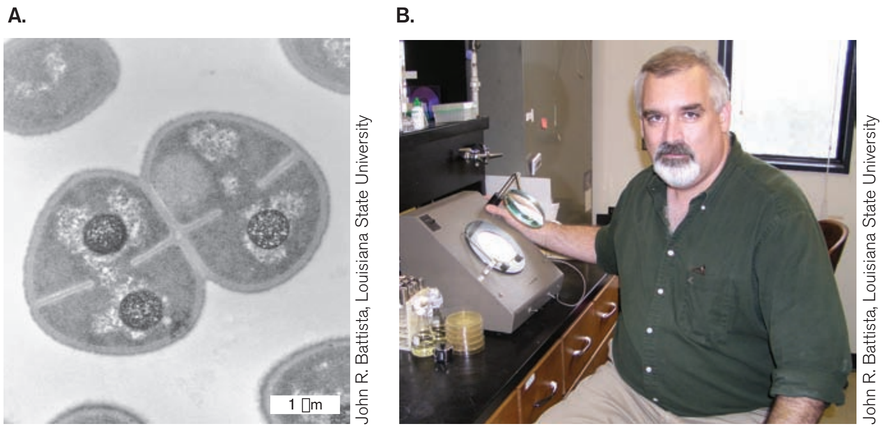
www | *Deinococcus*

Research by microbiologist John Battista has shown that *D. radiodurans* possesses an unusual capacity for repairing its damaged DNA, although the precise mechanisms remain a mystery. One possible mechanism is that a damaged chromosome in one member of the quartet shown can restore itself using DNA from another member of the quartet. Based on this research, *D. radiodurans* has been genetically engineered to treat radioactive mercury-contaminated waste from nuclear reactors, a process called **bioremediation** (discussed in Chapter 22). The genes for mercury conversion were spliced from a strain of *E. coli* resistant to particularly toxic forms of mercury and inserted into *D. radiodurans*. The genetically altered superbug was able to withstand the ionizing radiation and transform toxic waste into forms that could be removed safely. Fortunately, there is little need to worry about its being a super pathogen, because the organism does not cause disease and is susceptible to antibiotics.

Chemical Agents Supplement Physical Means of Controlling Microbes

Disinfection by physical agents is very effective, but numerous situations arise where their use is impractical (kitchen countertops) or plainly impossible (skin). In these instances, chemical agents are the best approach. There are a number of factors that influence the efficacy of a given chemical agent. These include:

- **The presence of organic matter.** A chemical placed on a dirty surface will bind to the inert organic material present, lowering the agent's effectiveness against microbes. It sometimes is not possible to clean a surface prior to disinfection (as in a blood spill), but the presence of organic material must be factored in when estimating how long to disinfect a surface or object.
- **The kinds of organisms present.** Ideally, the agent should be effective against a broad range of pathogens.
- **Corrosiveness.** The disinfectant should not corrode the surface or, in the case of an antiseptic, damage skin.



John R. Battista, Louisiana State University

John R. Battista, Louisiana State University

Figure 5.31 ***Deinococcus radiodurans.*** **A.** Based on the amount of radiation this organism can survive, the bacterium could withstand radiation equivalent to that from an atomic blast. The nature of the dark inclusion bodies in three of the four cells in the quartet is not known. **B.** John Battista of Louisiana State University showed that *D. radiodurans* has exceptional capabilities for repairing radiation-damaged DNA.

- **Stability, odor, and surface tension.** The chemical should be stable upon storage, possess a neutral or pleasant odor, and have a low surface tension so it can penetrate cracks and crevices.

The Phenol Coefficient Compares the Effectiveness of Disinfectants

Phenol, first introduced by Joseph Lister in 1867 to reduce the incidence of surgical infections, is no longer used as a disinfectant, but its derivatives, such as cresols and orthophenylphenol, are still in use. The household product Lysol is a mixture of phenolics. Phenolics are useful disinfectants because they denature proteins, are effective in the presence of organic material, and remain active on surfaces long after application.

Today we know phenolics are toxic and should not be used on living tissues. Nevertheless, based on its potency and its history, phenol is the benchmark against which other disinfectants are measured. The **phenol coefficient test** involves inoculating a fixed number of bacteria—for example, *Salmonella typhi* or *Staphylococcus aureus*—into dilutions of the test agent. At timed intervals, samples are withdrawn from each dilution and inoculated into fresh broth (which contains no disinfectant). The phenol coefficient is based on the highest dilution (lowest concentration) of a disinfectant that will kill all the bacteria in a test after 10 minutes of exposure, but leaves survivors after only 5 minutes of exposure. This concentration is known as the maximum effective dilution. Dividing the reciprocal of the maximum effective dilution for the test agent (for example, ethyl alcohol) by the reciprocal of the maximum effective dilution for phenol gives the phenol coefficient (**Table 5.3**). For example, if the maximum effective dilution for agent X is $^{1}/_{900}$ and that of phenol is $^{1}/_{90}$, then the phenol coefficient of X is 900/90 = 10; the higher the coefficient, the higher the efficacy of the disinfectant.

Table 5.3 Phenol coefficients for various disinfectants.

Chemical agent	*Staphylococcus aureus*	*Salmonella typhi*
Phenol	1.0	1.0
Chloramine	133.0	100.0
Cresols	2.3	2.3
Ethyl alcohol	6.3	6.3
Formalin	0.3	0.7
Hydrogen peroxide	–	0.001
Lysol	5.0	3.2
Mercury chloride	100.0	143.0
Tincture of iodine	6.3	5.8

Commercial Disinfectants

Ethanol, iodine, chlorine, and surfactants (for example, detergents) are all used to reduce or eliminate microbial content from commercial products (**Fig. 5.32**). The first three are highly reactive compounds that damage proteins, lipids, and DNA. Iodine complexed with an organic carrier forms an iodophor, a compound that is water-soluble, stable, nonstaining, and capable of releasing iodine slowly to avoid skin irritation. Wescodyne and Betadyne (trade names) are iodophors used respectively, for the surgical preparation of skin and for wounds. Chlorine is a disinfectant with universal application. It is recommended for general laboratory and hospital disinfection and kills the HIV virus.

Detergents can also be antimicrobial agents. The hydrophobic and hydrophilic ends of detergent molecules (which makes them amphipathic) will emulsify fat into water. Cationic (positively charged) but not anionic (negatively charged) detergents are useful as disinfectants because the cationic detergents contain positive charges that can gain access to the negatively charged bacterial cell and disrupt membranes. Anionic detergents are not antimicrobial but do help in the mechanical removal of bacteria from surfaces.

Low-molecular-weight aldehydes such as formaldehyde are highly reactive, combining with and inactivating proteins and nucleic acids. This, too, makes them useful disinfectants.

Disposable plasticware like petri dishes, syringes, sutures, and catheters are not amenable to heat sterilization or liquid disinfection. These materials are best sterilized using antimicrobial gases. Ethylene oxide gas (EtO) is a very effective sterilizing agent; it destroys cell proteins, is microbicidal and sporicidal, and rapidly penetrates packing materials, including plastic wraps. Using an instrument resembling an autoclave, EtO at 700 milligrams per liter (mg/L) will sterilize an object after 8 hours at 38°C or 4 hours at 54°C if the relative humidity is kept at 50%. Unfortunately, EtO is explosive. A less hazardous gas sterilant is betapropiolactone. It does not penetrate as well as EtO, but it decomposes after a few hours, which makes it easier to dispose of than EtO.

Antibiotics Selectively Control Bacterial Growth

Antibiotics as made in nature are chemical compounds made by one microbe that selectively kill other microbial species. Naturally occurring antibiotics act like tiny molecular land mines. As a defense against competitors, some organisms secrete antibiotic compounds into their surrounding environment, where they remain until encountered by an intruder. If the interloper is susceptible to the antibiotic, the compound will target specific structures or proteins, disrupting their function. The target cell is either rendered helpless (by bacteriostatic antibiot-

ics) or made nonviable (by bactericidal compounds). (See Chapter 27 for detailed modes of action.) When purified and administered to patients suffering from an infectious disease, these antibiotics can produce seemingly miraculous recoveries.

As we saw in Chapter 1, penicillin, produced by *Penicillium notatum*, was discovered serendipitously in 1929 by Alexander Fleming. **Figure 5.33A** shows a three-dimensional representation of this molecule, which mimics a part of the microbial cell wall. Because of this mimicry, penicillin binds to biosynthetic proteins involved in peptidoglycan synthesis and prevents cell wall formation. The drug is bactericidal because *actively growing* cells lyse without the support of the cell wall (**Fig. 5.34**). Other antibiotics target protein synthesis, DNA replication, cell membranes, and various enzyme reactions. These interactions are described throughout Parts 1–3 of this text.

So how do antibiotic-producing microbes avoid suicide? In some instances, the producing organism lacks the target molecule. *Penicillium* mold, for instance, lacks peptidoglycan and is immune to penicillin by default. Some bacteria produce antimicrobial compounds that target other members of the same species. In this case, the producing organism can modify its own receptors so that they no longer recognize the compound (as with some bacterial colicins). Another strategy is to modify the antibiotic if it reenters the cell. This is the case with streptomycin produced by *Streptomyces griseus.* Streptomycin inhibits bacterial protein synthesis and does not discriminate between the protein synthesis machinery of *Streptomyces*

and that of others. However, while making enzymes that synthesize and secrete streptomycin, *S. griseus* simultaneously makes the enzyme streptomycin-6-kinase, which remains locked in the cell. If any secreted streptomycin reenters the cell, this enzyme renders the drug inactive by attaching a phosphate to it.

Because many microorganisms have become resistant to commonly used antibiotics, pharmaceutical companies are continually using a variety of drug discovery approaches to search for new antibiotics. Traditional procedures include scouring soil and ocean samples collected from all over the world for new antibiotic-producing organisms and chemically redesigning existing antibiotics so that they can bypass microbial resistance strategies. These procedures are now supplemented by "mining the genomes" of microbes for potential drug targets. The frontiers of chemistry include rational drug design, which relies on computer-based methods for predicting the structure and function of potential new antibiotics.

TO SUMMARIZE:

- **Sterilization** kills all living organisms.
- **Disinfection** kills pathogens on inanimate objects.
- **Antisepsis** is the removal of potential pathogens from the surfaces of living tissues.
- **Antimicrobial** compounds can be **bacteriostatic** or **bactericidal.**
- **The D-value** is the time (or dose, in the case of irradiation) it takes an antimicrobial treatment to reduce the numbers of organisms to 10% of the original value.
- **The autoclave** uses high pressure to achieve temperatures that will sterilize objects.
- **The z-value** is a measure of how much more heat is needed to reduce D-value to $^{1}/_{10}$ its original value.
- **Pasteurization** is a heating process designed to kill specific pathogens in milk and other food products.
- **Refrigeration** is used to prevent microbial growth in foods. Extreme cold (freezing) is used to preserve bacteria.
- **Filtration** can remove cells from a solution, but it cannot remove the smallest viruses.
- **Irradiation** can kill pathogens in foods without damaging the food itself.
- **Chemical disinfectants** are compared to one another based on the phenol coefficient.
- **Antibiotics** are compounds produced by one living microorganism that kill other microorganisms.

5.9 Biological Control of Microbes

Pitting microbe against microbe is an effective way to prevent disease in humans and animals. One of the hallmarks of a healthy ecosystem is the presence of a diversity of organisms. This is true not only for tropical rain forests and coral reefs, but also for the complex ecosystems of human skin and the intestinal tract. In these environments, the presence of harmless microbial flora can retard the growth of undesired pathogens. The pathogenic fungus *Phytophthora cinnamomi*, for example, causes root rot in plants but is biologically controlled by fungi belonging to the genus

Myrothecium. Naturally occurring *Staphylococci* on human skin produce short-chain fatty acids that retard the growth of pathogenic strains. Another illustration is the human intestine, which is populated by as many as 500 microbial species. Most of these species are nonpathogenic organisms that exist in symbiosis with their human host. Vigorous competition between members of the normal intestinal flora and the production of permeant weak acids by fermentation help control the growth of numerous pathogens.

Microbial competition has been widely exploited for agricultural purposes and to improve human health in a process known as **probiotics**. In general, a probiotic is a food or supplement that contains live microorganisms and improves intestinal microbial balance. Newborn baby chicks, for instance, are fed a microbial cocktail of normal flora designed to quickly colonize the intestinal tract and prevent colonization by *Salmonella*, a frequent contaminant of factory-farmed chicken. In another example, *Lactobacillus* and *Bifidobacterium* have been used to prevent and treat diarrhea in children.

Russian Nobel laureate Elie Metchnikoff in 1908 first suggested that a high concentration of lactobacilli in intestinal flora was important for health and longevity in humans. Yogurt is an example of a probiotic containing *Lactobacillus acidophilus* and a number of other lactobacilli. It is often recommended as a way to restore a normal balance to gut flora (for example, after it has been disturbed by antibiotic treatment) and appears useful in the treatment of inflammatory bowel disease.

Phage therapy is another biocontrol method first described in 1907 by Felix d'Herelle at France's Pasteur Institute, long before antibiotics were discovered. Bacteriophages are viruses that prey on bacteria (discussed in Section 6.1). Each bacterial species is susceptible to a limited number of specific phages. Because the culmination of a phage infection is often bacterial lysis, it was considered feasible to treat infectious diseases with a phage targeted to the pathogen. At one time, doctors used phages as medical treatment for illnesses ranging from cholera to typhoid fever. In some cases, a liquid containing the phage was poured into an open wound. In other cases, phages were given orally, introduced via aerosol, or injected. Sometimes the treatments worked; sometimes they did not. When antibiotics came into the mainstream, phage therapy largely faded. Now that strains of bacteria resistant to standard antibiotics are on the rise, the idea of phage therapy has enjoyed renewed interest from the worldwide medical community. Several biotechnology companies have even been formed in the United States to develop bacteriophage-based treatments.

TO SUMMARIZE:

- **Biocontrol** is the use of one microbe to control the growth of another.
- **Probiotics** contain certain microbes that, when ingested, aim to restore balance to intestinal flora.
- **Phage therapy** offers a possible alternative to antibiotics in the face of rising antibiotic resistance.

Concluding Thoughts

Microbiology as a science was founded on the need to understand and control microbial growth. The initial impetus was to control the diseases of humans as well as the diseases of plants and animals. But as we will see in later chapters, microbiology has developed into a science that has helped us understand the molecular processes of life. Concepts such as biological diversity, food microbiology, microbial disease, and antibiotics will be revisited in later chapters.

CHAPTER REVIEW

Review Questions

1. Explain the nature of extremophiles and discuss why these organisms are important.
2. What are the parameters that define any growth environment?
3. List and define the classifications used to describe microbes that grow in different physical growth conditions.
4. What do thermophiles have to do with the PCR reaction?
5. Why is water activity important to microbial growth? What changes water activity?
6. How do cells protect themselves from osmotic stress?
7. Why do changes in H^+ concentration affect cell growth?
8. How do acidophiles and alkaliphiles manage to grow at the extremes of pH?
9. Because an organism can live in an oxygenated environment, does that mean that the organism uses oxygen to grow? Because an organism can live in an anaerobic environment, does that mean it cannot use oxygen as an electron acceptor? Why or why not?
10. What happens when a cell exhausts its available nutrients?

11. List and briefly explain the various means by which humans control microbial growth. What is a D-value? What is a phenol coefficient?
12. How do microbes prevent the growth of other microbes?

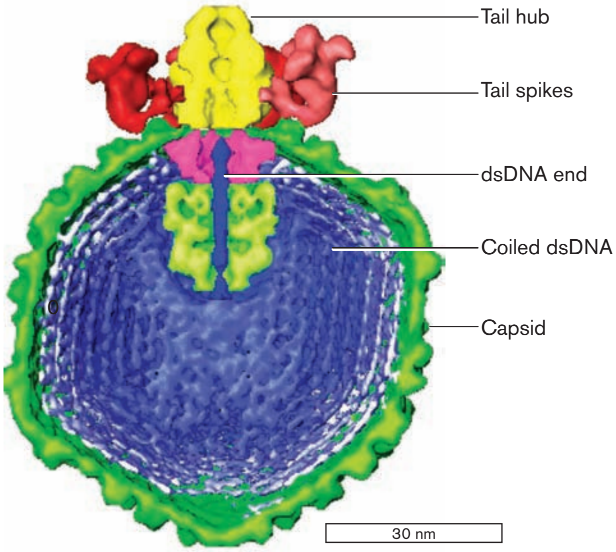
Chapter 6

Virus Structure and Function

6.1 What Is a Virus?
6.2 Virus Structure
6.3 Viral Genomes and Classification
6.4 Bacteriophage Life Cycles
6.5 Animal and Plant Virus Life Cycles
6.6 Culturing Viruses
6.7 Viral Ecology

All kinds of cells, including bacteria, eukaryotes, and archaea, can be infected by particles called viruses. Viruses are the smallest known units of reproduction, some with genomes of less than ten genes. Upon entering a cell, a viral genome subverts the cell's machinery to reproduce more virus particles, usually killing the host cell. Alternatively, some viral genomes are copied into the host genome, where they replicate silently with the host. Degenerate viral genomes from ancient viral insertions take up a large part of the human genome.

Virus structure varies in complexity from single RNA molecules to spore-like packages containing multiple layers of protein and membranes. Some viruses resemble degenerate cells. Viral intracellular life cycles enable them to divert complex host cell processes to the formation of new viruses. How can such particles, barely large enough to be detected by an electron microscope, subvert and consume entire cells and multicellular organisms? Alternatively, how can viruses integrate their genomes into the genome of their host, replicating with their host for future generations?



The bacteriophage epsilon 15 attacks *Salmonella* bacteria, pathogens of the human digestive tract. Such bacteriophages help control our enteric bacterial populations, but they also transfer DNA encoding resistance to antibiotics. The structure of the epsilon 15 bacteriophage was solved by cryo-electron microscopy, revealing details of the tail apparatus that inserts the DNA into the host cell.

In February 2003, travelers from Guangdong, China, began succumbing to a mysterious respiratory syndrome from which one in ten died. The disease spread alarmingly through hospitals in Hong Kong, Vietnam, and Toronto, Canada. Its rapid spread caused thousands of travelers worldwide to cancel plans, while residents of affected cities donned face masks (**Fig. 6.1A**). The disease became known as sudden acute respiratory syndrome (SARS). SARS was caused by a new virus, a member of the coronavirus family, named for their characteristic "corona" of spike proteins (**Fig. 6.1B**). To find clues for the treatment of SARS, the RNA genome of the new virus was sequenced by Canadian researchers with unprecedented speed. Comparison with known viruses showed SARS virus to be related to coronaviruses infecting pigs and birds (**Fig. 6.1C**). So the researchers hypothesized that SARS evolved from an animal virus in the food markets of Guangdong. Viruses evolve new strains even faster than cellular pathogens because of their tiny genomes and little or no proofreading of replication.

Despite their small size, viruses generate frightening epidemics, from smallpox and polio to AIDS and influenza. Other viruses play crucial roles in the environment, particularly in marine ecosystems, where they cycle carbon and curb toxic blooms of algae. Viral predation selects for much of the species diversity of marine protists and invertebrates.

In research, viruses have provided both tools and model systems for our discovery of the fundamental principles of molecular biology. The first genes mapped, the first regulatory switches defined, and the first genomes to be sequenced were all those of viruses. Vectors for gene cloning and gene therapy today continue to be derived from viruses.

In this chapter, we introduce major themes of virus structure and function and the fundamental challenges that all viruses face: genome packaging, cell attachment and entry, and the molecular strategies that enable viruses to divert the metabolism of their host cell. Viruses provide key tools and model systems for molecular biology. Our understanding of viruses, particularly bacterial viruses, called bacteriophages, provides a useful background for the molecular biology we will encounter in Part 2 of this book (**Chapters 7–12**). The molecular biology of viral life cycles is explored further in **Chapter 11**, and viral disease pathology and epidemiology are discussed in **Chapters 25–27**.

6.1 What Is a Virus?

A **virus** is a noncellular particle capable of infecting a host cell, where it reproduces. The virus particle, or **virion**, consists of an infective nucleic acid (DNA or RNA) con-

In 2003, as SARS first breaks out, a bride and groom in Hubei, China, wear masks to protect themselves from airborne infection. **B.** A SARS virion (diameter, 78 nm) bristles with spike proteins (TEM). **C.** The family tree of coronavirus shows that the SARS branch is as distant from a human cold-causing coronavirus as from animal coronaviruses.

tained within a protective shell made of protein, called the **capsid**. The capsid usually has a molecular delivery device that enables transfer of the virion's genome into the host cell.

Viruses that infect bacteria are known as **bacteriophages** or **phages**. An example is bacteriophage T2, which infects *Escherichia coli* (**Fig. 6.2A**). The T2 and T4 phages have a capsid with a tail that inserts the viral genome into the host cell, where it directs reproduction of progeny virions. Virions are released when the host cell lyses. As cells lyse, their disappearance can be observed as a **plaque**, a clear spot against a lawn of bacterial cells (**Fig. 6.2B**). Each plaque arises from a single virion or phage particle that lyses a host cell and spreads progeny to infect adjacent cells. Plaques can be counted as representing individual infective virions from a phage suspension.

An example of a virus that infects humans is measles virus. The measles virion has an envelope of membrane that, during infection, fuses with the host cell membrane. After replicating within the infected cell, newly formed measles capsids become enveloped by host cell membrane as they bud out of the host cell (**Fig. 6.2C**). The spreading virus generates a rash of red spots on the skin of infected patients (**Fig. 6.2D**) and is occasionally fatal (one in 500 cases).

Plants are also infected by viruses, such as tobacco mosaic virus (TMV). Within the plant cell, virions accumulate to high numbers (**Fig. 6.2E**) and travel through interconnections to neighboring cells. Infection by tobacco mosaic virus results in mottled leaves and stunted growth (**Fig. 6.2F**). Plant viruses cause major economic losses in agriculture worldwide.

Each species of virus infects a particular group of host species, known as the **host range**. Some viruses can infect only a single species; for example, HIV infects only humans. Close relatives of humans, such as the chimpanzee, are not infected, although they are susceptible to a closely related virus, simian immunodeficiency virus (SIV). On the other hand, the West Nile virus, transmitted by mosquitoes, has a much broader host range, including many species of birds and mammals.

THOUGHT QUESTION 6.1 Which viruses do you know that have a narrow host range, and which have a broad host range?

Viruses Propagate Their Genomic Information

Viral propagation exemplifies the central role of information in biological reproduction. The propagation of viruses is mimicked by the spread of "computer viruses," whose information "infects" computer memory (**Fig. 6.3**).

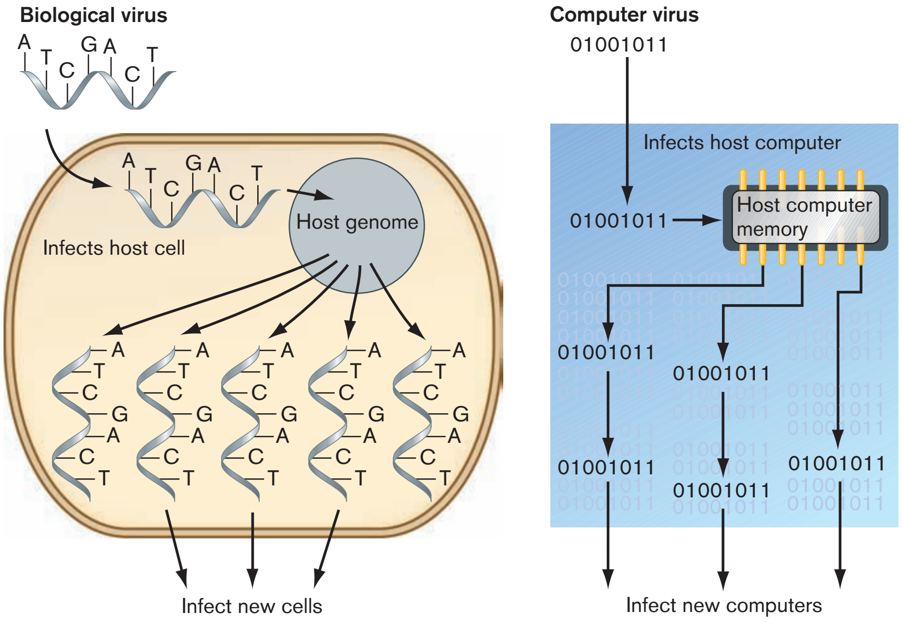

Figure 6.3 Biological viruses and computer viruses. From the standpoint of information, the behavior of biological viruses and computer viruses are analogous.

When a biological virus infects a host cell, the information in its genome subverts the host cell machinery to produce multiple copies of the virus; the multiple copies then escape to infect more host cells. Similarly, when a computer virus infects a host computer, its program code subverts the host to produce multiple copies of the virus, which then escape to infect more host computers. Computer viruses generate epidemics analogous to those of biological viruses. The virus's code can even be designed to "mutate" in order to foil the "immune system" of antivirus software.

Viruses Infect All Forms of Life

Viruses are ubiquitous, infecting every taxonomic group of organisms, including bacteria, eukaryotes, and archaea. In marine ecosystems, viruses act as major predators and sequester significant amounts of nutrients. For humans, viruses cause many forms of illness, whose influence on our history and culture would be hard to overstate. More people died of influenza in the global epidemic of 1918 than in the battles of World War I. In the past 30 years, the AIDS pandemic caused by HIV has killed 25 million people worldwide and continues to grow.

Viruses are part of our daily lives. The most frequent infections of college students are due to respiratory pathogens such as rhinovirus (the common cold) and Epstein-Barr virus (infectious mononucleosis), as well as sexually transmitted viruses such as herpes simplex (HSV) and papilloma (genital warts). Viruses also impact human industry; for example, bacteriophages (literally, "bacteria-eaters") infect cultures of *Lactococcus* during the production of yogurt and cheese. Plant pathogens such as cauliflower mosaic virus and rice dwarf virus continue to cause substantial losses in agriculture.

In contrast to our vast arsenal of antibiotics (effective against bacteria), the number of antiviral drugs remains depressingly small. Because the machinery of viral growth is largely that of the host cell, viruses present relatively few targets that can be attacked by antiviral drugs without harming the host. However, an understanding of viral life cycles at the molecular level is now leading to the development of new antiviral drugs, such as AZT and protease inhibitors, which combat HIV.

Despite their lethal potential, viruses have made surprising contributions to medical research. A bacteriophage provides a protein that lyses the cell walls of anthrax bacteria. Other bacteriophages are used as **cloning vectors**, small genomes into which foreign genes can be inserted and cloned for gene technology. Even lethal viruses such as HIV are being developed as vectors for human gene therapy.

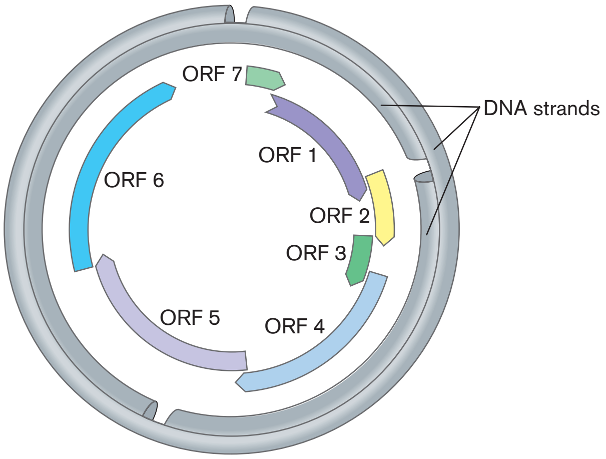
Some viruses introduce copies of their own genomes into the host's genome, a process that can mediate evolution of the host genome. Indeed, studies of molecular evolution reveal that viral genomes are the ancestral source of about a tenth of the human genome.

Viral Genomes

The genome of a virus can be small, encoding fewer than ten genes. In cauliflower mosaic virus, for example, the genome encodes only seven genes (**Fig. 6.4A**), which actually overlap each other in sequence. This overlap in sequence is made possible by the use of different **reading frames**, start positions for translating codons to amino acids. Many viral genomes, such as that of avian leukosis genome, are encoded by RNA. The RNA genome of avian leukosis virus has protein-encoding genes grouped by functional categories of core capsid, replicative enzymes, and envelope proteins.

On the other hand, larger viral genomes, such as that of herpes virus or of bacteriophage T4, have genes dispersed around the chromosome, similar to the genomes of bacteria. The giant Mimivirus, which infects amebas and may cause human pneumonia, is as large as some bacteria

A. Cauliflower mosaic virus genome (DNA)



B. Avian leukosis virus genome (RNA)

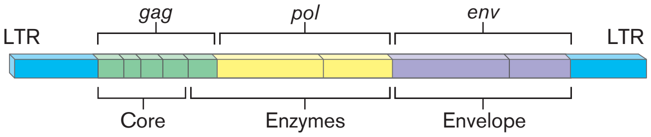


Figure 6.4 Simple viral genomes. A. Cauliflower mosaic virus has a circular genome of double-stranded DNA, whose strands are interrupted by nicks. The genome encodes seven overlapping genes (open reading frames, ORFs). **B.** Avian leukosis virus: a single-stranded RNA retrovirus resembling eukaryotic mRNA. Three genes (*gag*, *pol*, and *env*) encode polypeptides that are eventually cleaved to form a total of nine functional products. LTR = long terminal repeat.

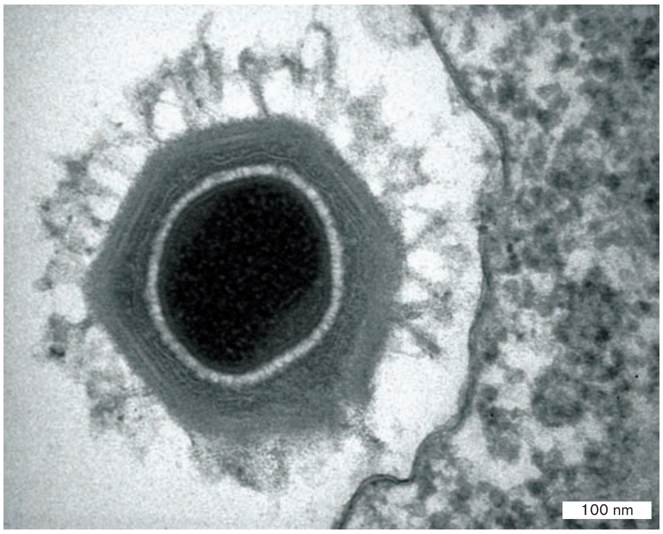


Didier Raoult, Mediterranean University, Marseille

Figure 6.5 Mimivirus infecting an ameba. About 300 nm across, the Mimivirus is larger than some bacteria.

(**Fig. 6.5**). Furthermore, Mimivirus has a bacterium-sized genome of 1.2 million base pairs. The Mimivirus virion conducts numerous cellular functions, including DNA repair and protein-folding by chaperones. It probably represents a descendant of a cell that parasitized protist cells until most of its cellular traits were lost through degenerative evolution.

Viroids: Infective Genomes with No Capsid

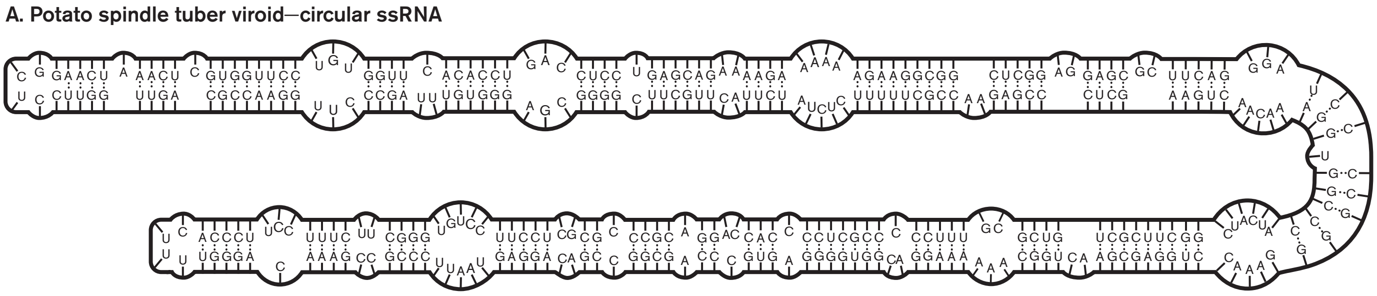
Early in the twentieth century, viruses were believed to be the smallest particles capable of infecting hosts and propagating themselves. Then even smaller virus-like infectious agents were discovered for which the nucleic acid genome is itself the entire infectious particle; there is no protective capsid. Such infectious agents are called **viroids**. Most viroids are RNA molecules that infect plants. An example is the potato spindle tuber viroid. This viroid consists of a circular, single-stranded molecule of RNA that doubles back on itself to form base pairs interrupted by short unpaired loops (**Fig. 6.6A**). The RNA folds up into a globular structure that interacts with host cell proteins. Most critically, the RNA genome requires a host RNA-dependent RNA polymerase to replicate itself and transcribe its genes. RNA-dependent RNA polymerases occur normally in plant cells, where they contribute to regulation of gene expression.

During viroid infection, the RNA-dependent RNA polymerase replicates progeny copies of the viroid, which encodes no products other than itself. Viroids can cause as much host destruction as "true viruses," and some authors, particularly in plant pathology, classify them as "viruses without capsids."

Some viroids have catalytic ability, comparable to enzymes made of protein. An RNA molecule capable of catalyzing a reaction is called a **ribozyme**. One class of plant-infecting viroids are the **hammerhead ribozymes** (**Fig. 6.6B**). Named for their hammer-shaped tertiary structure, hammerhead ribozymes possess the ability to cleave themselves or other specific RNA molecules. Their ability to cleave very specific RNA sequences has applications in medical research. Hammerhead ribozymes have been engineered to cleave human RNA molecules involved in cancer or in infection by viruses such as HIV. The engineering of ribozymes for medical therapy is an exciting field of biotechnology.

Prions: Infection without Nucleic Acid?

A remarkable class of infectious agents is believed to consist of protein only. These agents, known as **prions**, are believed to be aberrant proteins arising from the host cell. Prions gained notoriety when they were implicated in brain infections such as Creutzfeldt-Jakob disease, popularly known as "mad cow" disease because it may



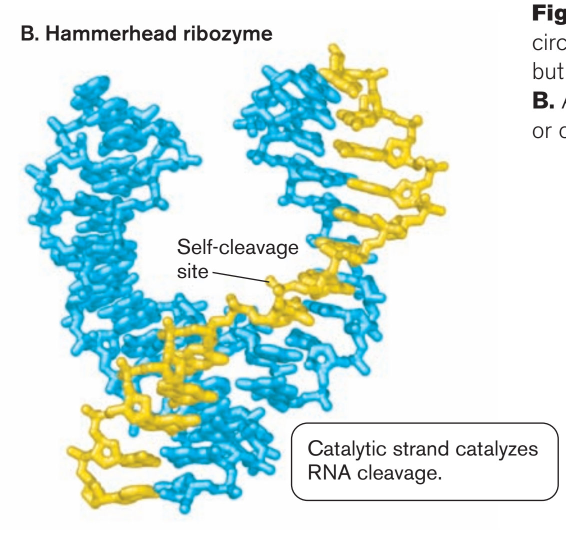


Figure 6.6 **Viroids: infective RNA.** **A.** Potato spindle tuber viroid consists of a circular single-stranded RNA that hybridizes internally. A viroid encodes no genes, but it hijacks the plant cell's RNA-dependent RNA polymerase to replicate itself. **B.** A hammerhead ribozyme catalyzes cleavage of itself (at "self-cleavage site") or of another RNA molecule. (PDB code: 1HMH)

be transmitted through defective proteins in beef from diseased cattle. Other diseases believed to be caused by prion transmission include scrapie, a disease of sheep, and kuru, a degenerative brain disease found in a tribe of people who customarily consumed the brains of deceased relatives.

In prion-associated diseases, the infective agent is unaffected by treatments that destroy RNA or DNA, such as nucleases or UV irradiation. A prion is an aberrant form of a normally occurring cell protein that assumes an abnormal conformation or tertiary structure (**Fig. 6.7A**). The prion form of the protein acts by binding to normally folded proteins of the same class and altering their conformation to that of the prion. The multiplying prion then alters the conformation of other normal subunits, forming harmful aggregates in the cell and ultimately leading to cell death. In the brain, prion-induced cell death leads to tissue deterioration and dementia (**Fig. 6.7B**).

Prion diseases can be initiated by infection with an aberrant protein. More rarely, the cascade of protein misfolding can start with the spontaneous misfolding of an endogenous host protein. The chance of spontaneous unfolding is greatly increased in individuals who inherit certain alleles encoding the protein; thus, spontaneous prion diseases can be inherited genetically. Overall, prion diseases are unique in that they can be transmitted by an infective protein instead of by DNA or RNA; and they propagate conformational change of existing molecules without synthesizing entirely new infective molecules.

TO SUMMARIZE:

- **Viruses** consist of noncellular particles that infect a host cell and direct its expression apparatus to produce virus particles.
- A **virion** consists of a capsid enclosing a nucleic acid genome. Some viruses are further enclosed by a membrane envelope.
- **All classes of organisms are infected by viruses.** Usually the hosts are limited to a particular host range of closely related strains or species.
- **Viruses contain infective genomes** that take over a cell, reprogramming its cell machinery to make progeny virus particles (virions). Some viral genomes consist of less than 10 genes; others have 100 or 200 genes and may represent degenerate cells.
- **Viroids** that infect plants consist of RNA hairpins with no capsid.
- **Prions** consist of infectious proteins that induce a cell's native proteins to fold incorrectly and impair cell function.

6.2 Virus Structure

A packaged structure of a virus achieves two goals: It keeps the viral genome intact, and it enables infection of the appropriate host cell. First, the stable capsid protects the viral genome from degradation and enables it to be transmitted outside the host. Second, in order for the viral genome to reproduce, the virion must either insert its genome into the host cell or disassemble within the host. In the process, the original particle loses its stable structure and its own identity as such, but it generates numerous progeny virions.

THOUGHT QUESTION 6.2 What would happen if a virus particle remained intact within a host cell instead of releasing its genome?

Symmetrical Virus Particles

Different viral species make different forms of capsids. Virus particles may be symmetrical, in which case the capsid is one of two types, icosahedral or filamentous (helical). Each type of capsid exhibits geometrical symmetry. The advantage of symmetry is that it provides a way to form a package out of repeating protein units generated by a small number of genes and encoded by a short chromosomal sequence. The smaller the viral genome, the more genome copies can be synthesized from the host cell's limited supply of nucleotides. Nevertheless, other viruses, such as smallpox virus, are asymmetrical and may have much larger genomes. Large genomes offer a greater range of functions for viral components.

Icosahedral viruses. Many viruses package their genome in an **icosahedral** (20-sided) capsid; examples include poliovirus and the herpes viruses. Icosahedral viral capsids take the form of a polyhedron with 20 identical triangular faces. Bacteriophages often supplement the icosahedral capsid or head coat with an elaborate delivery device. For example, bacteriophage T4 (**Fig. 6.8A**) has a complex structure consisting of an icosahedral headpiece containing the genome, six jointed "legs" that stabilize the structure on the host cell surface, and a neck piece that channels the nucleic acid into the host cell (**Fig. 6.8B**). The structure of phage T4 was first observed by microbiologists during the rise of the NASA space program, and its form was compared to that of the "lunar module" that landed on the moon (**Fig. 6.8C**). Indeed, in the 1960s, the "tailed phages," such as phage T4 and phage lambda, were to molecular biology what the lunar landings were to space exploration.

WWW **T4 Bacteriophage Cell-Puncturing Device**, a 3-D interactive tutorial

In the capsid, each triangle can be composed of three identical but asymmetrical protein units. An example of an icosahedral capsid is that of the herpes simplex virus (**Fig. 6.9A**). Each triangular face of the capsid is determined by the same genes encoding the same protein subunits. No matter what the pattern of subunits in the triangle, the structure overall exhibits rotational symmetry characteristic of an icosahedron (**Fig. 6.9B**): threefold symmetry around the axis through two opposed triangular faces; fivefold symmetry around an axis through opposite points; and twofold symmetry around an axis through opposite edges. Capsid symmetry is important for structure determination and visualization and for the design of antiviral drugs.

THOUGHT QUESTION 6.3 Why do viral capsids take the form of an icosahedron instead of some other polyhedron?

Virus particles can be observed by standard transmission electron microscopy (TEM), but the details of capsid structure as in **Figure 6.9A** require visualization by digital reconstruction of cryo EM (discussed in Section 2.6). Recall from Chapter 2 that in cryo EM, the viral samples for TEM are prepared flash-frozen, preventing formation of ice crystals. Flash freezing enables observation without stain. The electron beams penetrate the object; thus, images of individual capsids actually provide a glimpse of the virus's internal contents. By digitally combining and processing cryo TEM images from a number of capsids, a three-dimensional reconstruction is built for the entire virus particle.

In some icosahedral viruses, the capsid is enclosed in an **envelope** composed of membrane from the host cell in which the virion formed. **Figure 6.10A** shows how herpes virions capture cell membrane to form their envelopes as

they bud out of the cell. (Other viral species may derive their envelope from intracellular membranes, such as the nuclear membrane or endoplasmic reticulum.) The envelope and capsid contents of herpes virus are shown in **Figure 6.10B**. The mature envelope (**Fig. 6.10C**) bristles with glycoprotein **spike proteins** that plug it onto the capsid. The spike proteins enable the virus to attach and infect the next host cell.

Between the envelope and the capsid, additional proteins may be found, called the **tegument** (**Fig. 6.10D**). Tegument proteins, also called **accessory proteins**, serve the virus during the early stages of infection. As the virus enters its host cell, its envelope is dissolved and the tegument proteins are released to start reproduction of new viruses.

NOTE: Distinguish the **viral envelope** (membrane derived from a host cell membrane) from the *bacterial cell envelope* (protective layers outside the bacterial cell membrane). The bacterial envelope is discussed in Chapter 3.

Filamentous viruses. A second major category of virus structure is that of **filamentous viruses**. Filamentous viruses include bacteriophages, such as phage M13 (**Fig. 6.11A**), as well as animal viruses, such as Ebola virus, which causes a swiftly fatal disease of humans and related primates (**Fig. 6.11B**). Filamentous phages have applications in human medicine and industry. Phages similar to M13 infect the gram-positive species *Propionibacterium freudenreichii*, a key fermenting agent for Swiss cheese. Another filamentous phage, CTXΦ, integrates its sequence into the genome of *Vibrio cholerae*, where it carries the deadly toxin genes required for cholera. On the other hand, an application in nanoscience is the use of filamentous phages to nucleate the growth of crystalline "nanowires" for electronic devices.

The filamentous bacteriophage M13 (**Fig. 6.11A**) consists of a relatively simple capsid of protein monomers. The monomers are stacked around a coiled genome consisting of a circle of single-stranded DNA. At one end of the filament, short tail fibers mediate specific attachment to the host. Attachment occurs at the F pilus of an *E. coli* bacterium containing an F plasmid that encodes pili.

Filamentous viruses show helical symmetry. The pattern of capsid monomers forms a helical tube around the genome, which usually winds helically within the tube. In a helical capsid, the genome is a single-stranded DNA (as in phage M13) or RNA (as in tobacco mosaic virus). **Figure 6.12A** shows how the RNA strand of tobacco mosaic virus winds in a spiral within a tube of capsid monomers laid down in a spiral array. Such a tube can be imagined as a planar array of subunits that coils around such that each row connects to the row above, generating a spiral (**Fig. 6.12B**). The length of the helical capsid may extend up to 50 times its width, generating a flexible filament.

Unlike the icosahedral capsid, which has a fixed size, the helical capsid can vary in length to accommodate various lengths of nucleic acid. Furthermore, some viruses package several genome segments into separate

helical capsids. For example, influenza virus packages several different genome segments into separate helical packages of different sizes, contained together within a membrane envelope. Multiple helical packaging enables influenza virus to package different numbers of RNA segments into different virions, thus facilitating rapid evolution of new strains.

Asymmetrical Virus Particles

Some viruses lack a symmetrical capsid. In poxviruses, such as vaccinia and smallpox (**Fig. 6.13A**), the double-stranded DNA genome is stabilized by covalent connection of its two strands at each end (**Fig. 6.13B**). Instead of a capsid, the DNA is enclosed loosely by a core envelope studded with spike proteins, surrounded by an outer membrane. The core envelope also encloses a large number of accessory proteins needed early in viral infection, such as initiation proteins for transcription of viral genes and RNA-processing enzymes that modify viral mRNA molecules.

Asymmetrical viruses usually contain a large number of accessory proteins. The first viruses to be studied, including TMV and poliovirus, had extremely simple

The DNA is stabilized by a hairpin loop at each end.

structures that consisted only of nucleic acid and packaging proteins. Based on these models, it was concluded that a virion consists solely of a packaged genome. Further research, however, revealed that other kinds of viruses contain enzymes and regulatory proteins—encoded by the virus, its host, or both. The proteins may be found either inside the capsid or in the tegument between the capsid and the envelope. Examples include the reverse transcriptase and protease enzymes of HIV and the dozen different enzymes contained by vaccinia poxvirus. Large, asymmetrical viruses contain so many enzymes that they appear to have evolved from degenerate cells.

TO SUMMARIZE:

- **The viral capsid** is composed of repeated protein subunits, a structure that maximizes the structural capacity while minimizing the number of genes needed for construction.
- **The capsid packages the viral genome** and delivers it into the host cell.
- **Icosahedral capsids** have regular, icosahedral symmetry.
- **Filamentous (helical) capsids** have uniform width, generating a flexible filamentous virion.
- **Enveloped viruses** consist of a protein capsid and tegument proteins enclosed within membrane derived from the host cell. The envelope includes virus-specific spike proteins.
- **Accessory proteins** are contained within the capsid or as tegument components between the capsid and envelope.

6.3 Viral Genomes and Classification

Living organisms today are classified based on relatedness of their gene sequences. Genetic relatedness can also be used to compare closely related viruses, such as SARS and other coronaviruses. The definition of a virus species, however, is problematic, given the small size and high mutability of viral genomes and the ability of different viruses to recombine their genome segments within an infected host cell. Furthermore, it is not clear whether all viral species are monophyletic, that is, descended from a common ancestor. In fact, it is more likely that different classes of viruses arose from different sources—such as from parasitic cells or from host cell components such as DNA replication enzymes. Viruses are classified based on genome composition, virion structure, and host range.

The International Committee on Taxonomy of Viruses

For purposes of study and communication, a working classification system has been devised by the International Committee on Taxonomy of Viruses (ICTV). The ICTV classification system is based on several criteria:

- **Genome composition.** The nucleic acid of the viral genome can vary remarkably with respect to physical structure: it may consist of DNA or RNA; it may be single- or double-stranded; it may be linear or circular; and it may be whole or **segmented** (that is, divided into separate "chromosomes"). Genomes are classified by the Baltimore method (discussed next).

- **Capsid symmetry.** The protein capsid may be helical or icosahedral, with various levels of symmetry.
- **Envelope.** The presence of a host-derived envelope, and the envelope structure if present, are characteristic of related viruses.
- **Size of the virus particle.** Related viruses generally share the same size range; for example, enteroviruses such as poliovirus are only 30 nm across (about 1/30 the size of bacteria such as *E. coli*), whereas poxviruses are 200–400 nm, as large as a small bacterium.
- **Host range.** Closely related viruses usually infect the same or related hosts. However, viruses with extremely different hosts can show surprising similarities in genetics and structure. For example, both rabies virus and potato yellow dwarf virus are enveloped, bullet-shaped viruses of the rhabdovirus family.

> **NOTE:** In nomenclature, families of viruses are designated by Latin names with the suffix ***-viridae***: for example, *Papovaviridae*. Nevertheless, the common forms of such family names are also used, for example, the papovaviruses. Within a family, a virus species is simply capitalized, as in Papillomavirus.

The Baltimore Virus Classification Based on Genome Structure

Of the classification criteria just described, many virologists consider genome composition the most fundamental; that is, viruses of the same genome class (such as double-stranded DNA) are more likely to share ancestry with each other than with viruses of a different class of genome (such as RNA). In 1971, David Baltimore proposed that the primary distinction among classes of viruses be the genome composition (RNA or DNA) and the route used to express messenger RNA (mRNA). Baltimore, together with Renato Dulbecco and Howard Temin, were awarded the Nobel Prize in Physiology or Medicine in 1975 for discovering how tumor viruses cause cancer.

All cells and viruses need to make messenger RNA (mRNA) to make their fundamental protein components. The production of mRNA from the viral genome is central to a virus's ability to propagate its kind. Cellular genomes always make mRNA by copying double-stranded DNA. For viruses, however, different kinds of genomes require fundamentally different mechanisms to produce mRNA. The different means of mRNA production generate distinct groups of viruses with shared ancestry.

So far, the known mechanisms of replication and mRNA expression define seven fundamental groups of viral species (**Fig. 6.14**). These seven fundamental groups form the basis of the taxonomic survey of viruses in **Table 6.1**.

www | Viral Biorealm

Group I. Double-stranded DNA viruses such as herpes and smallpox make their own DNA polymerase or use that of the host for genome replication. Their genes can be transcribed directly by a standard RNA polymerase, in the same way that a cellular chromosome would be transcribed. The RNA polymerase used can be that of the host cell, or it can be encoded by the viral genome.

Group II. Single-stranded DNA viruses require the host DNA polymerase to generate the complementary DNA strand. The double-stranded DNA can then be transcribed by host RNA polymerase. An example is canine parvovirus.

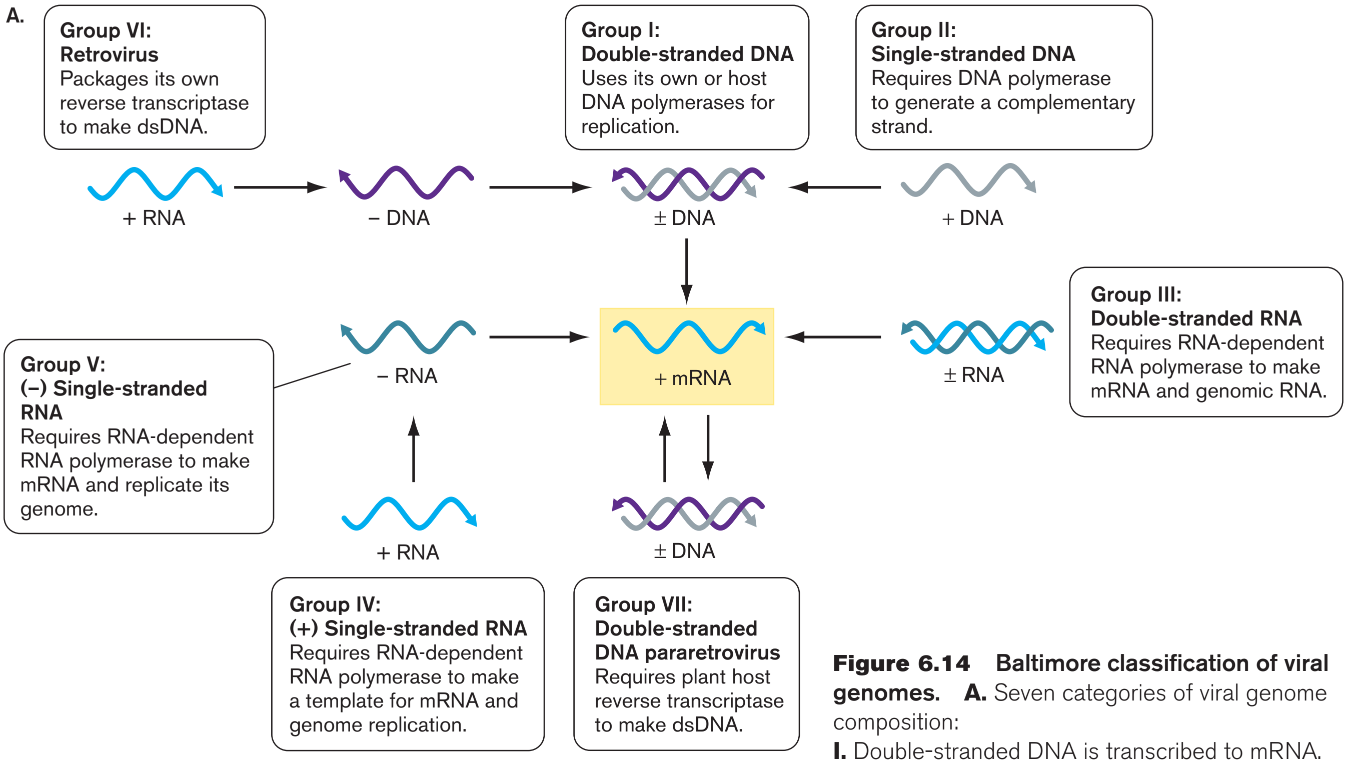
Group III. Double-stranded RNA viruses, such as the plant pathogenic reoviruses, require a viral **RNA-dependent RNA polymerase** to generate messenger RNA by transcribing directly from the RNA genome. Since the RNA polymerase is required immediately upon infection, such viruses usually package a viral RNA polymerase with their genome before exiting the host cell.

Group IV. (+) sense single-stranded RNA viruses consist of a positive-sense (+) strand, that is, the strand that can serve directly as mRNA to be translated to viral proteins. Replication of the RNA genome, however, requires synthesis of the template (–) strand, that is, the strand complementary to the (+) strand, to form a double-stranded RNA intermediate. Positive-sense (+) RNA viruses are very common. They include the coronaviruses, such as SARS, as well as hepatitis C virus and the flavivirus that causes West Nile encephalitis.

Group V. (–) sense single-stranded RNA viruses such as influenza virus have genomes that consist of template or "negative-sense" RNA. Thus, they need to package a viral RNA-dependent RNA polymerase for transcribing (–) RNA to (+) mRNA. The (–) RNA viral genomes are often segmented, that is, they consist of more than one separate linear chromosome—a key factor in the evolution of killer strains of influenza (see Section 11.4).

Group VI. Retroviruses, or RNA reverse-transcribing viruses such as HIV and feline leukemia virus, have genomes that consist of (+) strand RNA. Instead of RNA polymerase, they package a **reverse transcriptase**, which transcribes the RNA

A.



Group VI:
Retrovirus
Packages its own reverse transcriptase to make dsDNA.
Group I:
Double-stranded DNA
Uses its own or host DNA polymerases for replication.
Group II:
Single-stranded DNA
Requires DNA polymerase to generate a complementary strand.
+ RNA

Figure 6.14 Baltimore classification of viral genomes. **A.** Seven categories of viral genome composition:
I. Double-stranded DNA is transcribed to mRNA.
II. Single-stranded DNA generates a double-stranded form within the host cell, which is transcribed to mRNA.
III. Double-stranded RNA makes mRNA using RNA-dependent RNA polymerase.
IV. Single-stranded RNA (+) makes a complementary (–) strand, which is transcribed to mRNA.
V. Single-stranded RNA (–) is transcribed to mRNA.
VI. Single-stranded RNA (+) is reverse-transcribed to DNA, which is transcribed to mRNA.
VII. Double-stranded DNA is transcribed to mRNA, which is reverse-transcribed to regenerate viral genomes for packaging into virions.
B. David Baltimore (left), with a graduate student at the California Institute of Technology. Baltimore won the 1975 Nobel Prize in Physiology or Medicine for his work on retroviruses; co-winners were Renato Dulbecco and Howard Temin.

into a double-stranded DNA (for details, see Section 11.5). The double-stranded DNA is then integrated into the host genome, where it directs the expression of the viral genes.

Group VII. DNA reverse-transcribing viruses, or **pararetroviruses**, have a life cycle that requires reverse transcriptase. Animal viruses such as hepatitis B (a hepadnavirus) first copy their double-stranded DNA genomes into RNA, then reverse-transcribe the RNA to progeny DNA using a reverse transcriptase packaged in the original virion. In contrast, plant pararetroviruses, such as cauliflower mosaic virus, generate an RNA intermediate that replicates using a reverse transcriptase made by the host cell. Many plant genomes include a gene for reverse transcriptase. Cauliflower mosaic virus is of enormous agricultural significance for its use as a vector to construct pesticide-resistant food crops.

Molecular Evolution of Viruses

The phylogeny, or genetic relatedness, of viruses can be determined within families. For example, the herpes family includes double-stranded DNA viruses that cause several human and animal diseases, such as chickenpox, oral and genital herpes infection, and equine herpes respiratory and genital infections. Herpes genomes consist of double-stranded DNA, 120–220 kilobases (kb) encoding about 70–200 genes; an example is that of varicella-zoster virus, the causative agent of chickenpox (**Fig. 6.15A**). The genome includes two "unique" segments of genes, one long and one short (U_L and U_S), joined by two inverted repeats (IRs). Other herpes genomes share similar structure, though they differ in gene order and IR position.

The relatedness of different herpes viruses can be measured by comparing their genome sequences. Comparison is based on **orthologous genes**, or **orthologs**. Orthologs are genes of common ancestry in two genomes that share the same function, a topic discussed in Chapter 8. An example is the ribosomal RNA genes whose sequence is used to measure relatedness of cellular organisms. Viruses have no ribosomal RNA, but closely related viruses share other orthologous genes. In pairs of orthologs, the amount of difference in sequence correlates approximately with the time following divergence from a common ancestor (a topic discussed in Chapter 17). Sequence comparison places herpes into three classes designated alpha, beta, and gamma (**Fig. 6.15B**). The alpha class includes human varicella-zoster virus and the oral and genital herpes viruses (HSV-1 and HSV-2), as well as equine herpes virus. The beta class includes cytomegalovirus, a common cause of congenital infections (present at birth), as well as two less known viruses. The gamma class includes Epstein-Barr virus, the cause of infectious mononucleosis, as well as several viruses of animals.

The more ancient evolution of viruses, however, is difficult to assess based on DNA or RNA sequence. Unlike cells, viruses do not possess genes common to all species, such as the ribosomal RNA genes used to estimate times of divergence of cellular organisms (discussed in Chapter 17). Furthermore, the genomes of viruses are highly mosaic, that is, derived from multiple sources. Mosaic genomes result from recombination between different viruses coinfecting a host.

In some cases, phylogeny is inconsistent with the fundamental chemical composition of the genome. For example, some DNA bacteriophages actually share closer ancestry with RNA bacteriophages than they do with DNA animal viruses. This is because two or more viruses can coinfect a cell and exchange genetic components.

Thus, the genomic content of a virus can be influenced by its host range.

THOUGHT QUESTION 6.4 How can viruses with different kinds of genomes (RNA versus DNA) combine and exchange genetic information?

As more viral genomes are sequenced, classification methods have been devised to take advantage of sequence information without requiring gene products common to all species. One promising approach is that of **proteomics**, analysis of the **proteome**, the proteins encoded by genomes (discussed in Chapter 8). Proteins are identified through biochemical analysis of virus particles and through bioinformatic analysis of protein sequences encoded in the genomes. Proteomic analysis is useful for viruses because their small genomes encode a small number of proteins, which can be readily analyzed. Furthermore, because proteomic analysis is based on numerous gene products, it does not require a single gene (such as rRNA) common to all species. Statistical comparison of all proteins generated by a set of viral species reveals underlying degrees of relatedness.

An example of viral classification based on proteomic analysis is that of the "proteomic tree" of bacteriophages proposed by Rohwer and Edwards (**Fig. 6.16**). Unlike earlier trees based on a single common gene sequence, the proteomic tree is based on the statistical comparison of phage protein sequences predicted by genomic DNA of many different species of phages. The proteomic analysis predicts seven major

Figure 6.16 The bacteriophage proteomic tree. Comparison of all proteins encoded by each genome predicts distinct groups of bacteriophages. Within each group, there are subgroups of phages with shared hosts, since sharing of hosts facilitates genetic recombination and horizontal transfer of genes between different phages. *Source*: Based on F. Rohwer and R. A. Edwards. 2002. *J. Bacteriol.* 184:4529.

evolutionary categories of phage species. These categories appear to group phage species according to host bacteria. For example, phages that infect gram-negative hosts will show more genetic commonality with each other than with phages that infect gram-positive hosts. Shared hosts have a significant impact on phage evolution because coinfecting a host enables phages to exchange genes.

TO SUMMARIZE:

- **Classification of viruses** is based on genome composition, virion structure, and host range.
- **The Baltimore virus classification** emphasizes the form of the genome (DNA or RNA, single- or double-stranded) and the route to generate messenger RNA.
- **Proteomic classification** includes information from all viral proteins. Statistical analysis reveals common descent of viruses infecting a common host.

6.4 Bacteriophage Life Cycles

All viruses require a host cell for reproduction. While viruses display a remarkable diversity of reproductive strategies, they all face these same needs for host infection:

- **Host recognition and attachment.** Viruses must contact and adhere to a host cell that can support their particular reproductive strategy.
- **Genome entry.** The viral genome must enter the host cell and gain access to the cell's machinery for gene expression.
- **Assembly of virions.** Viral components must be expressed and assembled. Components usually "self-assemble"; that is, the joining of their parts is favored thermodynamically.
- **Exit and transmission.** Progeny virions must exit the host cell, then reach new host cells to infect. In the case of multicellular organisms, the virus must eventually reach other multicellular hosts (as discussed in Chapters 27 and 29).

Bacteriophages Attach to Specific Host Cells

To commence an infectious life cycle, bacteriophages need to contact and attach to the surface of an appropriate host cell. Contact and attachment is mediated by **cell surface receptors**, proteins on the host cell surface that are specific to the host species and that bind to a specific viral component.

Receptor proteins. The cell surface receptor for a virus is actually a protein with an important function for the host cell, but the virus has evolved to take advantage of its existence. An extensively studied model system of virus-receptor binding is that of bacteriophage lambda (see **Table 6.1**, top row). The phage lambda virion attaches specifically to the maltose porin in the outer membrane of *Escherichia coli* (**Fig. 6.17**). Although the protein is often called "lambda receptor protein," it actually evolved in the host as a way to acquire the sugar maltose to metabolize. Thus, natural selection maintains the maltose porin in *E. coli* despite the danger of phage infection.

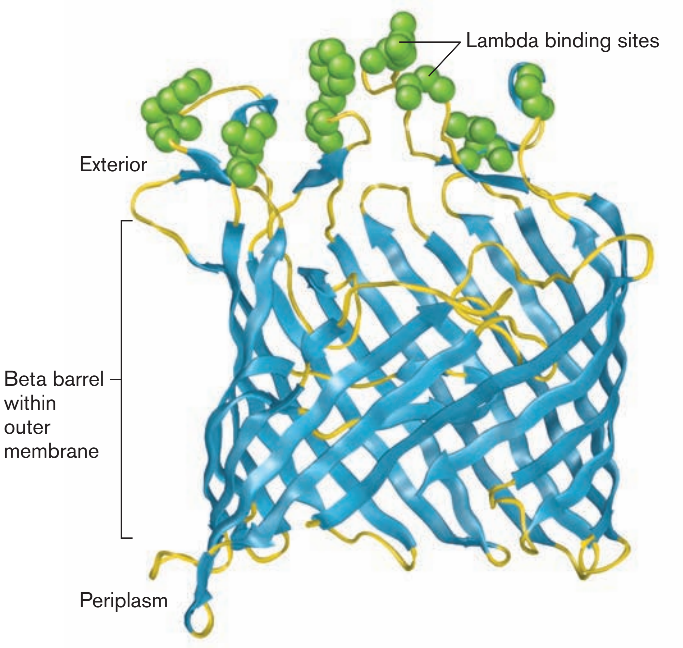

Figure 6.17 Bacteriophage lambda interacts with its host receptor. Phage lambda enters *E. coli* by first binding to the maltose porin. The "beta barrel" of maltose porin, shown in blue, is buried in the outer membrane. The phage lambda–binding sites, shown in green, were identified by amino acid substitution mutations that prevent phage binding and confer resistance to lambda on the host cell. (PDB code: 1MAL)

The precise domain of the maltose porin that binds to phage lambda was defined experimentally by mutations in *E. coli* that cause amino acid substitution in the protein. Some of the mutant *E. coli* strains were resistant to phage lambda infection. The mutations that conferred host resistance mapped to the domain of maltose porin that binds the phage capsid.

Phage Genomes Direct Host Cells to Produce Progeny Phages

Historically, the life cycles of bacteriophages have provided some of the most fundamental insights in molecular biology. In 1952, Alfred Hershey and Margaret Chase showed that the transmission of DNA by a bacteriophage to a host cell led to production of progeny bacteriophages, thus confirming that DNA is the hereditary material. In 1950, André Lwoff and Antoinette Gutman showed that a phage genome could integrate itself within a bacterial genome—the first recognition that genes could enter and leave a cell's genome. Other fundamental concepts of the genetic unit and the basis of gene transcription came from experiments on bacteriophages, as discussed in Chapters 7–9.

Most bacteriophages (or phages) insert only their genome into a cell through the cell envelope, thus avoiding the need for the capsid to penetrate the molecular barrier of the cell wall. For example, the phage T4 virion has a neck tube that contracts, bringing the headpiece near the cell surface to insert its DNA (**Fig. 6.18A**⏯). After the genome is inserted, the phage capsid remains outside attached to the cell surface and is termed a "ghost."

The lytic cycle. In a lytic cycle, when a phage particle injects its genome into a cell, it immediately proceeds to reproduce as many progeny phage particles as possible. The process of reproduction involves replicating the phage genome as well as expressing phage mRNA to make enzymes and capsid proteins. Some phages, such as T4, digest the host DNA to increase efficiency of phage production. Finally, the host cell lyses, releasing progeny phages.

Figure 6.18 Bacteriophage reproduction: lysis and lysogeny. **A.** Phage T4 attaches to the cell surface by its tail fibers, then contracts to inject its DNA. The empty capsid remains outside as a "ghost." **B.** Lysis occurs when the phage genome reproduces progeny phage particles, as many as possible, then lyses the cell to release them. In phage lambda, lysogeny can occur when the phage genome integrates into that of the host. The phage genome is replicated along with that of the host cell. The phage DNA, however, can direct its own excision by expressing a site-specific DNA recombinase. This excised phage chromosome then initiates a lytic cycle. ⏯

Phage T4 reproduces entirely by the lytic cycle; this is called a **virulent** phage. Other phages, such as phage lambda, have the options of reproducing by lysis or by lysogeny (**Fig. 6.18B**).

Lysis. After phage lambda inserts its DNA, its genes are expressed by the host cell RNA polymerase and ribosomes. "Early genes" are expressed early during the lytic cycle. Other phage-expressed proteins then work together with the cellular enzymes and ribosomes to replicate the phage genome and produce phage capsid proteins. The capsid proteins self-assemble into capsids and package the phage genomes, a process that takes place in defined stages, like a factory assembly line. At last, a "late gene" from the phage genome expresses an enzyme that lyses the host cell wall, releasing the mature virions. Lysis is also referred to as a **burst**, and the number of virus particles released is called the **burst size**.

Lysogeny. A **temperate phage**, such as phage lambda, can infect and lyse cells like a virulent phage, but it also has an alternative pathway: to integrate its genome into that of the host cell (see **Fig. 6.18B**). Phage lambda has a linear genome of double-stranded DNA, which circularizes upon entry into the cell. The circularized genome then recombines into that of the host by **site-specific recombination** of DNA. In site-specific recombination, a recombinase enzyme aligns the phage genome with the host DNA and exchanges the phosphodiester backbone links with those of the host genome. The process of exchange thus integrates the phage genome into that of the host. The integrated phage genome is called a **prophage**.

Integration of the phage genome as a prophage results in **lysogeny**, a condition in which the phage genome is replicated along with that of the host cell as the host reproduces. Implicit in the term *lysogeny*, however, is the ability of such a strain to spontaneously generate a lytic burst of phage. For lysis to occur, the prophage (integrated phage genome) directs its own excision from the host genome by an intramolecular process of site-specific recombination. The two ends of the phage genome exchange their phosphodiester backbone linkages so as to come apart from the host molecule. As the phage DNA exits the host genome, it circularizes and initiates a lytic cycle, destroying the host cell and releasing phage particles.

The "decision" between lysogeny and lysis is determined by proteins that bind DNA and repress transcription of genes for virus replication (see Section 10.7). Exit from lysogeny into lysis can occur at random, or it can be triggered by environmental stress such as UV light, which damages the cell's DNA.

The regulatory switch of lysogeny responds to environmental cues indicating the likelihood that the host cell will survive and continue to propagate the phage genome. If a cell's growth is strong, it is more likely that the phage DNA will remain inactive, whereas events that threaten host survival will trigger a lytic burst. An analogous phenomenon occurs in animal viral infections such as herpes, in which environmental stress triggers painful outbreaks arising from latent infection, reactivation of a virus that was dormant within cells. The lysogeny of phage lambda provided an early model system for investigating viral persistence in human viral diseases.

Viruses transfer host genes. During the exit from lysogeny or during latent growth of animal viruses, the virus can acquire host genes and pass them on to other host cells. This process of transferring host genes is known as **transduction**. A transducing bacteriophage can pick up a bit of host genome and transfer it to a new host cell. In some forms of transduction, the entire phage genome is replaced by host DNA packaged in the phage capsid, resulting in a virus particle that only transfers host DNA. Host DNA transferred by viruses can become permanently incorporated into the infected host genome. The mechanisms of phage-mediated transduction (generalized and specialized) are discussed in Chapter 9.

The integration and excision of viral genomes make extraordinary contributions to the evolution of host genomes. Lysogenic prophages often contribute key toxins and virulence factors to pathogens: For example, the CTXφ prophage encodes cholera toxin in *V. cholerae*; the Shiga toxin prophage confers virulence on enteric pathogens *Shigella* and *E. coli* H7:O157; and prophages encode toxins for *Corynebacterium diphtheriae* (diphtheria) and *Clostridium botulinum* (botulism). In natural environments, phage-mediated transduction mediates much of the recombination of bacterial genomes. In the laboratory, the ability of phages to transfer genes provided vectors for recombinant DNA technology, the artificial construction of phages to carry genes from animals and plants for gene cloning.

When viral transfer of genes was first discovered in the 1960s, it was thought that multicellular eukaryotes had a much lower tolerance for genome change. We have since learned, however, that much of the human genome also shows evidence of gene transfer mediated by ancient viruses, including possible retroviruses similar to HIV (discussed in Chapter 11).

Slow release. The **slow-release cycle** differs from lysis and lysogeny in that phage particles reproduce without destroying the host cell (**Fig. 6.19**). Slow release is performed by filamentous phages such as phage M13. In the slow-release life cycle, the single-stranded circular DNA of M13 serves as a template to synthesize a double-stranded intermediate. The double-stranded intermediate slowly generates single-stranded progeny genomes, which are packaged by supercoiling and coating with capsid proteins. The phage particles then extrude through the cell envelope

Cell replicates circular, single-stranded DNA.
Phages assemble and exit without lysis.
While phages reproduce and exit cell, the cell reproduces slowly.

Figure 6.19 Bacteriophage life cycle: slow release. In the slow-release life cycle, a filamentous phage produces phage particles without lysing the cell. The host continues to reproduce itself, but more slowly than uninfected cells because much of its resources are being used to make phages.

without lysing the cell. The host cell continues to reproduce, though more slowly than uninfected cells because much of its resources are diverted to virus production.

Some phage genomes consist of RNA. RNA phages include the leviviruses such as phage MS2 and Qβ. The RNA phages replicate their genomes through a double-stranded RNA intermediate, analogous to the double-stranded DNA intermediate of the filamentous phage M13; but RNA phages lyse their hosts. RNA phages have very simple genomes composed of only three or four genes. These genes encode a replicase, a coat protein, and a maturation factor. The RNA genomes of these phages are of historical interest as model systems to study ribosomal translation.

THOUGHT QUESTION 6.5 What are the relative advantages and disadvantages (to a virus) of the slow-release strategy, compared with the strategy of a temperate phage, which alternates between lysis and lysogeny?

TO SUMMARIZE:

- **Host cell surface receptors** mediate attachment of bacteriophages to a cell and confer host specificity.
- **Lytic cycle.** A bacteriophage injects its DNA into a host cell, where it utilizes host gene expression machinery to produce progeny virions.
- **Lysogeny.** Some bacteriophages can copy their genome into that of the host cell, which then replicates the phage genome along with its own. A lysogenic bacterium can initiate a lytic cycle.
- **Slow release.** Some bacteriophages use the host machinery to make progeny that bud from the cell slowly, slowing growth of the host without lysis.

6.5 Animal and Plant Virus Life Cycles

Animal and plant viruses solve problems similar to those faced by bacteriophages: host attachment, genome entry and gene expression, virion assembly, and virion release. The more complex structure of eukaryotic cells, however, leads to greater complexity and diversity of life cycles than is seen in phages. Viral reproduction may involve intracellular compartments such as the nucleus or secretory system and may depend on tissue and organ development in multicellular organisms. Study of animal virus life cycles reveals potential targets for antiviral drugs, such as protease inhibitors for HIV.

NOTE: The virus life cycles in Chapter 6 are simplified. For greater molecular detail, see Chapter 11.

Animal Viruses Bind Receptors and Uncoat Their Genomes

Like bacteriophages, animal viruses evolve to bind specific receptor proteins on their host cell. An example of a human virus-receptor interaction is that of rhinovirus (see Table 6.1, Group IV), which causes the common cold. Rhinovirus attaches to ICAM-1, a human glycoprotein needed for intercellular adhesion (**Fig. 6.20A**). The rhinovirus binds to a domain of ICAM-1 essential for it to bind a lymphocyte protein called integrin.

The host receptors play a key role in determining the host range, the group of host species permitting growth. Within a host, receptor molecules can also determine the **tropism**, or tendency to infect a particular tissue type. Some viruses, such as Ebola virus, exhibit broad tropism, infecting many kinds of host tissues, whereas others, such as papillomavirus, show tropism for only one type, the epithelial tissues. Poliovirus infects only a specific class of human cells that display the immunoglobulin-like receptor protein PVR. Children under age 3 do not yet

express the receptor PVR; thus, they do not experience polio infection of the nervous system. Mice are not normally infected by polio, but when transgenic mice were created to express PVR on their cells, the mice could then be infected.

Different strains of a virus may show radically different host tropisms based on their receptor specificity. An example is that of avian influenza strain H5N1. The H5N1 strain infects birds by binding to a glycoprotein (protein with sugar chains) receptor on cell surfaces of the avian respiratory tract. The H5N1 strain requires a receptor protein with a sialic acid sugar chain terminating in galactose linked at the C-3 position (α2, 3), common in the avian respiratory tract. In humans, however, most nasal upper respiratory cells have receptors with galactose linked at the C-6 position (α2, 6). Cells with the C-3 linkage are more common in the human lower respiratory tract. That is why avian influenza H5N1 infection of humans has been relatively rare. However, only a small mutation in the H5N1 envelope protein could enable it to bind to the (α2, 6) receptor more effectively, allowing rapid transmission between humans.

THOUGHT QUESTION 6.6 How could humans evolve to resist rhinovirus infection? Is such evolution likely? Why or why not?

Genome uncoating. Some animal viruses, such as poliovirus, attach to the host cell surface and insert their genome into the host cell, as do bacteriophages. In animal virology, this process is called "extracellular uncoating" of the genome. Most animal viruses, however, enter the host cell as intact virions, then undergo intracellular **uncoating**, a process of virion disassembly in which the genome is released for replication and gene expression.

Uncoating of the genome takes place in several different ways. For example, measles virus, a paramyxovirus, enters the cell by binding host receptor proteins, which causes the viral envelope to fuse with the host cell membrane (**Fig. 6.20B**). The measles RNA genome is then uncoated and released directly into the cytoplasm. Alternatively, a flavivirus such as hepatitis C is taken up by **endocytosis** (**Fig. 6.20C**). In endocytosis, the cell membrane forms a vesicle around the virion and engulfs it, forming an endocytic vesicle. The endocytic vesicle fuses with a lysosome, whose acidic environment activates entry of the capsid into the cytoplasm. The capsid then comes apart, uncoating the viral genome. Still other species, such as adenovirus, enter by endocytosis but require transport to the nucleus (**Fig. 6.20D**). At the nuclear membrane, the virion docks at a nuclear pore and injects its DNA genome into the nucleus. The adenoviral DNA then has access to cellular DNA polymerase and RNA transcriptase.

Animal Virus Life Cycles

The primary factor determining the life cycle of an animal virus is the physical form of the genome. A viral genome made of DNA can utilize some or all of the host replication machinery. If, however, the genome consists of single-stranded RNA, it first needs to synthesize either an RNA-dependent RNA polymerase to generate an RNA template or a reverse transcriptase to generate a DNA template (in the case of retroviruses).

DNA virus life cycle. An example of a double-stranded DNA virus is human papillomavirus (HPV) (see Table 6.1, Group I), the cause of genital warts (**Fig. 6.21A**). HPV is the most common sexually transmitted disease in the United States and one of the most common worldwide. Certain strains infect the skin, whereas others infect the mucous membranes through genital or anal contact (sexual transmission). Like phage lambda, papillomavirus has an active reproduction cycle and a dormant cycle in which the viral genome integrates into that of the host. Genome integration leads to abnormal cell proliferation causing cauliflower-like warts and can progress to cervical or penile cancer.

HPV initially infects basal epithelial cells (**Fig. 6.21B**). In the basal cells, papilloma virions enter the cytoplasm by receptor binding and membrane fusion. The virion then undergoes uncoating, the disintegration of the protein capsid or coat, releasing its circular double-strand genome (**Fig. 6.22**). The uncoated viral genome enters the nucleus, where it gains access to host DNA and RNA polymerases.

The process of viral reproduction is complicated by the developmental progression of basal cells into keratinocytes and ultimately cells to be shed or sloughed off from the surface (see **Fig. 6.21B**). Viral replication is largely inhibited until the basal cells start to differentiate into keratinocytes (mature epithelial cells). Host cell differentiation induces the viral DNA to replicate and undergo transcription by host polymerases. The mRNA transcripts then exit the nuclear pores, as do host mRNAs, for translation in the cytoplasm. The translated capsid proteins, however, return to the nucleus for assembly of the virion. Nuclear virion assembly is typical of DNA viruses (with the exception of poxviruses, which replicate entirely in the cytoplasm).

As the keratinocytes complete differentiation, they start to come apart and are shed from the surface. The DNA virions are released from the cell during this shedding process. Unfortunately, in the basal cells, HPV has an alternative pathway of integrating its genome into that of the host (analogous to phage lysogeny). Genome integration can disrupt the expression of key host genes, causing transformation to cancer.

As cells differentiate, viral synthesis is activated. Shedding cells then release virions. An alternative fate of HPV is to integrate in the genome of host basal cells, where it leads to carcinogenesis.

The viral DNA enters the nucleus for replication and transcription by host polymerases. Viral mRNA returns to the cytoplasm for translation of capsid proteins, which return to the nucleus for assembly of virions.

RNA virus life cycle. The picornaviruses include poliovirus as well as rhinovirus, which causes the common cold (see Table 6.1, Group IV). Picornavirus genomes contain (+) strand RNA, allowing viral reproduction to occur entirely in the cytoplasm, without any use of DNA.

Picornaviruses bind to a surface receptor, such as ICAM-1 for rhinovirus or the PVR receptor for poliovirus. The (+) strand RNA is uncoated by insertion through the cell membrane into the cytoplasm (**Fig. 6.23**). The role of endocytosis is debated; poliovirus requires no endocytosis, but rhinovirus genome uncoating may require endocytosis and low-pH induction.

Progeny virions

Figure 6.23 **Picornavirus life cycle.** A picornavirus inserts its (+) strand RNA into the cell. Reproduction occurs entirely in the cytoplasm. A key step is the early translation of a viral gene to make RNA-dependent RNA polymerase. The RNA-dependent RNA polymerase uses the picornavirus RNA template to make (–) strand RNA, which then serves as a template for other viral mRNAs as well as progeny genomic RNA.

After uncoating, a gene in the viral RNA is translated by host ribosomes to make RNA-dependent RNA polymerase. The RNA-dependent RNA polymerase uses the viral RNA template to make (–) strand RNA. The (–) strand RNA then serves as a template for other viral mRNAs as well as progeny genomic RNA. Capsid proteins are translated by host ribosomes, and the capsids self-assemble in the cytoplasm. Virions then assemble at the cell membrane and are released by budding out.

Note that other kinds of RNA virus, such as influenza virus, encapsidate a (–) strand genome. In this case, the (–) strand must serve as template to generate mRNA as well as (–) strand progeny genomes. Influenza virus replication includes other interesting molecular complications, discussed in Chapter 11.

RNA retroviruses. Retroviruses include human immunodeficiency virus (HIV), the causative agent of AIDS, and feline leukemia virus (FeLV), a disease commonly afflicting domestic cats (see Table 6.1, Group VI). A retrovirus uses a reverse transcriptase to make a DNA copy of its RNA genome (**Fig. 6.24**). Instead of being translated from an early gene, the reverse transcriptase is actually carried within the virion, bound to the RNA genome with a primer in place. The virion contains two copies of the HIV genome, each carrying its own reverse transcriptase. After uncoating in the cytoplasm, the viral RNA is copied into double-stranded DNA.

The DNA copy then enters the nucleus, where it integrates by recombining with the host genome. The viral genome then replicates silently in the host cell, generating only a small number of virions without apparent effect on the host. To generate virions, a host RNA polymerase transcribes viral mRNA and viral genomic RNA. The viral mRNA reenters the cytoplasm for translation to produce coat proteins and envelope proteins. The coat proteins are transported by the endoplasmic reticulum (ER) to the cell membrane, where virions self-assemble and bud out.

At a certain point, the host cell can suddenly begin to generate large numbers of virions. The cause of accelerated reproduction is poorly understood, although it

can involve stress conditions such as poor health or pregnancy. The mechanism of control involves several protein regulators encoded by the virus. The full process and regulation of HIV reproduction is exceedingly complex; further molecular details are discussed in Chapter 11.

Oncogenic viruses. DNA viruses such as HPV and adenovirus can insert their genomes into the chromosome of a host cell in a manner analogous to that of a lysogenic bacteriophage. In some cases, the transfer of host genes to abnormal chromosome locations can generate **oncogenes**, genes whose expression at inappropriate times causes uncontrolled proliferation of the cell and ultimately cancer. Viruses that carry oncogenes are known as **oncogenic viruses**. This capacity for gene transfer may be manipulated artificially for gene therapy (discussed in Chapter 12). For example, adenovirus and related viruses are being engineered to deliver a corrective gene to the lungs of people with cystic fibrosis.

THOUGHT QUESTION 6.7 What are the advantages and disadvantages to the virus of replication by the host polymerase, compared with using a polymerase encoded by its own genome?

Plant Virus Life Cycles

All kinds of plants are subject to viral infection. Plant viruses pose enormous challenges to agriculture, where the concentrated growth of a single strain (monoculture) provides ideal conditions for a virus to spread.

Plant virus entry to host cells. In contrast to animal viruses and bacteriophages, plant viruses infect cells by mechanisms that do *not* involve specific membrane receptors. This may be because plant cell membranes are covered by thick cell walls impenetrable to virion uptake or genome insertion. Thus, the entry of plant viruses usually requires **mechanical transmission**, nonspecific access through physical damage to tissues, such as abrasions of the leaf surface by the feeding of an insect. The means of mechanical transmission of plant viruses are limited by the cell wall and by the sessile nature of plants. Most plant viruses gain entry to cells by one of three routes:

- **Contact with damaged tissues.** Viruses such as tobacco mosaic virus appear to require nonspecific entry into broken cells.
- **Transmission by an animal vector.** Insects and nematodes transmit many kinds of plant viruses. For example, the geminiviruses are inoculated into cells by plant-eating insects such as aphids, beetles, or grasshoppers.
- **Transmission through seed.** Some plant viruses enter the seed and infect the next generation.

Figure 6.25 Plum pox is caused by potyvirus. **A.** Potyvirus, a filamentous (+) strand RNA virus, approximately 800 nm in length (TEM). **B.** Potyvirus is transmitted by aphids, which suck the plant sap and release potyvirus into the damaged tissues. **C.** Streaking of flowers caused by potyvirus infection. **D.** Ring-shaped "pox" appear on the infected fruit and the stone inside.

An economically important plant virus is the potyvirus plum pox virus (see Table 6.1, Group IV), a major pathogen of plums, peaches, and other stone fruits. Plum pox virus, a (+) strand RNA virus, is transmitted by aphids (**Fig. 6.25**). Following infection, the spread of the virus generates streaked leaves and flowers as well as ring-shaped "pox" marks on the surfaces of the fruit and of the stone within.

Plant virus transmission through plasmodesmata. Within a plant, the thick cell walls prevent a lytic burst or budding out of virions. Instead, plant virions spread to uninfected cells by traveling through **plasmodesmata** (singular, **plasmodesma**). Plasmodesmata are membrane channels that connect adjacent plant cells (**Fig. 6.26**). The outer channel connects the cell membranes of the two cells, whereas the inner channel connects the endoplasmic reticulum.

Passage through the plasmodesmata requires action by **movement proteins** whose expression is directed by the viral genome. In some cases, the movement proteins transmit the entire plant virion; in other cases, only the nucleic acid itself is small enough to pass through. The independent movement and transmission of plant viral genomes suggest infective strategies in common with those of viroids, which lack capsids altogether.

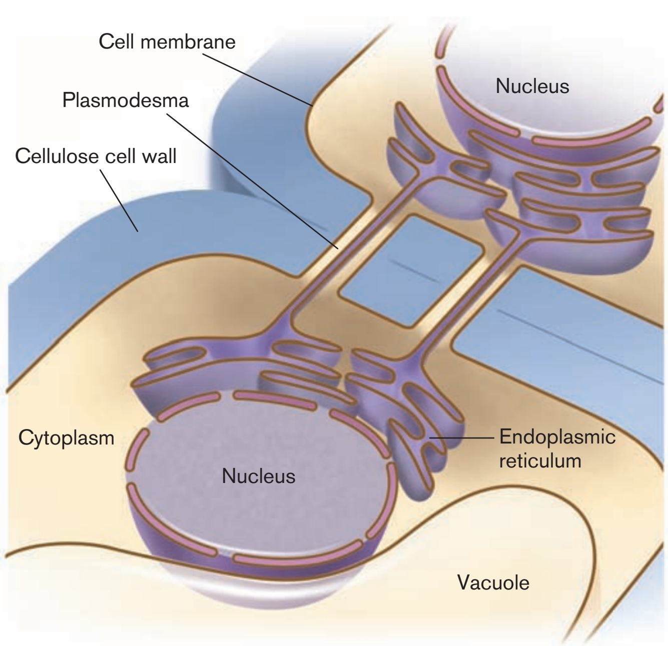

Figure 6.26 Plant cells connected by plasmodesmata. Plasmodesmata offer a route for plant viruses to reach uninfected cells.

DNA pararetroviruses. Pararetroviruses possess a DNA genome that requires transcription to RNA in the cytoplasm, followed by reverse transcription to form DNA genomes for progeny virions (**Fig. 6.27**). While some pararetroviruses infect humans, such as hepadnavirus, the best-known pararetrovirus is cauliflower mosaic virus, or caulimovirus (see Table 6.1, Group VII). Caulimovirus is an important tool for biotechnology because it has a highly efficient promoter for gene transcription, allowing high-level expression of cloned genes. Vectors derived from caulimoviruses are often used to construct transgenic plants.

Caulimovirus is transmitted by secretions from an insect whose bite damages plant tissues, providing access to the cytoplasm. The caulimovirus genome moves from the cytoplasm to the cell nucleus through a nuclear pore. Within the nucleus, two promoters on its DNA genome direct transcription to RNA. The two RNA transcripts exit the nucleus for translation by host ribosomes to make viral proteins. A host reverse transcriptase, present in plant cells, generates DNA viral genomes. After virions are assembled in the cytoplasm, movement proteins help transfer them through plasmodesmata into an adjacent cell.

A caulimovirus promoter sequence is commonly used in gene transfer vectors for plant biotechnology. The advantage of viral promoters is their highly efficient transcription of a transferred gene, such as one conferring pesticide resistance. In the field, 10% of cruciferous vegetables are typically infected with caulimovirus. Some critics of gene technology are concerned that the prevalence of the caulimovirus promoter in transgenic crops may lead to the evolution of new pararetroviruses.

Figure 6.27 Caulimovirus life cycle. The cauliflower mosaic virus, a caulimovirus, uses host RNA polymerase to copy its DNA into RNA and uses host reverse transcriptase to make DNA copies. The DNA genomes are packaged into progeny virions that use virus-encoded movement proteins to travel through plasmodesmata to an adjacent uninfected cell.

TO SUMMARIZE:

- **Host cell surface receptors** mediate animal virus attachment to a cell and confer host specificity and tropism.
- **Animal DNA viruses** either inject their genome or enter the host cell by endocytosis. The viral genome requires uncoating for gene expression.
- **RNA viruses** use an RNA-dependent RNA polymerase to transcribe their messenger RNA.
- **Retroviruses** use a reverse transcriptase to copy their genomic sequence into the chromosome of a host cell.
- **Plant viruses** enter host cells by transmission through a wounded cell surface or an animal vector. Plant viruses travel to adjacent cells through plasmodesmata.
- **Pararetroviruses** contain DNA genomes but generate an RNA intermediate that requires reverse transcription to DNA for progeny virions.

6.6 Culturing Viruses

To study any living microorganism, we must culture it in the laboratory. Culturing viruses provides large numbers of virions and their components for analysis. A complication of virus culture is the need to grow the virus within a host cell. Therefore, any virus culture system must be a double culture of host cells plus viruses. Culturing viruses of multicellular animals and plants creates additional complications, as viruses show tropism for particular tissues or organs.

Batch Culture of Bacteriophages in Large Populations

Batch culture, or culture in liquid medium, enables growth of a large population of viruses for study. Bacteriophages can be inoculated into a growing culture of bacteria, usually in a culture tube or a flask. The culture fluid is then sampled over time and assayed for phage particles. The growth pattern usually takes the form of a step curve (**Fig. 6.28**).

To observe one cycle of phage reproduction, phages are added to host cells at a multiplicity of infection (MOI, ratio of phage to cells) such that every host cell is infected. The

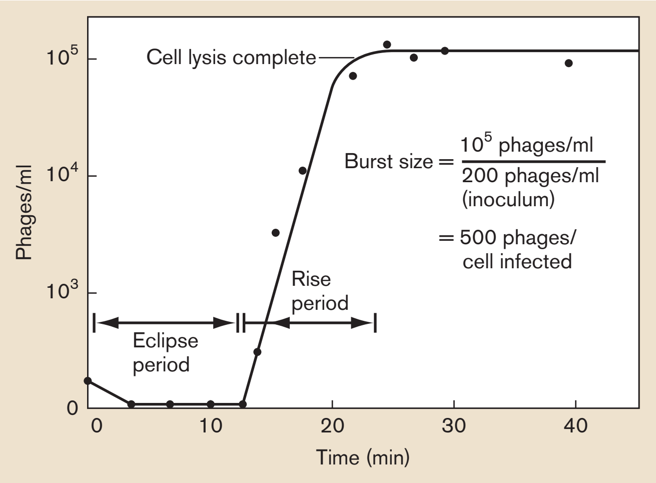

Figure 6.28 **One-step growth curve of a bacteriophage.** After initial infection of a liquid culture of host cells, the titer of virus drops near zero as all virions attach to the host. During the eclipse period, progeny phages are being assembled within the cell. As cells lyse (the rise period), virions are released until they reach the final plateau. The infectious cycle is typically complete within less than an hour.

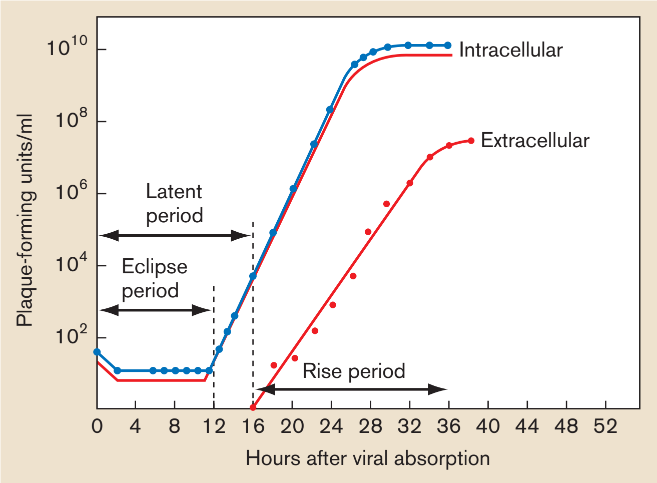

Figure 6.29 **One-step growth curve for a virus.** The titer of extracellular virus drops near zero during the latent period, as all virions adsorb to the host. Then progeny virions begin to emerge by budding out from the infected cell. The growth curve of a rapidly replicating animal virus typically takes hours to level off; the "burst" event is not defined as clearly as for phages.

phage particles immediately adsorb to surface receptors of host cells and inject their DNA. As a result, virions are virtually undetectable in the growth medium for a short period after infection; this is called the **eclipse period**.

For some species, it is possible to distinguish between the eclipse period and a **latent period**, which includes the eclipse period plus the time during which progeny viruses have been formed but remain trapped within the cell. The latent period is particularly significant in animal viruses, where large numbers of virions usually generate progeny through budding out of the host cell (**Fig. 6.29**).

NOTE: The *latent period* of a lytic virus is the period between initial phage-host contact and the first appearance of progeny phage. This must be distinguished from the *latent infection* of a virus that maintains its genome within a host cell without reproducing virions.

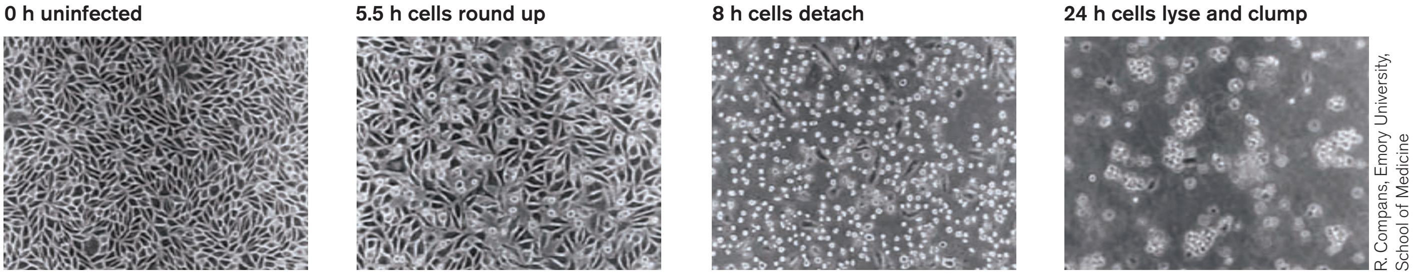
As cells begin to lyse and liberate progeny viruses, the culture enters the **rise period**, in which virus particles are appearing in the growth medium. The rise period ends when all the progeny viruses have been liberated from their host cells. If the number of viruses that go on to reinoculate further host cells is small, then the virus concentration at the end point divided by the original concentration of inoculated phage approximates the **burst size**; that is, the number of viruses produced per infected host cell. The burst size may be estimated by dividing the concentration of progeny virions by the concentration of inoculated virions, assuming that all the original virions infect a cell.

The burst size, together with the cell density prior to lysis, determines the concentration of the resultant suspension of virus particles, called a **lysate**. In the case of bacteriophages, a lysate of phage particles can be extremely stable, remaining infective at room temperature for many years. Eukaryotic viruses tend to be less stable and need to be maintained in culture or deep freeze.

THOUGHT QUESTION 6.8 Why does bacteriophage reproduction give a step curve, whereas cellular reproduction generates an exponential growth curve? Could you design an experiment in which viruses generate an exponential curve? Under what conditions does the growth of cellular microbes give rise to a step curve?

Animal Viruses Are Grown in Tissue Culture

In the case of animal and plant viruses, the multicellular nature of the host is an important factor in the pathology and transmission of the pathogen (discussed in Chapters 26 and 27). Animal viruses can be cultured within whole animals by serial inoculation, where virus is transferred from an infected animal to an uninfected one. Culture within animals ensures that the virus strain maintains its original **virulence** (ability to cause disease). But the process is expensive and laborious, involving large-scale use of animals.



R. Compans, Emory University, School of Medicine

Figure 6.30 **Poliovirus replication in human tissue culture.** Before infection (0 hours), the cultured cells grow in a smooth layer. At 5.5 hours after infection, cells are starting to retract and round up. At 8 hours, infected cells detach from the culture dish. By 24 hours, cells have lysed or in some cases clumped with other cells.

A historic event in 1949 was the first successful growth of a virus in tissue culture. Poliovirus, the causative agent of the devastating childhood disease poliomyelitis, was grown in human cell tissue culture (**Fig. 6.30**) by John F. Enders, Thomas J. Weller, and Frederick Robbins at the Children's Hospital in Boston. As heralded that year in *Scientific American*, "It means the end of the 'monkey era' in poliomyelitis research. . . . Tissue-culture methods have provided virologists with a simple in vitro method for testing a multitude of chemical and antibiotic agents." Since then, tissue culture has remained the most effective way to study the molecular biology of animal and plant viruses and to develop vaccines and antiviral agents.

Some viruses can be grown in a tissue culture of cells growing confluently on a surface. The fluid bathing the tissue layer is sampled for virus concentration. As in the case of bacteriophage batch culture, we can define an eclipse period, a latent period before appearance of the first progeny virions in the culture fluid, and a rise period. The intracellular completion of virion assembly within the cell is important for transmission of viral infection because some viruses have the ability to spread their virions from cell to cell without ever existing as such outside. In this way, they can avoid detection by the immune system to which they might be vulnerable.

In tissue culture, the time course of animal virus replication is usually much longer (hours or days) than that of bacteriophages (typically less than an hour under optimal conditions). The burst size, however, of animal viruses is typically several orders of magnitude larger than that of phages. The reason for the larger burst size is probably that the volume of the eukaryotic host cell is usually much larger than that of a bacterial host, thus providing a larger supply of materials to build virions.

Not all animal viruses exhibit growth that can be represented by a step curve. Some species, called **slow viruses**, bud off virions relatively slowly, without immediately lysing the host cell. A well-known family of slow viruses is the **lentiviruses** (literally, "slow viruses"), a group of retroviruses that includes HIV. HIV and related retroviruses are known for their long incubation periods, in some cases many years, during which time extremely low concentrations of virions are produced by infected cells.

Plaque Isolation and Assay of Bacteriophages

For the investigation of cellular microbes, an important tool is the culturing of individual colonies on a solid substrate that prevents dispersal throughout the medium, as described in Chapters 1 and 4. Plate culture of colonies enables us to isolate a population of microbes descended from a common progenitor. But viruses cannot be isolated as "colonies." The reason is that although viruses can be obtained at incredibly high concentrations, they disperse in suspension. Even on a solid medium, viruses never form a solid visible mass comparable to the mass of cells that constitutes a cellular colony.

In viral plate culture, viruses from a single progenitor lyse their surrounding host cells, creating a clear area called a plaque. The **plaque assay** for lytic bacteriophages was invented early in the twentieth century by the French microbiologist Felix d'Herelle, who was the first to recognize that bacterial cells can be infected by bacteriophages.

To perform a plaque assay of bacteriophages, a diluted suspension of bacteriophages is mixed with bacterial cells in soft agar, and the mixture is then poured over a nutrient agar plate (**Fig. 6.31**). If no bacteriophages are present, the bacteria grow homogeneously as an opaque sheet over the surface (confluent growth). The presence of a phage is detected as a plaque, a clear circle seemingly cut out of the bacterial growth. A plaque is formed when a single virus infects a cell, replicates, and spreads progeny phages to adjacent cells, killing them as well (**Fig. 6.32**). In contrast to the clear plaques produced by lytic phages (as shown in the figure), temperate (lysogenic) phages make cloudy plaques containing lysogenized viable cells. The prophage in the host genome protects the cells from subsequent infection and lysis by another phage.

Plaques offer a convenient way to isolate a recombinant DNA molecule contained in a bacteriophage vector. In **Figure 6.32B**, the blue plaques result from the phage vector, a derivative of phage M13 that carries a gene encoding the enzyme β-galactosidase. This enzyme converts a colorless compound into a blue dye. When the indicator gene is interrupted by an inserted recombinant gene, the phage produces white plaques, which indicate the successful production of recombinant DNA phages.

Plaques can be counted and used to calculate the concentration of phage particles, or **plaque-forming units (PFUs)**, in a given suspension of liquid culture. The liquid culture can be analyzed by serial dilution in the same way one would analyze a suspension of bacteria.

Plaque Isolation and Assay of Animal Viruses

For animal viruses, the plaque assay has to be modified because it requires infection of cells in tissue culture. Tissue culture usually involves growth of cells in a monolayer on the surface of a dish containing fluid medium, which would quickly disperse any viruses released by lysed cells. To solve this problem, in 1952 Renato Dulbecco, at the California Institute of Technology, modified the tissue culture procedure for plaque assays (**Fig. 6.33A**). In Dulbecco's method, the tissue culture with liquid medium is first inoculated with virus. After sufficient time to allow for viral attachment to cells, the fluid is removed and replaced by a gel medium. The gel retards dispersal of viruses from infected cells, and as the host cells die, plaques can be observed. **Figure 6.33B** shows a plate culture of adenovirus.

Animal viruses that do not kill their host cells require a different kind of assay based on identification of a **focus** (plural, **foci**), a group of cells infected by the virus. In a **fluorescent-focus assay**, the infected cells under the gel overlay are incubated for a sufficient period to allow production of progeny virions. The plasma membranes of the cells are then made permeable by treatment with an organic solvent, and an antiviral antibody is added. Unattached antibodies are then washed away, and a second antibody is added that recognizes the first antibody molecule. The second antibody is conjugated to a fluorophore whose fluorescence reveals

foci of cells, each of which has arisen from a single virion in the original inoculum.

Another kind of fluorescent-focus assay uses green fluorescent protein (GFP). The viruses are genetically engineered to contain a GFP gene fusion, a labeling technique discussed in Chapter 3. The GFP fluorescence reveals foci of virus-infected cells (**Fig. 6.34A**).

A focus assay can also be used to isolate oncogenic viruses. Oncogenic, or cancer-causing, viruses actually **transform** their host cells into cancer cells. Cancer cells lose contact inhibition; they grow up in piles instead of remaining in the normal monolayer. These piles of transformed cells, or transformed foci, can easily be visualized and counted. This is known as the **transformed-focus assay** (**Fig. 6.34B**).

Cells infected by an oncogenic virus have produced three foci of transformed cells. Transformed cells grow in an uncontrolled manner, which can produce a tumor.

TO SUMMARIZE:

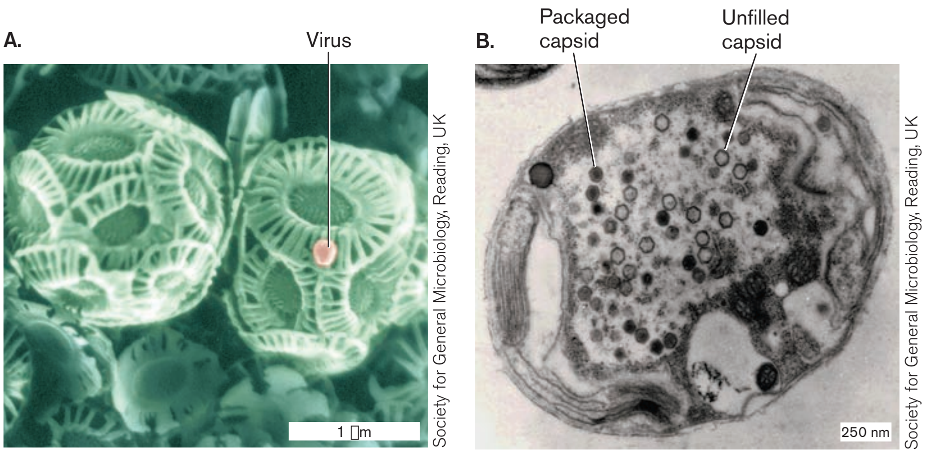
- **Culturing viruses** requires growth in host cells. Bacteriophages may be cultured either in batch culture or as isolated plaques on a bacterial lawn.
- **Batch culture** of viruses generates a step curve.
- **Animal viruses** are cultured within animals or as plaques in a tissue culture.
- **Fluorescent-focus assays** reveal foci of virus-infected cells.
- **Oncogenic viruses** are cultured as foci of cancer-transformed host cells.

6.7 Viral Ecology

Viruses exist naturally within host organisms in complex ecosystems. Viral persistence in natural ecosystems is significant for human health and for agricultural plants and animals. Persistence in wild populations provides a reservoir of infection that hinders eradication of a pathogen, especially when it is associated with an insect vector (carrier organism) such as ticks or mosquitoes.

Environmental Change Leads to Emergence of Viral Pathogens

Changing distribution patterns of insect vectors and animal hosts can generate new epidemics of a pathogen in



Society for General Microbiology, Reading, UK

regions where the virus could not spread before. Such changes in distribution can be brought about by many factors, including global climate change (**Special Topic 6.1**).

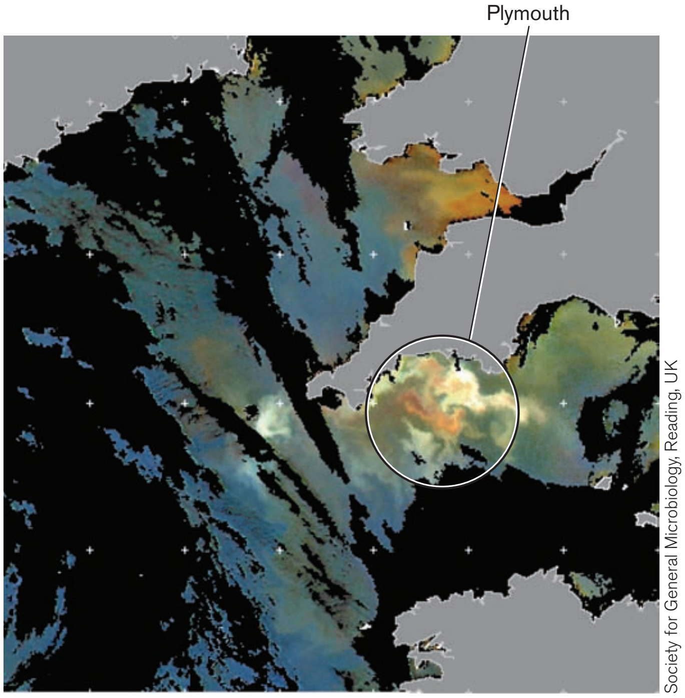
Some emerging viruses arise as variants of endemic milder pathogens. Viruses long associated with a host, such as the common cold viruses (rhinoviruses), tend to have evolved a moderate disease state that provides ample opportunities for host transmission. A virus that "jumps" from an animal host, however, may cause a more acute syndrome with higher mortality. The best-known case is the exceptionally virulent emerging strains of influenza, which generally result from intracellular recombination of human strains with strains from pigs or ducks (discussed in Chapter 11). Wild animals consumed for food introduce entirely new species of viruses to human populations. For example, HIV is believed to have emerged from apes whose meat was consumed by humans.

Viruses Have Important Roles in Ecosystems

Viruses fill important niches in all ecosystems. Two important roles of viruses are:

- **Limiting host population density.** An increase in host population density increases the rate of transmission of viral pathogens. As the host population declines, natural selection results in individuals that are less susceptible. Thus, viruses can limit host density without extinction of the host. An example is the myxovirus introduced into Australia to curb the population of rabbits (which had been previously introduced by British colonists). The myxovirus ultimately maintained the rabbits at a reduced density, less destructive to the ecosystem.
- **Selecting for host diversity.** Each viral species has a limited host range and requires a critical population density to sustain the chain of infection. The virus limits its host species to a population density far lower than that sustainable by the available resources, thus preventing the dominance of any one species. In this way, the presence of viruses fosters the evolution of many distinct host species. The role of viruses in diversity is exemplified in marine phytoplankton, which are highly susceptible to viruses and display an exceptional range of species diversity.

In the oceans, viruses are the most numerous and genetically diverse forms of life. The number of bacteriophages and algal viruses can reach 10^7 (10 million) per milliliter. **Figure 6.35** shows examples of marine viruses infecting phytoplankton such as the algae *Emiliana huxleyi* and *Pavlova vivescens*. When marine algae overgrow, generating an algal bloom, viruses play a decisive role in controlling the bloom, such as the overgrowth of *Emiliana huxleyi* (**Figure 6.36**). Consumer organisms apparently cannot grow fast enough to control such blooms, but



Society for General Microbiology, Reading, UK

Special Topic 6.1 West Nile Virus, an Emerging Pathogen

In the spring of 1999, New Yorkers noticed an unusual number of dead crows and other local birds. Then people began falling ill with an unfamiliar form of encephalitis (brain inflammation) caused by an avian virus never before seen in North America. The virus, a (+) single-stranded RNA virus, comes from the flavivirus family, which includes yellow fever and dengue (breakbone fever). These pathogens are all endemic to warmer environments, such as the Mediterranean and North Africa—hence the name, West Nile virus. Like yellow fever, a disease made infamous by its devastation of the southern United States in the nineteenth century, West Nile virus is transmitted between humans and animals by mosquitoes (**Fig. 1**).

Why the sudden appearance of West Nile virus in the United States? The answer is not known for certain, but some climatologists argue that West Nile and other emerging pathogens arise from unusual weather patterns related to global climate change (**Fig. 2**). West Nile virus is generally found in species of mosquitoes that fare poorly in the cold of winter. In 1998–1999, however, the unusually warm winter enabled a few mosquitoes carrying the virus to survive until the spring. The spring that followed was drier than usual, forcing birds to spend more time at dwindling water pools, where mosquitoes were concentrated. The July heat wave then increased the rate of viral replication in the mosquitoes, which reached unusual population densities later that summer. As the cycle continued, mosquitoes reinfected birds, which then infected more mosquitoes. Eventually, the cycle included mosquitoes infecting humans.

As of this writing, West Nile virus has spread to most of the United States and appears to be endemic to North America. Meanwhile, research continues to determine whether clearer links can be established between climate changes and emerging pathogens.

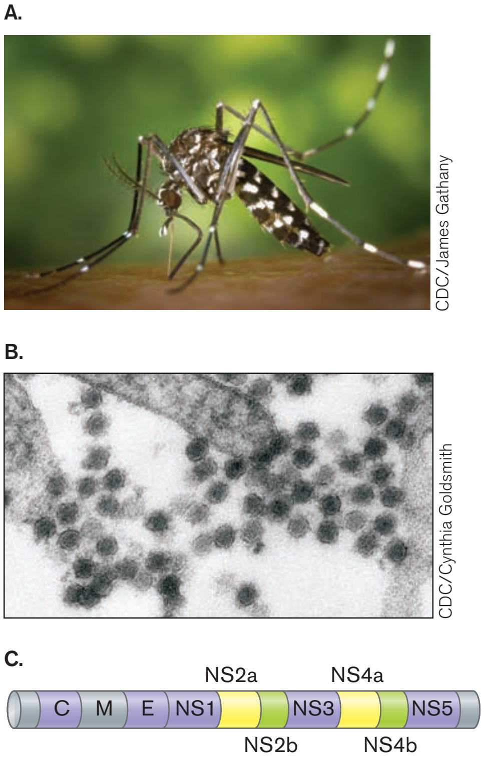

Figure 1 West Nile virus. A. The mosquito carries West Nile virus. **B.** West Nile virus particles (50 nm in diameter) forming within an infected cell (TEM). **C.** Like hepatitis C, West Nile virus is a flavivirus, with a (+) strand RNA of 10,000 nucleotides. The genome encodes ten proteins, three of which are structural proteins (C, M, and E) and seven of which are nonstructural proteins (NS1, NS2a, NS2b, NS3, NS4a, NS4b, and NS5).

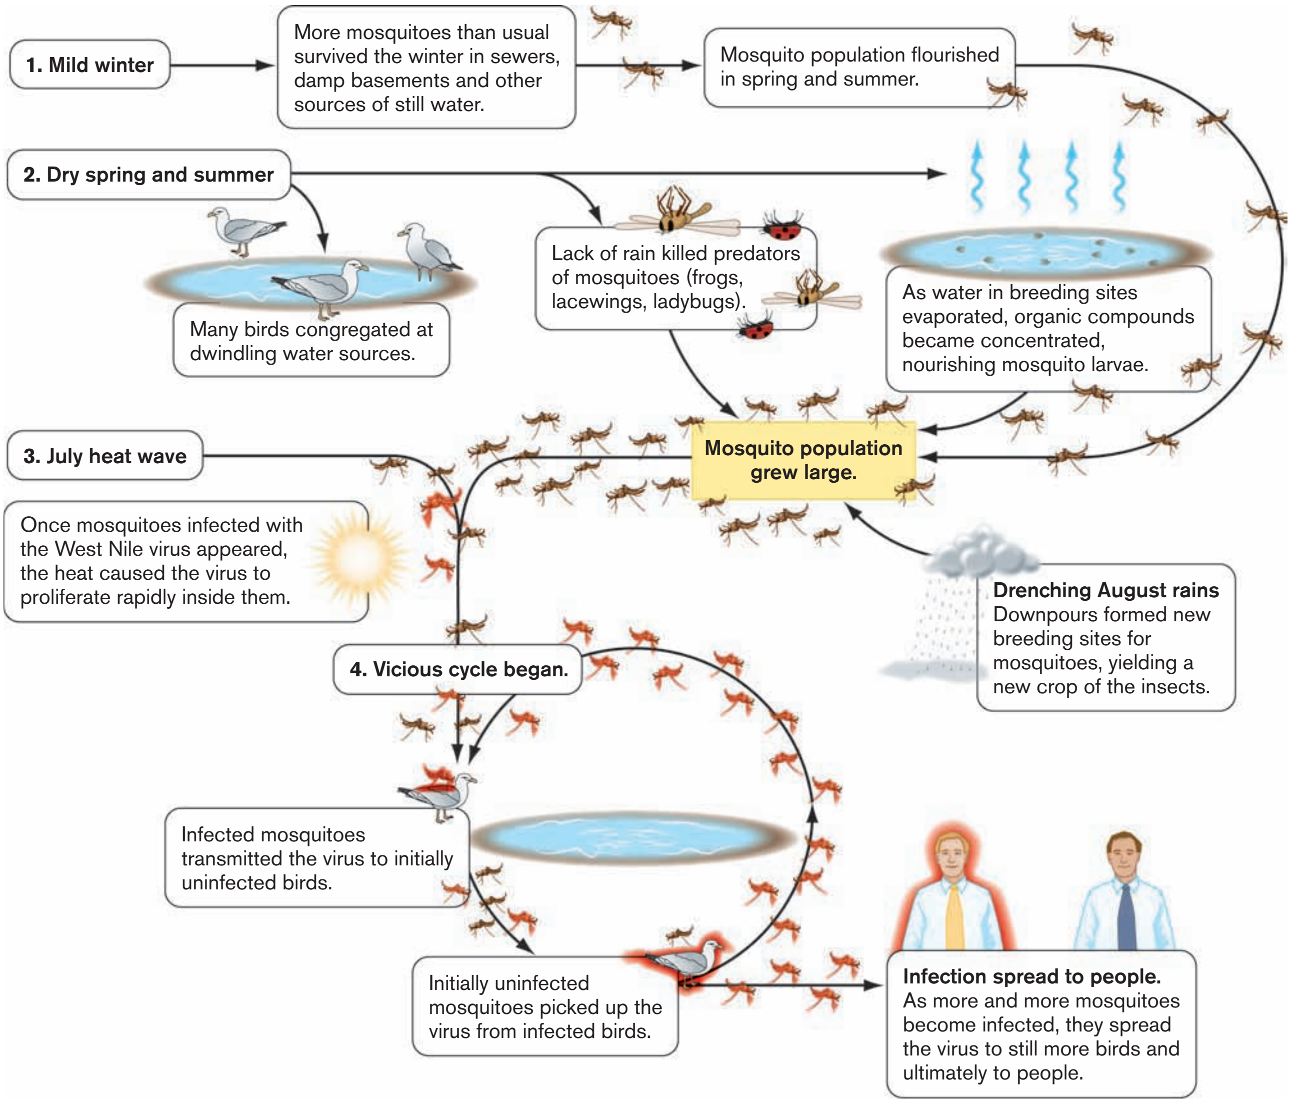
viruses spread rapidly through the population. By lysing the algae as they grow, viruses return algal carbon and minerals to the surface water before the algae starve to death and their bodies sink to less productive depths.

On a global scale, marine viruses play a significant role in the carbon balance. Models of ocean carbon flux typically emphasize the consumption of phytoplankton by grazers and the consumption of grazers by carnivores (**Fig. 6.37**). At each level, some of the carbon fixed as biomass sinks to the ocean floor, removed from the carbon cycle. But at each level, viral infection and lysis converts the bodies of phytoplankton, grazers, and carnivores into detritus consisting of small organic particles. The organic material is consumed by bacteria, whose rapid respiration releases much CO_2. Thus, carbon is diverted from the ocean sink into CO_2 returning to the atmo-



1. Mild winter
More mosquitoes than usual survived the winter in sewers, damp basements and other sources of still water.
Mosquito population flourished in spring and summer.
2. Dry spring and summer
Many birds congregated at dwindling water sources.
Lack of rain killed predators of mosquitoes (frogs, lacewings, ladybugs).
As water in breeding sites evaporated, organic compounds became concentrated, nourishing mosquito larvae.
Mosquito population grew large.
3. July heat wave
Once mosquitoes infected with the West Nile virus appeared, the heat caused the virus to proliferate rapidly inside them.
Drenching August rains
Downpours formed new breeding sites for mosquitoes, yielding a new crop of the insects.
4. Vicious cycle began.
Infected mosquitoes transmitted the virus to initially uninfected birds.
Initially uninfected mosquitoes picked up the virus from infected birds.
Infection spread to people.
As more and more mosquitoes become infected, they spread the virus to still more birds and ultimately to people.

Figure 2 **An emerging pathogen.** In the changing global climate, an emerging pathogen threatens wildlife and people. West Nile virus, originally found in Africa and the Mediterranean, is now spreading through the Western Hemisphere, probably owing to an increase in warm weather. The spread of the virus involves transfer between mosquitoes and avian, animal, or human hosts.

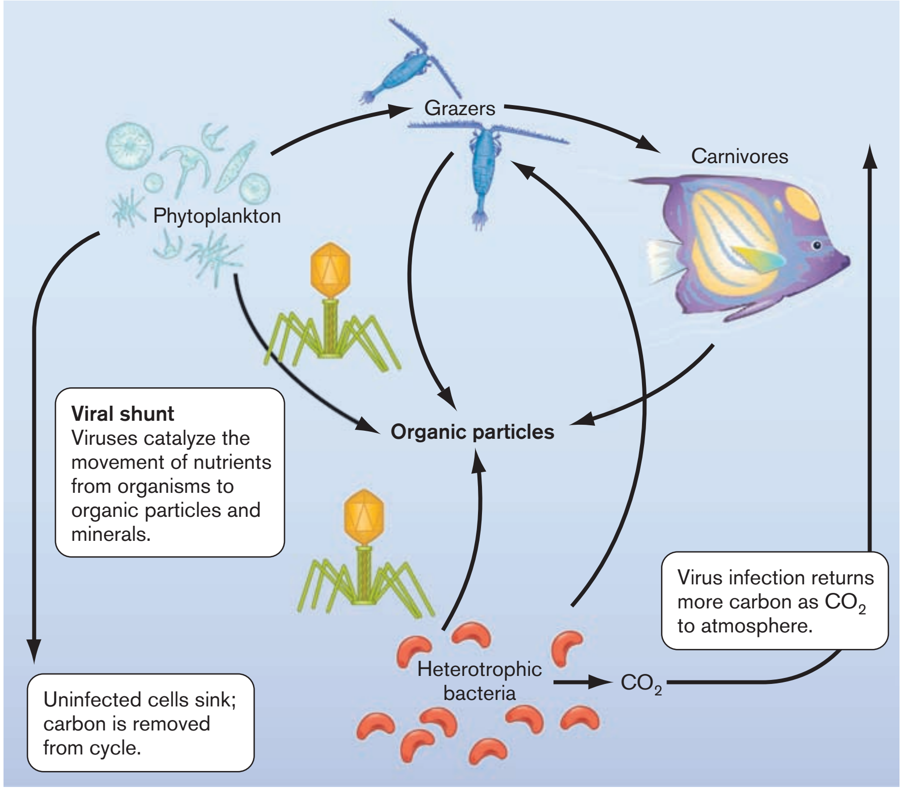
sphere—a factor that must be considered in models of global warming.

TO SUMMARIZE:

- **Environmental change** results in new emerging viral pathogens.
- **Host population density** is limited by virus infection, and host genetic diversity is increased.
- **Marine viruses** are the major consumers of phytoplankton. Viral activity substatially impacts the global carbon balance.

Concluding Thoughts

In this chapter, we have covered general approaches to studying the structure and function of all kinds of



Grazers
Carnivores
Phytoplankton
Viral shunt
Viruses catalyze the movement of nutrients from organisms to organic particles and minerals.
Organic particles
Virus infection returns more carbon as CO_2 to atmosphere.
Heterotrophic bacteria
CO_2
Uninfected cells sink; carbon is removed from cycle.

Figure 6.37 Marine viruses recycle carbon. Viruses divert the flow of carbon from marine phytoplankton and bacteria away from consumers and into organic particles (detritus). The organic particles are consumed by bacteria that respire CO_2.

viruses. As devastating as viruses can be to their hosts, they also provide engines of genomic change (see Chapter 9) and ecological balance (see Chapter 21). Understanding virus function prepares us to discuss microbial genetics in Chapters 7–10. Chapter 11 then explores in depth the molecular basis of viral genomes and reproduction. Molecular virology is a field of growing importance for medical and agricultural research, for genetic engineering and gene therapy, and for understanding natural ecosystems.

CHAPTER REVIEW

Review Questions

1. Compare and contrast the form of icosahedral and filamentous (helical) viruses, citing specific examples.
2. How do viral genomes gain entry into cells in bacteria, plants, and animals?
3. Explain the structure and function of the seven Baltimore groups of viral genomes.
4. How do viral genomes interact with host genomes, and what are the consequences for host evolution?
5. Compare and contrast the lytic, lysogenic, and slow-release life cycles of bacteriophages. What are the strengths and limitations of each?
6. Compare and contrast the life cycles of RNA viruses and DNA viruses in animal hosts. What are the strengths and limitations of each?
7. Explain the plate titer procedure for enumerating viable bacteriophages. How must this procedure be modified to titer animal viruses? Oncogenic viruses?
8. Explain the generation of the step curve of virus proliferation. Why is virus proliferation generally observed as a single step, or generation, in contrast to the life cycles of cellular microbes, outlined in Chapter 4?
9. Explain the key contributions of viruses to natural ecosystems. What may happen in an ecosystem where viruses are absent or fail to cause significant infection?

Genes and Genomes

AN INTERVIEW WITH

RICHARD LOSICK: THE THRILL OF DISCOVERY IN MOLECULAR MICROBIOLOGY

Richard Losick has taught at Harvard for more than three decades, and his creative teaching was honored when he was named a Howard Hughes Medical Institute (HHMI) Professor. A member of the National Academy of Sciences, Losick has authored more than 200 research articles on bacterial genetics and cell biology. He discovered how *Bacillus* sporulation is controlled by alternative sigma factors that regulate transcription. To dissect sporulation and the cell division cycle, he uses fluorescent proteins to visualize individual subcellular parts of bacteria.

Courtesy of Richard Losick

Richard Losick, Harvard College Professor. Losick has made major discoveries on the molecular and cellular biology of *Bacillus subtilis.*

Why did you decide to make a career in microbiology? Did you begin research as an undergraduate?

When I was in grade school, I used to read science books and do experiments on my own. I thought that school was boring, and I didn't realize that science was a subject that I would learn about later in school!

When I was an undergraduate at Princeton, I joined the laboratory of a newly arrived professor, Charles Gilvarg, who studied amino acid biosynthesis in bacteria. I fell in love with bacteria from that experience, and I have remained fascinated by bacteria ever since.

Why do you study *Bacillus subtilis*? How is your work relevant to the insecticide *B. thuringiensis* and the human pathogen *B. anthracis*?

Bacillus subtilis is extraordinarily rich in its biology. Its ability to metamorphose into a spore is endlessly fascinating. *B. subtilis* has the capacity to differentiate into specialized cells for DNA uptake (competence), to swim, to swarm on surfaces, to cannibalize sibling cells, and to form architecturally elaborate, multicellular communities. At the same time, its property of genetic competence (gene transfer between cells) makes it exceptionally facile for molecular genetic manipulation.

B. thuringiensis and *B. anthracis* are less favorable than *B. subtilis* for genetic manipulation, but the main features of spore formation are very similar in all three organisms. The crystal toxin of *B. thuringiensis* that has useful insecticidal properties is produced under sporulation control. The remarkable environmental resistance properties of *B. subtilis* spores are shared with its evil cousin *B. anthracis* and help us understand the challenge posed by the bioterrorism agent.

Your career has spanned a generation of revolutionary developments in genetics and molecular biology, such as the discovery of the sigma factors that regulate transcription of many genes. Would you describe how one of these developments came about?

After winning my PhD from MIT, I came to Harvard to work on a project involving the effect of a virus on bacterial cell membranes. The sigma subunit of *E. coli* RNA polymerase had just been discovered (by Dick Burgess and Andrew Travers at Harvard and by John Dunn and Ekkehard Bautz at Rutgers), and people were excited about the possible existence of alternative sigma factors (proteins that regulate large groups of genes). Meanwhile, A. L. Sonenshein was studying how certain bacterial viruses (bacteriophages) get trapped during spore formation by *Bacillus subtilis*. The phage is virulent but is shut off transcriptionally upon entering a sporulating cell. The phages are unable to grow in cells that have started to sporulate and instead become trapped in what will become the spore. So the poor spore, after waiting for long periods of time to germinate, gets killed upon germination by the enemy within.

Putting two and two together, we reasoned that maybe changes in the RNA polymerase during entry into sporulation could help explain the shutdown in viral gene expression. We got so excited about this idea that we began to work on RNA polymerase full time. This eventually led to the discovery that sporulation is governed by a cascade of bacterial sigma factors.

Meanwhile, in collaboration with Jan Pero, we found that phage SP01 encodes and produces two alternative sigma factors upon infecting growing cells. These regulatory proteins, the first examples of alternative sigmas, drive the phage program of gene transcription. Since then, alternative sigmas have emerged as a widespread

Sporulating cells of *Bacillus subtilis* with molecular parts labeled by fluorophores. Red fluorescence (FM4-64) labels the cell membrane; blue (DAPI) the DNA; and green (green fluorescent protein) a DNA pump that translocates a chromosome across the division septum from the mother cell (the big cell) into the forespore (the small cell on the upper right). (Cell length, 2–3 μm.)

theme in the control of gene sets in many different kinds of bacteria.

What is the significance of sporulation as a developmental process?

Sporulation is an extremely attractive system for understanding cellular differentiation because it is both complicated enough to mimic features of development in higher organisms and accessible enough to be subject to genetic, biochemical, and cytological manipulation. Sporulating cells undergo a true process of cellular differentiation, in which the two cellular compartments of the sporangium communicate with each other in a back-and-forth manner by intricate signaling systems.

How was the technology developed to visualize chromosome dynamics in *Bacillus*?

In the old days, bacteria were viewed as an amorphous vessel with enzymes floating around inside. Now we understand that bacteria are highly organized, that proteins often have subcellular addresses in bacteria; thus, cytology has become an important aspect of bacterial research.

One of the keys to this revolution was the introduction of green fluorescent protein (GFP) as a tool for visualizing the subcellular localization of proteins in cells. Andrew Murray and Andrew Belmont figured out that GFP could also be harnessed to visualize the location of sites on DNA by attaching the fluorescent protein to a protein that binds to specific sequences in DNA. Murray and Belmont used this trick to visualize centromeres in yeast. Andrew Wright and I extended this methodology to visualizing sites on chromosomes in bacteria. Traditional thinking was that origins tended to remain in cell middles, but we found that replication origins moved toward the cell poles during chromosome segregation, and with GFP we could visualize this in living cells.

How do students get involved with your research? Do you work with undergraduates as well as graduate students?

Yes, I always have undergraduates as well as graduate students in my lab, and both have contributed to some of our most significant findings. One special undergraduate was Aurelio Teleman, who was both a brilliant student and a gifted investigator. Working with a graduate student, Teleman helped create and exploit the system for visualizing the movement of a specific site in the bacterial chromosome that had been tagged with tandem lactose operon operators. He is now at the European Molecular Biology Laboratory.

As an educator, what innovations have you developed?

I enjoy the challenge of explaining complicated concepts and of making large-class instruction lively and interactive. I run a program for placing freshmen from disadvantaged backgrounds in laboratories of faculty for long-term research mentoring. Such students are often at greatest risk for dropping out of science, but a long-term relationship with a laboratory that begins early during the college years can keep these students (indeed all students) excited about science throughout college and beyond.

I believe that a positive experience in experimental work can represent one of the most memorable aspects of undergraduate education. And its benefit is not limited to future scientists. A science major with an associated experience in discovery research is excellent preparation for a wide variety of careers, including medicine, business, law, public policy, journalism, and education.

What advice do you have for today's students?

Join a lab! In science you can learn something that nobody else on Earth ever knew before. There's a special thrill about learning how living things function—the inner workings of living things. If you learn some new aspect of it, even if it's a tiny part, you've advanced knowledge for the whole of humankind.

Chapter 7

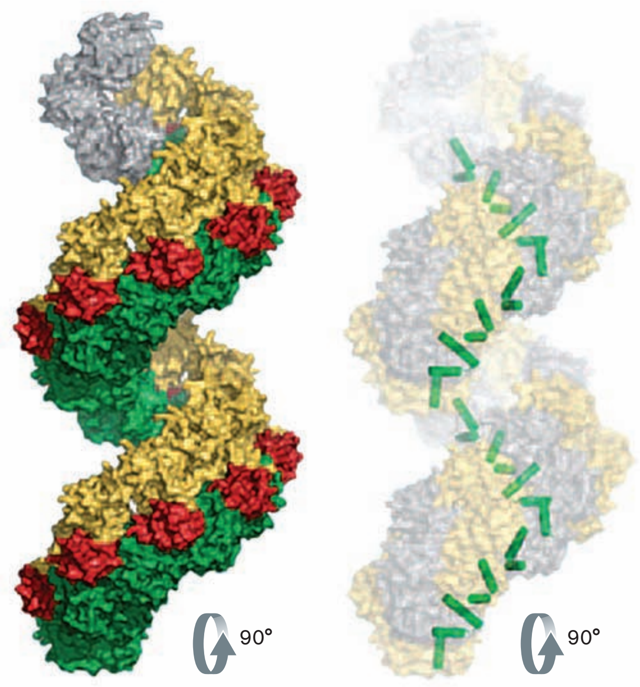
Genomes and Chromosomes

7.1 DNA: The Genetic Material
7.2 Genome Organization
7.3 DNA Replication
7.4 Plasmids and Bacteriophages
7.5 Eukaryotic Chromosomes: Comparison with Prokaryotes
7.6 DNA Sequence Analysis

A genome is all the genetic information that defines a species. We have known that chromosomes consist of DNA for over a hundred years, yet we have only recently been able to sequence complete genomes. Now we are in the postgenomic era in which biological research is driven, in large part, by knowledge of complete genome sequences.

Microbial genomes consist of one or more chromosomes made of DNA. Many bacteria have a single, circular chromosome, but some species have multiple chromosomes or even a mixture of linear and circular chromosomes. For example, the genome of *Sinorhizobium melliloti*, a major contributor to nitrogen fixation, consists of three circular chromosomes.

This chapter addresses basic as well as some advanced issues of DNA and genomes. What is DNA? How is it packaged in the cell? Because DNA is essential to life, nature must have devised a remarkable machine to replicate it. But how does this machine work? And do different species use different machines? Microbiology has played a leading role in answering these difficult questions—opening the door to post-genomic studies of all living things.



All cells accurately time the initiation of chromosome replication to cell division. In bacteria, DnaA protein accomplishes this by accumulating during growth and binding to the origin of replication, forming a right-handed helical filament. The figure shows four DnaA tetramers bound to origin DNA. On the left, the initial monomer of is colored grey to distinguish a single subunit of the filament. Gold, green and red mark different domains of subsequent monomers. The image on the right uses different colors to show individual monomers. The torsional strain caused by the filament may destabilize the adjacent DNA to allow assembly of the replication machine.

Source: Melissa L. Mott and James M. Berger. 2007. *Nature Reviews Microbiology* 5:343–354.

What makes each species unique is its genome, the sum total of its genes. The human genome is also supplemented by the genomes of all the microbes in the digestive tract. Collectively, intestinal microbes contain 100 times more genes than the human genome and provide key metabolic capabilities that humans lack, such as digesting complex plant materials. In the mid-twentieth century, one intestinal bacterium, *Escherichia coli*, became the focus of efforts to understand genes and genetics. The choice of *E. coli* was fortunate, as its genetics proved to be especially pliable.

In one remarkable experiment, a cell of *E. coli* was lysed, releasing its chromosome for electron microscopy. What spewed out of this single cell was a strand of DNA 1,500 times longer than *E. coli* itself. Scientists wondered how this enormous molecule could fit into a single cell, and how an enzyme could duplicate that much DNA (over 4.6 million base pairs) without the whole DNA molecule getting tangled up (**Fig. 7.1**). And how did it manage to do this in under 20 minutes, the doubling time of the organism? Half a century later, those questions continue to intrigue us.

Chapter 7 explores the nature of DNA, the structure of prokaryotic genomes, and the mechanisms used for their replication. We also examine how microbial enzymes that manipulate DNA were used to develop the fundamental techniques of present-day biotechnology, such as DNA restriction analysis, DNA sequencing, and the polymerase chain reaction (PCR). The expression of genes to make RNA and protein is discussed in Chapter 8. The remaining chapters of Part 2 present gene recombination and transmission (Chapter 9), the regulation of gene expression (Chapter 10), the specialized genetic mechanisms of viruses (Chapter 11), and the use of microbial genetic tools for research and biotechnology (Chapter 12). From the advances of the last 50 years, a new molecular and genomic perspective of biology has emerged.

7.1 DNA: The Genetic Material

The ability of plants and animals to transfer genetic traits was known well before we knew that DNA was the carrier of genetic information. Early researchers understood the Mendelian model of gene inheritance and how it dictated the passage of traits from parent to offspring in eukaryotes. This type of gene transfer is known as **vertical transmission**, as from parent to child. Bacteria, however, appeared to operate differently, because in addition to vertical transmission, they were able to conduct **horizontal transmission**—the transfer of small pieces of genetic information from one cell into another. The study of horizontal gene transfer in bacteria ultimately led to the discovery of horizontal transfer throughout animals and plants, albeit on a slower time scale because of their longer generation times. Mechanisms of horizontal transmission are discussed in Chapter 9.

Our path to understanding DNA began in 1928 with the discovery by Fred Griffith (1881–1941) that some unknown substance from dead cells of a virulent strain of *Streptococcus pneumoniae* could transfer virulence to living but otherwise harmless strains when both strains were coinjected into mice. This form of horizontal gene transfer, called transformation, led to the discovery in 1944 that genetic information is embedded in the base sequence of deoxyribonucleic acid (DNA) (see Section 1.6). A more contemporary example of transformation is the toxic shock gene that can be moved horizontally among strains of *Staphylococcus aureus*. As a result of these and many other experiments, we now appreciate that chromosomes are made of contiguous packets of information, called genes.

Genes are units of information composed of a sequence of DNA nucleotides of four different types, adenine (A), guanine (G), thymine (T), and cytosine (C). (For review at the level of introductory biology, see Appendix 1.) A **structural gene** is a string of nucleotides that can be decoded by an enzyme to produce a functional RNA molecule. A structural gene usually produces an RNA molecule that in turn encodes a protein. A **DNA control sequence**, on the other hand, regulates the expression of a structural gene. DNA control sequences do not encode RNA but regulate the expression (RNA production) of an adjacent structural gene, for example, by binding a repressor protein (discussed in Chapter 8). DNA control sequences are not really genes, since they do not encode RNA or protein. Control sequences include the promoters that signal the start of RNA synthesis from a structural gene and the binding sites for regulatory proteins that can activate or inactivate that promoter.

As noted previously, the entire genetic complement of DNA in a cell that defines it as a species is called its genome. Our primary goal in this chapter is to convey what is known about how genomes are maintained and replicated. Information about how computers are used to mine the informational content of DNA sequences and genes is described more fully in Chapters 8 and 10.

Bacterial Genomes Can Be Circular or Linear

In the early twentieth century, the chromosomes of bacteria, unlike those of eukaryotes, could not be observed by light microscopy. The reason for this is that bacteria, unlike eukaryotes, do not undergo mitosis, a process in which chromosomes are condensed and thickened about 1,000-fold. Important clues to bacterial chromosome structure were, however, gleaned from painstaking genetic studies. In the 1950s, it was discovered that **conjugation**, a horizontal gene transfer mechanism requiring cell-to-cell contact, could transfer large segments of the bacterial chromosome—not all at once, as in the established Mendelian model of plants and animals, but sequentially over a period of time (it takes 100 minutes to move the entire *E. coli* chromosome from one cell to another).

Thus, even though the bacterial chromosome could not be seen, conjugation allowed genes to be mapped relative to each other based on time of transfer. For example, a donor strain that can synthesize the amino acids alanine and proline can directly transfer the responsible genes to a recipient cell defective in those genes. The transfer process is nonspecific; any gene can be transferred in this way. Completion of transfer also requires **recombination**, in which the donor DNA fragment replaces the recipient DNA fragment. Successful transfer of the genes for amino acid synthesis enables the formerly defective recipient to form colonies on minimal media lacking either amino acid. But because transfer occurs over time from a fixed starting point (that is, not all genes are transferred at the same time), it might take one gene 10 minutes of cell contact to be transferred while the second gene, farther away from the starting point of DNA transfer, takes an additional 20 minutes.

Knowing that eukaryotic chromosomes are linear, scientists initially expected that bacterial chromosomes would be linear, too. However, the early genetic maps drawn from conjugation experiments just would not fit together in a manner consistent with a linear model—for the simple reason that the bacterial chromosome in *E. coli*, the organism under study at the time, is circular. We now know that many microbes have circular chromosomes, although some, like the Lyme disease agent *Borrelia burgdorferi*, have linear chromosomes and others, like *Agrobacterium tumefaciens*, have a mixture of circular and linear chromosomes (**Table 7.1**).

It is instructive to compare genome sizes across the phylogenetic tree, from viruses to humans. The size range is enormous. In general, the simpler the organism, the smaller its genome. At some point, as DNA content is trimmed, the organism loses independence and *must* parasitize another organism. This begs the question, what constitutes a "minimal" genome? How "lean" can a chromosome become and still support independent growth?

TO SUMMARIZE:

- **A genome** is all the genetic information that defines a species.
- **Prokaryotic genomes** are made up of chromosomes and plasmids made of DNA.
- **Prokaryotic chromosomes** can be circular or linear, as can plasmids.
- **Functional units** of DNA sequences include structural genes and regulatory sequences.

7.2 Genome Organization

New techniques for constructing physical maps of genomes and determining the sequences of whole genomes have revealed tremendous diversity in the size and organization of prokaryotic genomes.

Genomes Vary in Size

Bacterial chromosomes range from 580 kilobase pairs (kbp) to 9,400 kbp, and archaeal chromosomes range from 935 kbp to 6,500 kbp. For comparison, eukaryotic chromosomes range from 2,900 kbp (microsporidia) to over 4,000,000 kbp (humans).

NOTE: The designation kbp refers to the length of a double-stranded DNA molecule. A 1,000-base-pair double-stranded genome is 1 kbp in size. In contrast, a 1,000-*base* single-stranded genome (as in some viruses) is referred to as 1 kb.

The smallest cellular genomes identified thus far are those of *Mycoplasma*. These pathogens rely on their host environment for many products but can still grow outside a host cell. The complete genome of *Mycoplasma genitalium* consists of only 580 kbp and encodes 480 proteins. *M. genitalium* lacks the genes required for many biosynthetic functions. These organisms cannot synthesize amino acids or construct cell walls, and they do not have a functional tricarboxylic acid (TCA) cycle. In contrast, free-living bacteria that can grow in soil have larger genomes and dedicate many genes

Table 7.1 Genomes of representative bacteria and archaea.

Species (strain)	Genomic chromosome(s)* (kilobase pairs, kbp)	Plasmid(s)* (kbp)	Total (kbp)
Bacteria			
Mycobacterium tuberculosis Tuberculosis	4,400 		4,400
Mycoplasma genitalium Normal flora, human skin	580 		580
Burkholderia cepacia	3,870 + 3,217 + 876 	93 	8,056
Escherichia coli K-12 (W3110) Model strain for *E. coli* proteomics	4,600 		4,600
Anabaena species (PCC 7120) Cyanobacteria: Major photosynthetic producer of carbon source for aquatic ecosystems	6,370 	110 + 190 + 410 	7,080
Borrelia burgdorferi Lyme disease	911 	21 plasmids with sizes between 9–58 	>1,250
Agrobacterium tumefaciens Tumors in plants; genetic engineering vector	2,840 + 2,070 	214 + 542 	5,666
Archaea			
Methanocaldococcus jannaschii Methanogen from thermal vent	1,660 	16 + 58 	1,734
Haloarcula marismortui Halophile from volcanic vent	3,130 + 288 	33 + 33 + 39 + 50 + 155 + 132 + 410 	4,270
	 1,000 kbp	 500 kbp

to the synthesis or acquisition of amino acids or TCA cycle intermediates. Even different strains of one species, such as *Salmonella enterica*, may vary considerably in gene distribution (**Fig. 7.2**).

Another feature that distinguishes prokaryotic and eukaryotic genomes is the amount of so-called noncoding DNA. Many, but not all, eukaryotes contain huge amounts of noncoding DNA scattered between genes. In some species (such as humans), over 90% of the total DNA is noncoding. These noncoding regions include **enhancer** sequences needed to drive transcription of eukaryotic promoters and DNA expanses that separate enhancers. Enhancer sequences can function at large distances from the gene they regulate. A **promoter** is the DNA sequence immediately in front of a gene that is needed to activate the gene's expression. Most of the noncoding spacers appear to be remnants of genes lost over the course of evolution and pieces of defunct viral genomes. Noncoding regions may, however, provide raw material for future evolution.

Figure 7.2 The genome of *Salmonella enterica* serovar Typhimurium LT2. The circular chromosome. Base pairs are indicated around the perimeter. The two outer multicolored circles indicate genes encoded on the separate strands, which means they are transcribed in opposite directions. Color codings represent homologies between eight compared species. Blue indicates genes present only in *S. typhimurium* LT2. Orange indicates that the gene has a close homolog in all eight genomes compared. Green indicates genes with a close homolog in at least one other *Salmonella* (*S. typhi*, *S. paratyphi A*, *S. paratyphi B*, *S. arizonae*, or *S. bongori*) but not in *E. coli* K12, *E. coli* O157:H7, and *Klebsiella pneumoniae*. Gray indicates other combinations. The black inner circle is the GC content of the LT2 DNA (peaks pointing outward indicate GC-rich areas).

In contrast to many eukaryotes, prokaryotes tend to have very little noncoding DNA (typically less than 15% of the genome). The completed genome sequence of the bacterium *Mycobacterium leprae*, however, has a substantial amount (about 50%) of DNA with no known or predicted function, and this noncoding DNA may represent degenerate or inactivated genes. Still, this is less than the percentage of noncoding DNA seen in most eukaryotes.

Genes Are Organized into Functional Units

In the simplest case, a gene can stand alone, operating independently of other genes. The RNA produced from a stand-alone gene is said to be monocistronic, coding for one protein. Alternatively, a gene may exist in tandem with other genes in a unit called an **operon** (**Fig. 7.3A**). All genes in an operon are situated head to tail on the chromosome and are controlled by a single regulatory sequence located in front of the first gene. The single RNA molecule produced from the operon contains all the information from all the genes in that operon.

On a functional level, a collection of genes and operons at multiple positions on the chromosome can hold membership in a **regulon** when they have a unified biochemical purpose (such as amino acid biosynthesis; **Fig. 7.3B**). The various mechanisms regulating expression of these functional genetic units are discussed in Chapter 10.

Figure 7.3 Gene organization. A. Diagram of a segment of DNA containing a single gene producing a monocistronic message (codes for one protein) and an operon of three genes producing a polycistronic message (from which three different proteins are made, one corresponding to each gene). **B.** Diagram of a circular bacterial genome, containing genes and operons coordinately controlled by a regulatory protein.

NOTE: In bacteria, the names of genes are given as a three-letter abbreviation of the encoded enzyme's name (for example, the gene *dam* encodes deoxyadenosine methylase) or the function of related genes (for example, genes designated *proA*, *proB*, and *proC* encode enzymes involved in proline biosynthesis). Bacterial gene names are written in italics with lowercase letters. For example, the genes involved in catabolizing lactose are the *lac* genes. If several genes are involved in the pathway, a fourth letter, capitalized, is used. Thus, the three genes *lacZ*, *lacY*, and *lacA* are all associated with lactose catabolism. When speaking of a gene product, a nonitalic (roman) font is used, and the first letter is capitalized. Thus, *lacZ* is the gene, and LacZ is the protein product of that gene.

WWW | Microbial Genome Database

DNA Function Depends on Chemical Structure

DNA is composed of four different nucleotides linked by a phosphodiester backbone (**Fig. 7.4A**). Each nucleotide consists of a nitrogenous base attached through a ring of nitrogen to carbon 1 of 2-deoxyribose in the phosphodiester backbone. The 2-deoxy position that distinguishes DNA from RNA is circled in the figure. A **phosphodiester bond** (marked) joins adjacent deoxyribose molecules in DNA to form the phosphodiester backbone. Phosphodiester bonds link the 3′ carbon of one ribose to the 5′ carbon of the next ribose. The two backbones are **antiparallel** so that at either end of the DNA molecule, one strand ends with a 3′ hydroxyl group and the opposite strand ends with a 5′ phosphate. This antiparallel arrangement is necessary so that complementary bases protruding from the two strands can pair properly via hydrogen bonding. Base pairing is not possible if one tries to model DNA strands in a parallel arrangement.

Figure 7.4 Structures of DNA and RNA.

The nitrogenous bases in DNA are planar heteroaromatic structures stacked perpendicular to the phosphodiester backbone and parallel to each other (see **Fig. 7.4A**). **Purines** (bicyclic bases, adenine or guanine) pair with **pyrimidines** (monocyclic bases, thymine or cytosine). Under physiological conditions of salt (about 0.85%) and pH (pH 7.8), the hydrogen bonding of the bases permits adenine to pair only with thymine (via two hydrogen bonds) and likewise guanine with cytosine (via three hydrogen bonds). These complementary base interactions enable the two phosphodiester backbones to wrap around each other to form the classic double helix, or duplex.

The thousands of H-bonds that form between purines and pyrimidines along the interior of a DNA duplex (**Fig. 7.5**) make the bonding of the two complementary strands of DNA highly specific, so that a duplex is formed only between complementary strands. Although H-bonds govern the specificity of strand pairing, the thermal stability of the helix is predominantly due to the stacking of the hydrophobic base pairs. Stacking creates interactions between these base pairs so that water and ions can interact with the negatively charged, hydrophilic phosphate backbone but not with the interior of the double helix.

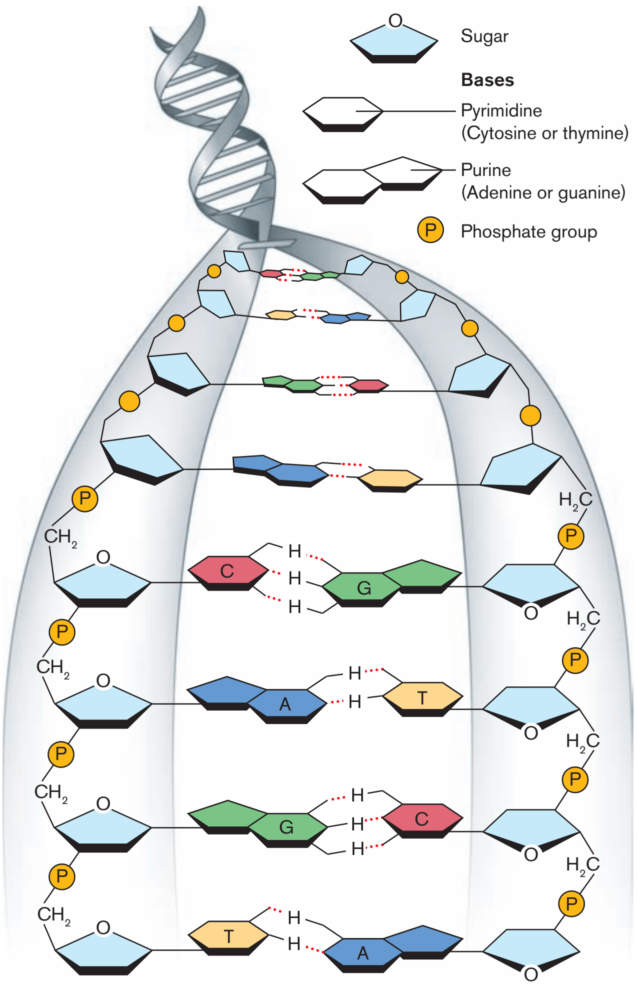

Figure 7.5 Progressive magnification of the DNA helix. The top half of the molecule illustrates the typical double-helix structure that becomes magnified in the lower half to show individual bases and hydrogen bonding.

THOUGHT QUESTION 7.1 What do you think happens to two single-stranded DNA molecules isolated from *different* genes when they are mixed together at very high concentrations of salt?

At high temperatures (50–90°C), the hydrogen bonds in DNA break, and the duplex falls apart, or **denatures**, into two single strands. The temperature required to denature a DNA molecule depends on the GC/AT ratio of a sequence. More energy is required to break the three hydrogen bonds of a GC base pair than the two bonds of an AT base pair. Thus, DNA with a high GC content requires a higher denaturing temperature than a similar-sized DNA with a lower GC content. The black center ring in **Figure 7.2** illustrates how the GC content of bases can change around a single chromosome.

When DNA has been heated to the point of strand separation, lowering the temperature permits the two single strands to find each other and reanneal into a stable double helix. The kinetics of DNA denaturation is much faster than that of renaturation, since the latter is a random, hit-or-miss process of complementary sequences finding each other. This melting/reannealing property of DNA is exploited in a number of molecular techniques (see the discussion of the polymerase chain reaction in Special Topic 7.3). Note, however, that bacteria and archaea growing at extreme pH or temperature protect their DNA from denaturation through the use of remarkable DNA-binding proteins. The role of DNA-binding proteins in microbial survival is the subject of considerable research.

THOUGHT QUESTION 7.2 How do you think the kinetics of denaturation and renaturation are dependent on DNA concentration?

Ribonucleic Acid (RNA) Differs Slightly from DNA

As we learned in Chapter 3, the growing cell continually makes temporary copies of its genes in the form of RNA molecules that direct the synthesis of proteins. DNA and RNA are chemically similar, except that in RNA the sugar ribose replaces deoxyribose and the pyrimidine base uracil replaces thymine (**Fig. 7.4B**). Functionally,

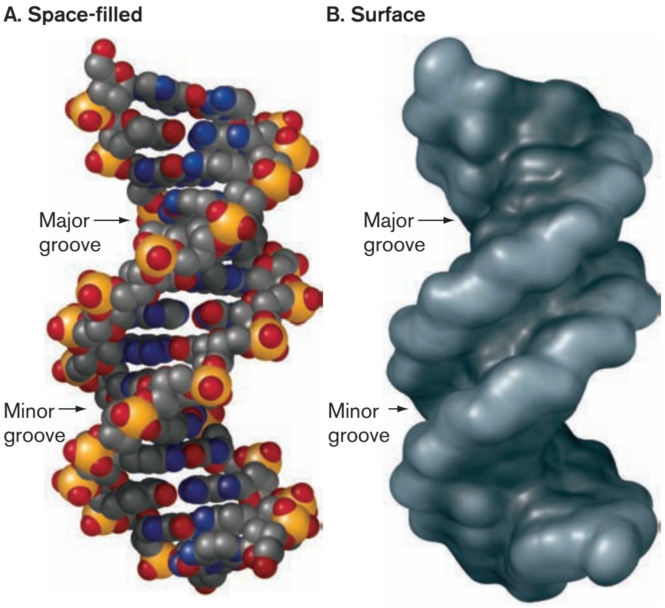

Figure 7.6 Models of DNA. A. Space-filling model of DNA. **B.** DNA surface modeled using nuclear magnetic resonance. (PDB code: 1K8J)

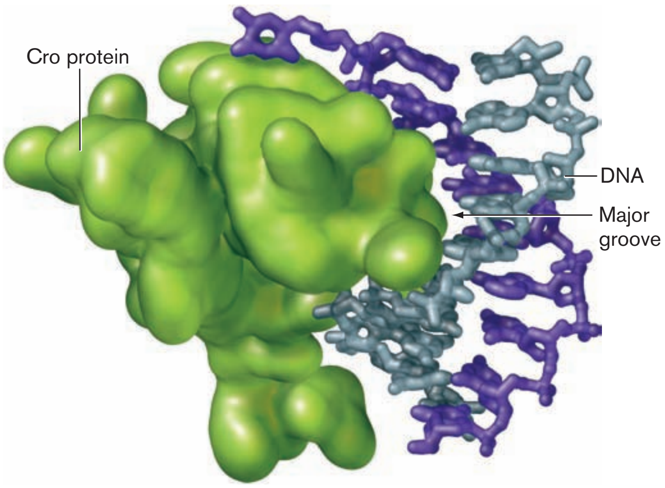

Figure 7.7 Protein recognizing DNA. Cro repressor protein binds DNA within the major groove. (PDB code: 6CRO)

these two differences prevent enzymes meant to work on DNA, such as DNA polymerases, from acting on RNA. However, uracil can still base-pair with adenine, which means that hybrid RNA-DNA double-stranded molecules (**hybridization**) can form when base sequences are complementary. In fact, hybridization is a necessary step in the decoding of genes to make proteins. Also, note that DNA in a cell is usually double-stranded, whereas RNA is usually single-stranded.

As seen in the space-filling model of DNA in **Figure 7.6A** and the contour map in **Figure 7.6B**, the B form of the DNA double helix has grooves: the wider major groove and the narrow minor groove. The two grooves are generated by the angles at which the paired bases meet each other. These grooves provide DNA-binding proteins access to base sequences buried in the center of the molecule, so that proteins can interact with the bases without the strands being separated (**Fig. 7.7**).

Bacterial Chromosomes Are Compacted into a Nucleoid

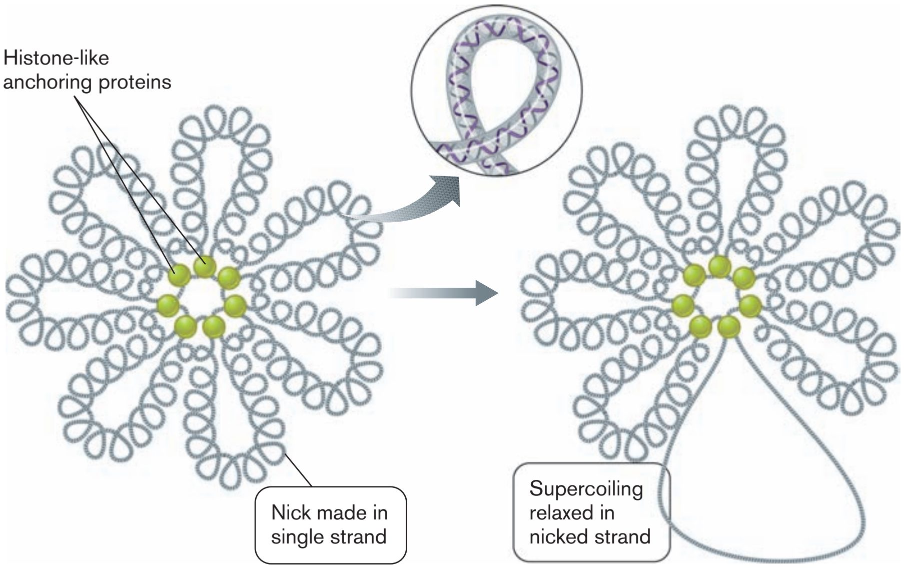
The chromosome of *E. coli* has over 4.6 million bases in one strand, or over 9 million counting both strands. This is a huge molecule. In fact, this one molecule contributes greatly to the overall negative charge of the cytoplasm. This is because at the normal pH of the cell (pH 7.8), all the phosphates in the backbone (9 million) are unprotonated and negatively charged. You might wonder how the cell handles this macromolecule.

In **Figure 7.1**, we see DNA spewing out of a damaged bacterial cell. Laid out, the chromosome is 1,500 times longer than the cell. It is obvious from this photomicrograph that an intact, healthy cell must compact a huge bundle of DNA into a very small volume. DNA is the second largest molecule in the cell (only peptidoglycan is larger) and comprises a large portion of a bacterial cell's dry mass, about 3–4%. While packaging 3% of a cell's dry weight may not seem like a challenge, realize that DNA is further confined only to ribosome-free areas of the cell, so the chromosome-packing density reaches about 15 mg/ml. In a test tube, DNA at 15 mg/ml is almost a gel, so how can anything move inside a cell? And how does all this DNA keep from getting hopelessly entangled?

As introduced in Chapter 3, cells pack their DNA into a manageable form that still allows ready access to DNA-binding proteins. While bacteria lack a nuclear membrane, they pack their DNA into a series of protein-bound domains collectively called the **nucleoid** (see Section 3.5). The bacterial nucleoid is distributed throughout the cytoplasm, unlike the compact nucleus of eukaryotes.

DNA Supercoiling Compacts the Chromosome

A nucleoid gently released from *E. coli* appears as 30–100 tightly wound loops (**Fig. 7.8A**). The boundaries of each loop are defined by anchoring proteins called histone-like proteins for their similarity to histones, the DNA-binding proteins of eukaryotes. The double helix within each domain is itself helical, or supercoiled. The easiest way to envision supercoiling is to picture a coiled telephone cord. After much use, a phone cord twists, or supercoils, upon itself. Note that supercoiled phone cords are quite compact, taking up less space than a relaxed cord. Circular DNA works the same way, a property used by the cell to pack its chromosome.



Histone-like anchoring proteins
Nick made in single strand
Supercoiling relaxed in nicked strand

Figure 7.8 Bacterial nucleoid. Nucleoid showing domain loops after gentle release from cells. The single-strand nick unwinds (relaxes) only one loop.

Remarkably, the supercoiling of one domain of DNA is maintained independently of other loops. The independence of supercoiled domains was demonstrated by introducing one single-strand nick in the phosphodiester backbone of one domain (see **Fig. 7.8**). You can do this by adding very small amounts of a nuclease (an enzyme that cleaves a nucleic acid). The ends of the broken strand, driven by the energy inherent in the supercoil, rotate about the unbroken complementary strand of the duplex and relax the supercoil. However, supercoils were removed from only the one domain. How is this possible if the chromosome is one circular molecule? The unaffected chromosomal domains remained supercoiled because they were constrained at their bases by anchoring proteins such as Hu and HNS (histone-like proteins) that prevent rotation.

How does DNA achieve the supercoiled state? The bacterial cell produces enzymes that can twist DNA into supercoils and relieve supercoils. A single twist introduced into a 300-bp circular DNA molecule creates a single supercoil as shown in **Figure 7.9**. An enzyme makes a double-stranded break at one point in the circle, passes another part of the DNA through the break, and reseals it. This produces the same result as if one end of the broken circle were twisted one full turn. Twisting in the opposite direction of the helical turn tightens the helix by adding more turns (overwinding). Think of the phone cord again. Look down the length of the cord from one end. If the cord turns left to right (that is, clockwise) down its length, twist it from one end right to left (counterclockwise). This *increases* the number of twists.

The resulting torsional stress of overwinding is relieved when the DNA (or phone cord) subsequently twists upon itself, introducing positive supercoils. In contrast, negative supercoils are formed if one end of a DNA molecule is turned in the *same* direction as the helix (thereby underwinding the DNA). In terms of the phone cord, if the cord naturally turns clockwise down its length, turn one end clockwise several more times. Torsional stress results in this case, as well, because the maneuver tries to *decrease* the number of turns in the helix. To maintain the same number of turns, the molecule must supercoil in the opposite direction and form negative supercoils that reduce the torsional strain. The nucleoids of bacteria and most archaea, as well as the nuclear DNA of eukaryotes, are

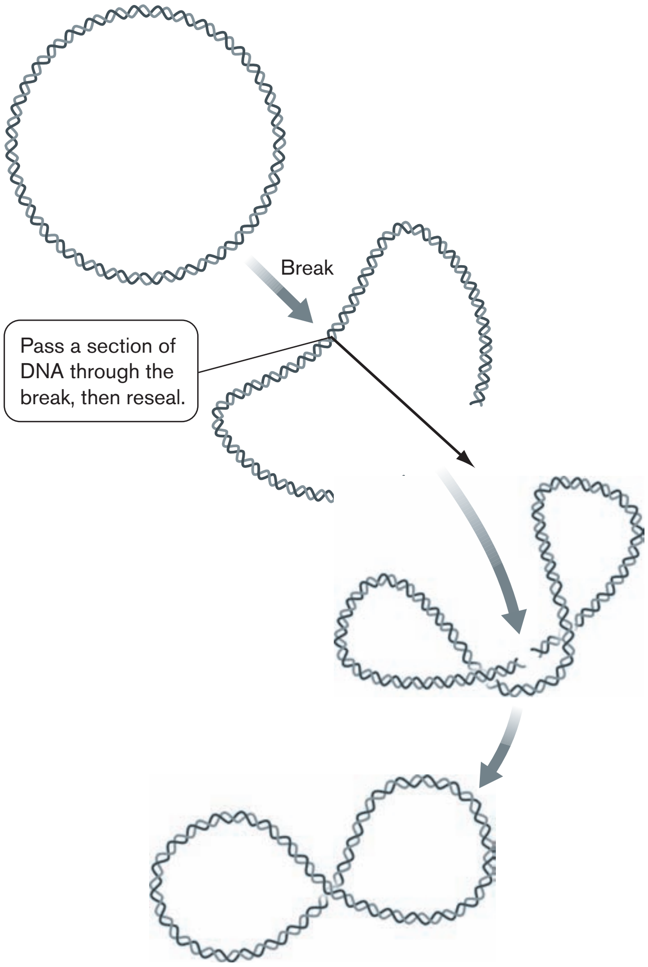


Figure 7.9 Supercoiling of 300-bp circular DNA. A supercoil can be introduced into a double-stranded circular DNA molecule by (1) cleaving both strands at one site in the molecule, (2) passing an intact part of the molecule between ends of the cut site, and (3) reconnecting the free ends.

kept *negatively* supercoiled. Because the DNA is underwound, the two strands of negatively supercoiled DNA are easier to separate than positively supercoiled DNA. This is important for transcription enzymes like RNA polymerase that must separate strands of DNA to make RNA.

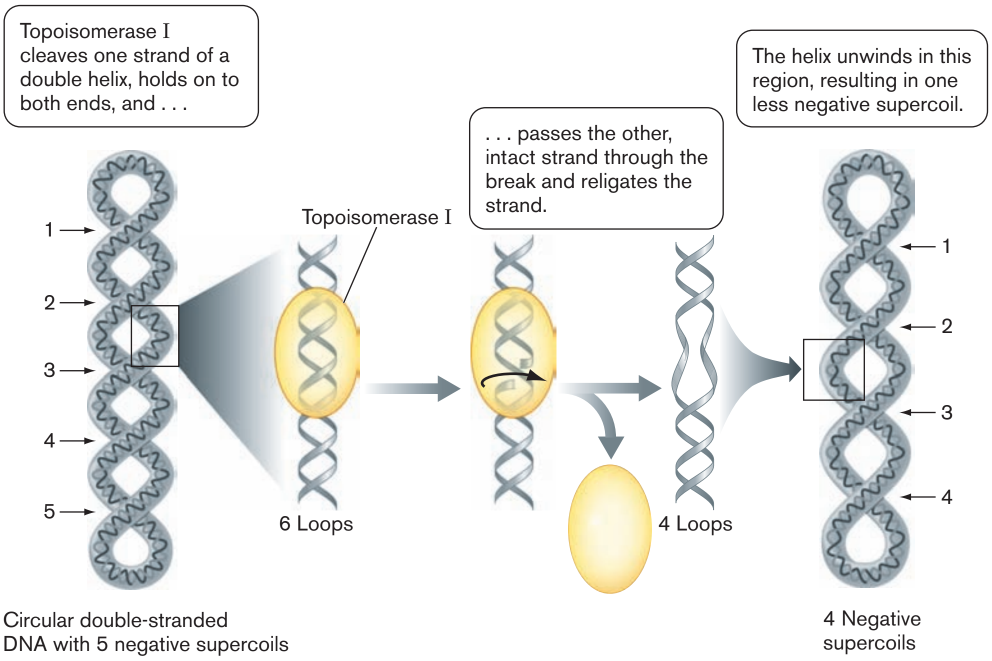
Note, however, that some archaeal species living in acid at high temperature have nucleoids that are *positively* supercoiled to keep DNA double-stranded in these inhospitable environments (discussed below). Positively supercoiled DNA is harder to denature because it takes excess energy to separate overwound DNA.

Topoisomerases Regulate the Supercoiling of DNA

Supercoiling changes the topology of DNA. Topology is a description of how spatial features of an object are connected to each other. Thus, enzymes that change DNA supercoiling are called **topoisomerases**. To maintain proper DNA supercoiling levels, a cell must delicately balance the activities of two types of topoisomerases. Type I topoisomerases cleave only one strand of a double helix, while type II enzymes cleave both strands. Type I enzymes are generally used to relieve or unwind supercoils, while type II enzymes use energy to introduce them. **Figures 7.10** and **7.11** illustrate the mechanisms used by type I and type II topoisomerases, respectively. Type I enzymes are usually single proteins, while type II enzymes have multiple subunits. An example of a type II topoisomerase is DNA gyrase, whose function is to introduce negative supercoils in DNA (see **Fig. 7.11**). The active gyrase complex is a tetramer composed of two GyrA and two GyrB proteins. **Figure 7.12** shows a three-dimensional representation of DNA gyrase in the midst of generating a supercoil.

Enzymes that make or manage bacterial DNA, RNA, and proteins are common targets for antibiotics. For instance, the **quinolone antibiotics** specifically target bacterial type II topoisomerases. A modern quinolone, ciprofloxacin, was the treatment of choice for anthrax pneumonia during the 2001 anthrax attacks. The patriarchs of this drug family, nalidixic and oxolinic acids, were used to map *gyrA* and *gyrB*, the first drug resistance genes identified in *E. coli*. The modern successors of these drugs, the fluoroquinolones, are among the most widely used antimicrobials in the world. These drugs do not block topoisomerase action but stabilize the complex in which DNA gyrase is covalently attached to DNA (see **Fig. 7.11**). This forms a physical barrier in front of the DNA replication complex, and the bacterial cell dies.

Extreme thermophiles (hyperthermophilic archaea) possess an unusual gyrase called reverse DNA gyrase. In contrast to the DNA gyrase from mesophiles, reverse gyrase introduces positive supercoils into the chromosome. It is proposed that tightening the coil helps protect the chromosome against thermal denaturation. Because the DNA has *extra* turns, it takes more energy (heat) to separate the strands.



Topoisomerase I cleaves one strand of a double helix, holds on to both ends, and . . .
. . . passes the other, intact strand through the break and religates the strand.
The helix unwinds in this region, resulting in one less negative supercoil.

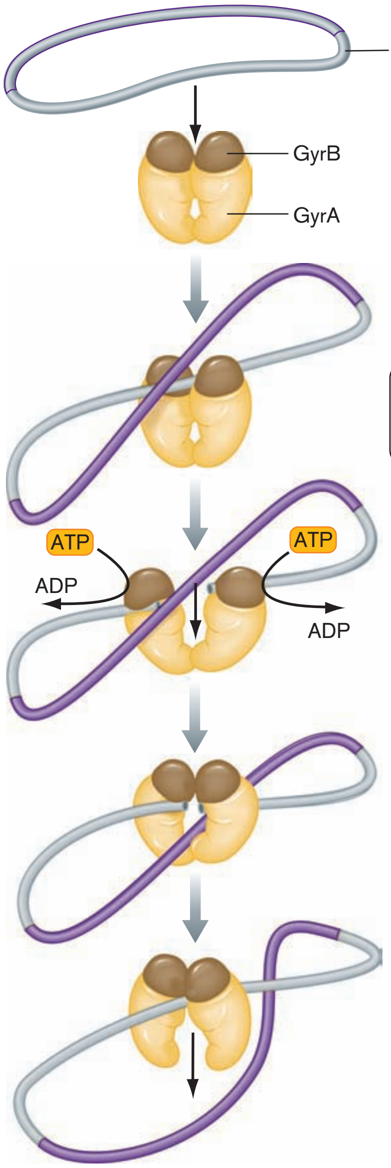
Figure 7.10 Mechanism of action for type I topoisomerases (Topo I of *E. coli*). Topoisomerase I relaxes a supercoiled DNA molecule. From left to right: Circular, supercoiled, double-stranded DNA is nicked by topoisomerase I, unwound, and released with one less superturn.



GyrB grabs one section of double-stranded DNA (represented by cylinder).

GyrA introduces double-strand break in this section (cylinder) and holds the two ends apart while remaining covalently attached to the DNA.

GyrA ATPase passes the intact double-stranded section through the double-stranded break.

GyrB rejoins the cleaved DNA and opens at the other end to allow the strand that has passed through to exit.

Figure 7.11 Mechanism of action for type II topoisomerases (DNA gyrase of *E. coli*). The gyrase enzyme grabs DNA and, in an ATP-dependent process, introduces a double-strand break, passes another part of the double helix through the break, and then reseals the break. The result is the introduction of a negative supercoil.

THOUGHT QUESTION 7.3 DNA gyrase is essential to cell viability. Why, then, are nalidixic acid–resistant cells that contain mutations in *gyrA* still viable?

THOUGHT QUESTION 7.4 Bacterial cells contain many enzymes that can degrade linear DNA. How, then, do linear chromosomes in organisms like *Borrelia burgdorferi* (the causative agent in Lyme disease) avoid degradation?

Figure 7.12 Three-dimensional representation of DNA gyrase. The 3-D model of gyrase was determined using data from X-ray crystallographic studies (blue and red regions). The gyrase complex is modeled in the process of gripping a broken DNA duplex (shown in green) and transporting a second duplex (the multicolored rosette).

TO SUMMARIZE:

- **The smallest genome known** for a free-living microbe encodes a possible 480 proteins.
- **Noncoding DNA** can constitute a large amount of a eukaryotic genome, while prokaryotes have very little noncoding DNA.
- **DNA is composed of two antiparallel chains** of purine and pyrimidine nucleotides in which phosphate links the 5′ carbon of one nucleotide with the 3′ carbon of the next in the chain. This forms a double helix containing a deep major groove and a more shallow minor groove.
- **Hydrogen bonding and interactions between the stacked bases** hold together complementary strands of DNA.
- **Supercoiling** by topoisomerases compacts DNA into an organized nucleoid.
- Bacteria, eukaryotes and most archaea possess **negatively supercoiled DNA**. Archaea living in extreme environments have **positively supercoiled genomes**.
- **Type I topoisomerases** cleave one strand of a DNA molecule and *relieve* supercoiling; **type II enzymes** cleave both strands of DNA and use ATP to *introduce* supercoils.

Table 7.2 **Some genes and proteins involved in DNA replication of *E. coli*.**

Protein	Gene	Size	Function
	oriC	245 bp	Origin of replication
DnaA	*dnaA*	52,300 Da	Initiation, binds *oriC*, DnaB loading
DnaB	*dnaB*	52,200 Da	Helicase (hexamer), prepriming priming, DNA-dependent rNTPase
DnaC	*dnaC*	27,800 Da	Loading factor for DnaB
Pol III (alpha)	*dnaE*	129,700 Da	DNA Pol III holoenzyme, elongation
Primase (DnaG)	*dnaG*	65,400 Da	Priming, RNA primer synthesis, rifampin resistant RNA polymerase
Gamma and tau subunits	*dnaX*	47,500 Da; 71,000 Da	Synthesis, part of the gamma complex, promotes dimerization of Pol III
Beta (EFI)	*dnaN*	40,400 Da	Beta clamp, processivity
Single-stranded binding protein	*ssb*	19,000 Da	Helix destabilizing
Delta (EFIII)	*holA*	38,500 Da	Part of gamma complex, clamp loading
Delta prime	*holB*	36,700 Da	Part of gamma complex, clamp loading
Psi	*holD*	15,000 Da	Part of gamma complex, clamp loading
Chi	*holC*	16,500 Da	Part of gamma complex, clamp loading
Theta	*holE*	8,700 Da	Pol III dimerization
Epsilon subunit	*dnaQ (mutD)*	27,000 Da	Proofreading, 3′-to-5′ exonuclease
DNA gyrase (subunit beta)	*gyrB*	89,800 Da	Relaxation of supercoils
DNA Pol II	*polB*	120,000 Da	DNA repair
RNA Pol, beta subunit	*rpoB*	150,000 Da	Initiation of replication, also bulk RNA synthesis
Pol I	*polA*	103,000 Da	Gap filling
DNA ligase	*ligA*	73,400 Da	Joins phosphodiester ends

7.3 DNA Replication

Microbial DNA needs to replicate itself as accurately and as quickly as possible so that the organism can grow and compete with other species. Replication efficiency is one reason why bacterial pathogens such as *Salmonella* can cause disease so quickly after ingestion. In this respect, bacteria differ from multicellular organisms, which need to regulate cell division carefully within their tissues; unregulated growth within tissues leads to cancer. The process of bacterial replication involves an amazing number of proteins and genes coming together in a complex machine (**Table 7.2**). Its operation is all the more remarkable considering that some bacteria, such as thermophilic *Bacillus* species that live in hot springs, can double in less than 15 minutes.

The molecular details of bacterial DNA replication are important because they provide targets for new antibiotics, as well as tools for biotechnology such as the polymerase chain reaction (PCR). In addition, the proteins of DNA replication have homologs in the human genome, in which defects are the basis of inherited human diseases such as xeroderma pigmentosum, and can cause a predisposition to certain cancers.

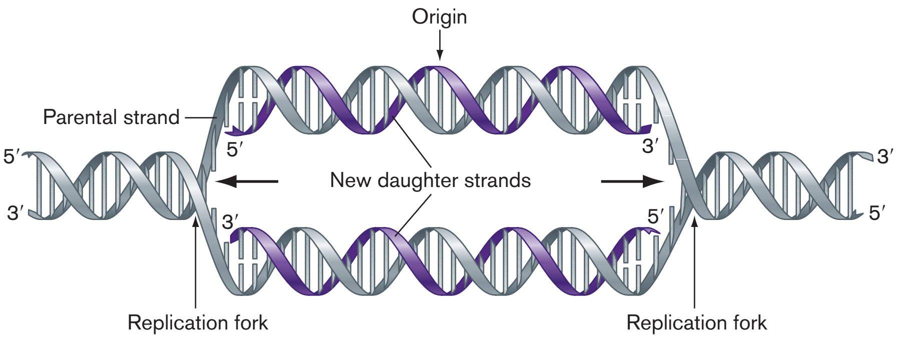

Figure 7.13 **Semiconservative replication.** A replication bubble with two replication forks. Parental strands are gray, and newly synthesized daughter strands are purple. Replication is called semiconservative because one parental strand is conserved and inherited by each daughter cell genome. It is called bidirectional because it begins at a fixed origin and progresses in opposite directions.

Overview of Bacterial DNA Replication

To replicate a molecule containing millions of base pairs poses formidable challenges. How does replication begin and end? How can two identical copies be generated? How is accuracy checked and maintained?

Semiconservative replication. Replication of cellular DNA in most cases is **semiconservative**, meaning that each daughter cell receives one parental strand and one newly synthesized strand (**Fig. 7.13**). At the **replication fork**, the advancing DNA synthesis machine separates the parental strands while extending the new, growing strands. The semiconservative mechanism provides a means for each daughter duplex to be checked for accuracy, based on its parent strand.

Enzymes that synthesize DNA or RNA can only connect nucleotides together in a 5′-to-3′ direction. That is, every newly made strand begins with a 5′ triphosphate and ends with a 3′ hydroxyl group (see **Fig. 7.4A**). A polymerase (a chain-lengthening enzyme complex) fastens the 5′ alpha-phosphate of an incoming nucleoside triphosphate to the 3′ hydroxyl end of the growing chain, thus forming a phosphodiester bond. (The alpha-phosphate is the phosphate closest to the sugar base.) This 5′-to-3′ enzymatic constraint produces an interesting mechanistic puzzle. If polymerases can only synthesize DNA in a 5′-to-3′ direction and the two phosphodiester backbones of the double helix are antiparallel, how are both strands of a moving replication fork synthesized simultaneously? One strand presents no problem because it is synthesized in a 5′-to-3′ direction toward the fork, but synthesizing the other new strand in a 5′-to-3′ direction would seem to dictate that it move *away* from the fork (**Fig. 7.14**). How is this possible? The answer was revealed in Chapter 3 but is discussed in greater detail here.

THOUGHT QUESTION 7.5 Suppose you have the following capabilities: You can label DNA in a bacterium by growing cells in medium containing either nitrogen ^{14}N or the heavier isotope ^{15}N; you can isolate pure DNA from the organism; and you can subject DNA to centrifugation in a cesium chloride solution, a solution that forms a density gradient when subjected to centrifugal force, thereby separating the light (^{14}N) and heavy (^{15}N) forms of DNA to different locations in the test tube. Given these capabilities, how might you prove that DNA replication is semiconservative?

The process of DNA replication is divided into three phases: (1) initiation, which is the melting (unwinding) of the helix and the loading of the DNA polymerase enzyme complex; (2) elongation, which is the sequential addition of deoxyribonucleotides from deoxynucleotide triphosphates, followed by proofreading; and (3) termination,

in which the DNA duplex is completely duplicated, the negative supercoils are restored, and key sequences of new DNA are methylated!

Replication from a Single Origin

Replication begins at a single defined DNA sequence called the **origin** (***oriC***). Following initiation, a circular microbial chromosome replicates *bidirectionally* (see **Fig. 7.14**, step 1) until it terminates at defined **termination** (***ter***) **sites** located on the opposite side of the molecule. Once the process has begun, the cell is committed to completing a full round of DNA synthesis. As a result, the decision of when to start copying the genome is critical. If it starts too soon, the cell accumulates unneeded chromosome copies; if it starts too late, the dividing cell's septum "guillotines" the chromosome, killing both daughter cells. Consequently, elaborate fail-safe mechanisms link the initiation of DNA replication with cell mass, generation time, and cellular health, making the timing of initiation remarkably precise.

Fundamentals of DNA replication. The basic process of chromosome replication is outlined in **Figure 7.14**. After initiation of replication, a replication bubble forms at the origin. The bubble contains two replication forks that move in opposite directions around the chromosome (**Fig. 7.14**, step 2). DNA polymerases synthesize DNA in a 5′-to-3′ direction. Thus, at each fork, one new DNA strand can be synthesized continuously until the terminus region (**Fig. 7.14**, step 3). However, because the two DNA strands are antiparallel and the DNA polymerases only synthesize 5′-to-3′, the other daughter strand has to be synthesized discontinuously, in stages—seemingly backward relative to the moving fork (**Fig. 7.14**, step 4). The fragments of DNA formed on this discontinuously synthesized strand are called **Okazaki fragments**, after the scientist who discovered them. As we will discuss later, the Okazaki fragments are progressively stitched together to make a continuous, unbroken strand. Ultimately, the two replicating forks meet at the terminus sequence (see **Fig. 7.14**, step 5) and the two daughter chromosomes separate. Overall, copying of the whole chromosome in *E. coli* takes about 40 minutes. Chromosome-partitioning processes then move each chromosome to different ends of the cell so that a cell wall can form at midcell. Once the cell wall is complete (this time is variable but generally about 20 minutes), the two daughter cells, with their new chromosomes, can separate. So you would imagine the whole process from the start of replication to cell separation would take about 60 minutes for *E. coli*.

Under optimal growth conditions, however, *E. coli* cells divide in 20 minutes. How is this possible if the process of replication takes at least 40 minutes? The answer is that a partially replicated chromosome can start new rounds of replication at the two daughter origins even before the first round is complete. This overlapping of generations enables the cell to accommodate the 40-minute DNA replication time within a 20-minute generation time. During these rapid cell divisions, the DNA-partitioning mechanisms ensure that the two actively replicating chromosomes move to different ends of the cell, which keeps them from being severed when the cell septum forms.

Now let's examine each step in molecular detail to answer some important questions about mechanism.

Initiation of Replication

What determines when replication begins? Initiation is controlled by DNA methylation, and by the binding of a specific initiator protein to the origin sequence. Further molecular events load the elaborate DNA polymerase complex and generate the first RNA primer for the new DNA strand.

DNA Methylation Controls Timing

The chromosomal origin of *E. coli* is a sequence of 245 base pairs designated *oriC*. It is subject to a critical molecular control mechanism that dictates the precise timing of replication initiation. Initiation of replication at *oriC* is activated by one protein, DnaA, and inhibited by another, SeqA. Immediately after a cell has divided, the level of active DnaA (DnaA bound to ATP) is low, and the inhibitor SeqA will bind to *oriC* and prevent ill-timed initiations (before the cell has grown enough to divide again).

How does SeqA know to bind just after the origin has replicated? The key is DNA methylation. *E. coli* uses the enzyme deoxyadenosine methylase (Dam) to attach a methyl group to the adenine residue at position N-6. The methylated adenines appear in all GATC sequences. GATC sequences (the recognition sites of Dam methylase) are scattered throughout the chromosome and occur on both strands. However, just after the origin has replicated, there is a short lag before the newly synthesized strand is methylated. As a result, the origin is temporarily hemimethylated, a situation in which only one of the two complementary strands is methylated. Because SeqA has a high affinity for hemimethylated origins, this inhibitor will bind most tightly immediately after the origin has been replicated and prevent another initiation event. Eventually, the Dam methylase will methylate the new strand and decrease SeqA binding.

The replication initiator protein, DnaA. The onset of the initiation phase is determined by the concentration of the replication initiator protein, DnaA. DnaA protein recognizes specific 9-bp repeats at *oriC*. As the cell grows, the level of active DnaA initiator protein rises until it is sufficient to bind to a series of 9-bp repeats at *oriC* (**Fig. 7.15**, step 1). DnaA actually binds as a complex with ATP (DnaA-ATP). This binding initiates the assembly of

1. DnaA-ATP proteins bind to the repeated 9-mer sequences within *oriC*.

2. Binding of DnaA leads to strand separation at the 13-mer repeats.

3. DNA helicase (DnaB) and DNA helicase loader (DnaC) associate with the DnaA bound origin.

4. DNA helicase loaders open the DNA helicase protein ring and place the ring around the ss (single-stranded) DNA at the origin. Loading of the DNA helicase leads to release of the helicase loader.

5. The DNA helicases each recruit a DNA primase, which synthesizes an RNA primer on each template.

6. The clamp loader with DNA polymerase III loads a sliding clamp onto each leading-strand DNA at an RNA primer.

7. DNA polymerase binds to the clamp. Leading-strand synthesis begins and continues to the end of the template. At each lagging strand, a sliding clamp is then loaded.

Figure 7.15 **Initiation of DNA replication.** The start of DNA replication is precisely timed and linked to the ratio of DNA to cell mass. In *E. coli*, the initiator protein DnaA accumulates during growth and then triggers the initiation of replication. It begins with DnaA-ATP complexes binding to 9-mer (9-bp) repeats upstream of the origin. This binding (along with other proteins not shown), first causes the DNA to loop in preparation for melting open by the helicase (DnaB).

a membrane-bound replication hyperstructure, a complex assembly of numerous proteins forming a functional unit, at midcell (at the cell equator).

The origin sequence (Ori), after moving through the replication complex, cannot trigger another round of replication because of inhibition by SeqA and decreasing levels of unbound DnaA-ATP. Another round of replication can only begin after (1) the origin becomes fully methylated, (2) SeqA dissociates, and (3) the DnaA-ATP concentration rises.

Initiation Requires RNA Polymerases

An unexpected feature of DNA replication is that its initiation actually requires RNA polymerases. One RNA polymerase helps separate the strands of the DNA helix at the origin, and a second RNA polymerase produces the *primer,* or starter, fragments needed to synthesize new DNA. The first of these polymerases (the housekeeping RNA polymerase used to make most of the RNA in the cell; discussed in Chapter 8) transcribes DNA at *oriC* to produce RNA that helps separate the two DNA strands (**Fig. 7.15**, step 2, this RNA polymerase is not shown). This separation allows a special DNA helicase (protein DnaB) in association with a DNA helicase loader (DnaC) to bind the two replication forks formed during bidirectional replication (**Fig. 7.15**, step 3, and see **Fig. 7.16**).

As the lead protein of the replication machine, the helicase (DnaB) uses energy from ATP hydrolysis to unwind the DNA helix as the DNA moves into the DNA polymerase replicating complex. The ringlike DnaB is assembled around one DNA strand at each replication fork. After loading DnaB at the origin, DnaC is released (**Fig. 7.15**, step 4). Coincident with the unwinding of DNA, small single-strand DNA binding proteins (ssb, seen in **Fig. 7.17**) coat the exposed single-stranded DNA, protecting it from nuclease activities patrolling the cell.

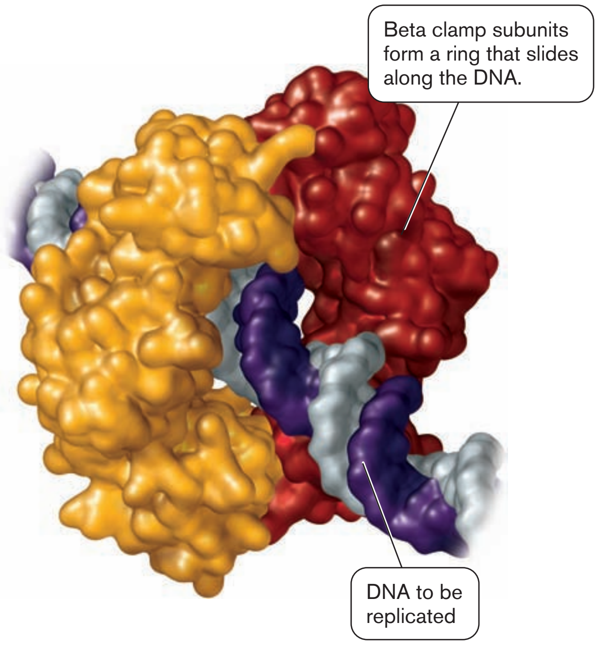

Figure 7.16 **DNA replication: The sliding clamp of *E. coli.*** The clamp dimer encircles the gray and purple DNA strand. (PDB codes: 1OK7, 1K8J)

DNA-dependent DNA polymerases possess the unique ability to “read” the nucleotide sequence of a DNA template and synthesize a complementary DNA strand. The discovery of this activity earned Arthur Kornberg (1918–) the Nobel Prize in 1959. As remarkable as these enzymes are, *no* DNA polymerase can start synthesizing DNA unless there is a preexisting DNA or RNA fragment to extend—a primer fragment. The primer fragment possesses a 3′ OH end that can receive incoming deoxynucleotides. Consequently, once DnaB (helicase) is bound to DNA, the next step in initiation is to make RNA primers at each fork (**Fig. 7.15**, step 5). In contrast to DNA polymerases, RNA polymerases *can* synthesize RNA without a primer. A specific RNA polymerase called DNA **primase** (DnaG) synthesizes short (10–12 nucleotides) RNA primers at the origin, which launches DNA replication. One primase is loaded at each of the two replication forks. Note that primase is different from the RNA polymerase involved in initially separating the DNA strands at the origin.

A Sliding Clamp Tethers DNA Polymerase to DNA

At this point, the DNA is almost ready for DNA polymerase. But first, a **sliding clamp** protein (the beta subunit) must be loaded to keep the DNA polymerase affixed to the DNA (**Fig. 7.15**, step 6). Without this clamp, DNA polymerase would frequently “fall off” the DNA molecule (see **Special Topic 7.1**). A multisubunit complex (called the clamp-loading complex) places the beta clamp, along with an attached pair of DNA polymerase molecules, onto DNA. DNA polymerase (specifically DNA Pol III; discussed later) can then bind to the 3′ OH terminus of the primer RNA molecule and begin to synthesize new DNA (**Fig. 7.15**, step 7). **Figure 7.16** presents the molecular structure of the beta clamp loaded onto DNA.

Elongation: DNA Polymerases Synthesize DNA

Escherichia coli contains five different DNA polymerase proteins designated Pol I through Pol V. All polymerases catalyze synthesis of DNA in the 5′-to-3′ direction. However, only the replication polymerases Pol III and Pol I participate directly in chromosome replication. The other polymerases conduct operations to rescue stalled replication forks and repair DNA damage.

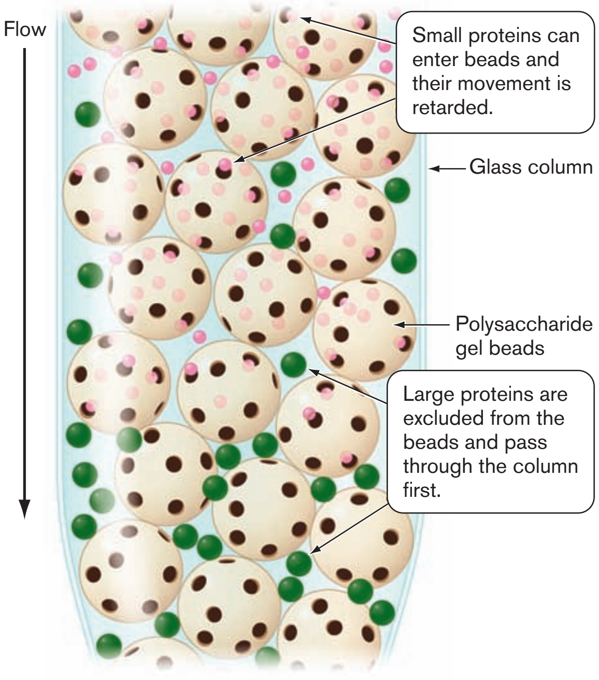
Special Topic 7.1 Trapping a Sliding Clamp

Michael O'Donnell and colleagues in 1991 performed an elegant experiment that supports the sliding clamp model. O'Donnell hypothesized that if the beta subunit were really a sliding clamp, then once it was loaded onto a small *circular* DNA molecule, the protein would never come off. It would continually slide around the circle. However, the protein complex would easily slide off a linear DNA molecule.

The experiment required detecting differences in molecular weight (or size) between DNA and DNA-protein complexes. Free protein is smaller than the DNA-protein complex formed when the same protein binds to DNA. To measure these size differences, various mixtures of DNA and ^{3}H-labeled clamp proteins were passed through a gel filtration column, a column filled with tiny, hollow gel beads, each of which contains channels that serve as molecular sieves (**Fig. 1A**). The smaller the molecule, the more easily it can enter the bead channel. Thus, small molecules become temporarily trapped in each bead, taking a long time to move from the top of the gel column to the bottom. Larger molecules, however, are too large to enter the beads. They flow quickly around the beads and exit the column first. Fractions of defined volume are collected over time. Proteins collected in early fractions are larger than those collected in later fractions. Consequently, a DNA–clamp protein complex, being large, will move more quickly through the gel and will appear in the early fractions. Unbound protein will travel more slowly and appear in later fractions.

The beta clamp complex was loaded onto a circular DNA molecule and onto the same molecule cut with the restriction enzyme *Sma*I. The separate mixtures were passed through identical gel filtration columns. Fractions were collected and counted for radioactivity (see **Fig. 1B**). Note that the protein loaded onto the circular molecule eluted in a much earlier fraction (fraction 12) than did protein loaded onto the linear molecule (fraction 25). The earlier elution indicated that the protein did not slide off the circular molecule and was maintained as a large complex. The late-elution profile of the protein loaded onto the linear molecule indicated that the protein was free to slide off the DNA and failed to maintain a large complex. The bottom panel, however, shows that a protein (for example, eukaryotic EBNA1) bound to the ends of the linear molecule will block exit of the beta clamp. This is evident in the fact that both the circular and linear DNA molecules eluted in the same fractions.

A.



Flow
Small proteins can enter beads and their movement is retarded.
Glass column
Polysaccharide gel beads
Large proteins are excluded from the beads and pass through the column first.

B.

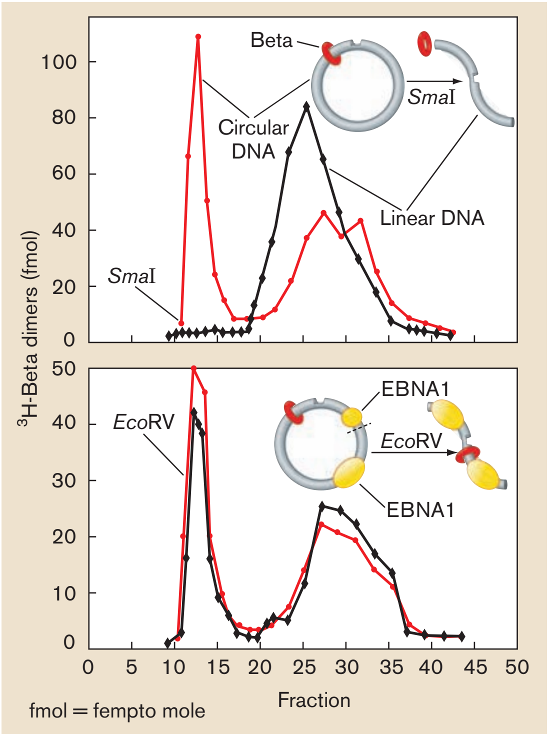


Figure 1 Gel filtration evidence supports the sliding clamp model. **A.** Principle of gel filtration. Porous beads separate small molecules from large molecules because small molecules are temporarily trapped inside the beads. **B.** *Top:* ^{3}H-labeled beta clamp dimers were added to nicked, circular DNA (red line) or linear DNA (black line). After passing through separate gel filtration columns, radioactivity was measured in the material that eluted from the column. The results show that the clamp cannot leave the circular model, so the large protein–DNA complex elutes from the column in an early fraction (fraction 12). The second red peak eluting at fraction 25 is protein that did not load onto DNA. Protein loaded on linear DNA, however, slides off of the molecule and does not form a large complex. *Bottom:* This is the same experiment, but the DNA contained two EBNA1 binding sites. Clamp protein was loaded onto circular DNA (red line) or the same DNA cut between the sites with *Eco*RV (linear). EBNA1 protein blocks the ends and prevents the beta clamp from sliding off the linear molecule. Note that the beta clamp mixed with linear DNA (black line) in the bottom panel eluted earlier from the column than in the top panel. Again, the peaks at fraction 28 reflect protein that did not load onto DNA. *Source*: B. P. Todd Stukenberg, et al. 1991. *Journal of Biological Chemistry* 266:11328.

1. The leading-strand DNA Pol III enzyme replicates the leading strand. SSBs cover and protect the unreplicated single strand. The DNA helicase remains on the lagging strand, unwinding the dsDNA moving into the replisome complex.

2. Lagging-strand DNA polymerase synthesizes the lagging strand. The lagging strand loops out after passing through the polymerase.

Actual strand movement threading through the replisome.

3. After DNA helicase has moved approximately 1,000 bases, a second RNA primer is synthesized on each lagging strand.

4. When the lagging-strand polymerase bumps into the 5′ end of a previously synthesized fragment, the DNA polymerase is released and the clamp is disengaged.

Figure 7.17 **A. The DNA polymerase dimer acting at a replication fork.** Both the leading and lagging strands are synthesized simultaneously in the 5′-to-3′ direction. For clarity, the beta clamp on the lagging strand is shown on the opposite side of Pol III as compared to its position on the leading strand. If the clamp was placed on the left side of polymerase, as it is shown in many models, the lagging strand would have to completely loop around the polymerase and enter the polymerase from the left.

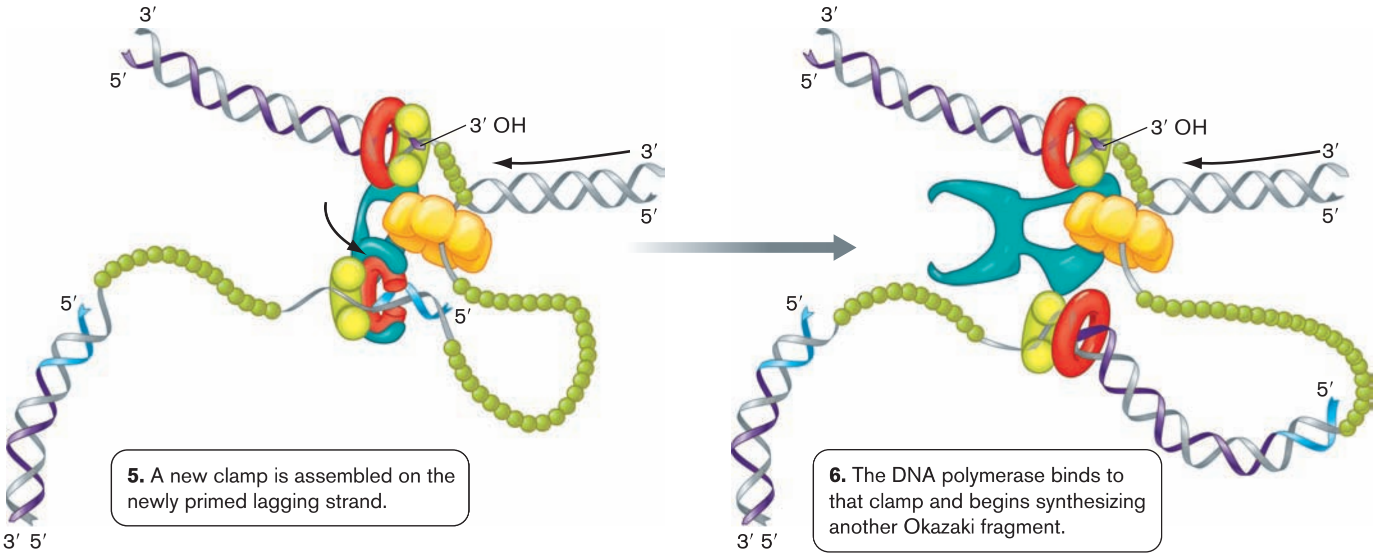
DNA polymerase III. The main replication polymerase, Pol III, is a complex, multicomponent enzyme. Because of its complexity, it is often referred to as a "molecular machine." The DNA synthesis activity of Pol III is held in the alpha subunit of the complex, while other subunits are used for improving fidelity (accuracy of replication) and processivity (a measure of how long the polymerase remains attached to, and replicates, a template). The Pol III epsilon subunit (DnaQ), for example, contains a **proofreading** activity that prevents mistakes and improves fidelity.

Proofreading activities within DNA polymerases scan for mispaired bases that have been inappropriately added to a growing chain. Mispaired bases are detected by their increased mobility. A mispaired base mistakenly linked by a phosphodiester bond to a growing DNA chain is more mobile than the correct base because it does not hydrogen-bond to the template base. This motion halts DNA elongation by Pol III because the base is not properly positioned at the enzyme's active site. This stalling of Pol III activity triggers an intrinsic 3′-to-5′ **exonuclease** activity in the epsilon subunit. Exonucleases degrade DNA starting from either the 5′ end or the 3′ end. The exonuclease activity of Pol III cleaves the phosphodiester bond, releasing the improperly paired base from the growing chain. Once the wayward mispaired base has been excised, Pol III activity can proceed.

Both DNA Strands Are Elongated Simultaneously

After initiation, each replication fork contains one elongating 5′-to-3′ strand called the leading strand (look back at **Fig. 7.15**, step 7). But how is the opposite strand at each fork replicated? There are no known DNA polymerases capable of synthesizing DNA in the 3′-to-5′ direction, which would seem to be needed if both strands are to be synthesized simultaneously. DNA synthesis of one strand continuing all the way back to the origin is not a solution because it would leave the unreplicated strand at each fork exposed to possible degradation for too long and would double the time needed to complete DNA replication. The cell has solved this dilemma by coordinating the activity of *two* DNA Pol III enzymes in one complex, one for each strand. The two associated Pol III complexes together are called the replisome. As the dsDNA unwinds at the fork, the problem strand loops out and primase (DnaG) synthesizes a primer. The second Pol III enzyme binds to the primed section of the loop and synthesizes DNA in the 5′-to-3′ direction (imagine the lower template strand in **Fig. 7.17A** threading from left to right, through the polymerase ring). All the while the second polymerase is moving along in tandem with the first polymerase (on the leading strand) relative to the fork (**Fig. 7.17A**, step 1). Realize that in actuality, the replisome remains at a fixed, midcell location in the cell, probably attached to the membrane, and the template DNA threads through it (discussed later).

Note that simultaneous extension of the two strands requires that synthesis of the looped strand *lag* behind the leading strand and that new RNA primers be synthesized periodically by primase (DnaG) every thousand bases or so. Thus, the lagging strand is synthesized discontinuously, in pieces called Okazaki fragments, while the leading strand can be synthesized continuously. As the leading strand moves forward,



5. A new clamp is assembled on the newly primed lagging strand.

6. The DNA polymerase binds to that clamp and begins synthesizing another Okazaki fragment.

Figure 7.17 (*continued*) **B. The DNA polymerase dimer acting at a replication fork.**

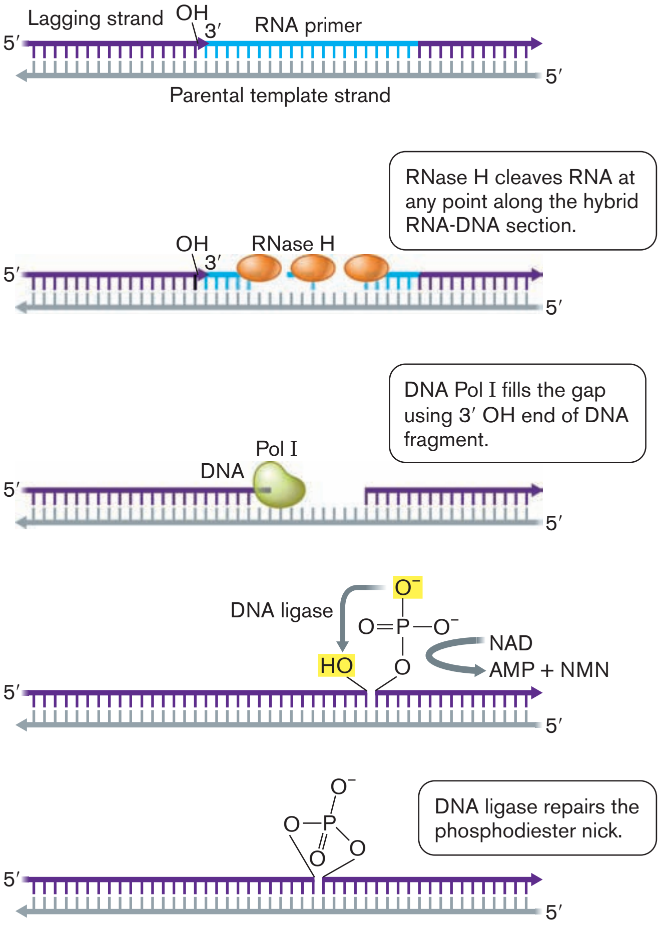
advancing the fork, there remains a long stretch of lagging strand complementary to the already replicated leading strand. This lagging strand remains single-stranded but protected by single-stranded DNA binding proteins (SSBs) (**Fig. 7.17A**, step 2). After about 1,000 bases, DNA primase reenters and synthesizes a new RNA primer in anticipation of lagging strand DNA synthesis (**Fig. 7.17A**, step 3). At some point, the lagging-strand polymerase bumps into the 5′ end of the previously synthesized fragment. This interaction causes DNA polymerase to disengage from that strand (**Fig. 7.17A**, step 4), and the clamp loader loads a new clamp near the new RNA primer (**Fig. 7.17B**, step 5). The DNA polymerase binds to that clamp and begins synthesizing another Okazaki fragment (**Fig. 7.17B**, step 6). This process repeats every 1,000 bases or so around the chromosome.

DNA polymerase I. Discontinuous DNA synthesis results in a daughter strand containing long stretches of DNA punctuated by tiny patches of RNA primers. This RNA must be replaced with DNA to maintain chromosome integrity. To remove the RNA, cells typically use an RNase enzyme specific for RNA-DNA hybrid molecules (called RNase H). A DNA Pol I enzyme enters after the RNase and synthesizes a DNA patch using the 3′ OH end of the preexisting DNA fragment as a priming site (**Fig. 7.18**). When DNA Pol I reaches the next fragment, the enzyme removes the 5′ nucleotide and resynthesizes it. This process of replicating DNA increases accuracy and decreases mutations.

Once DNA Pol I stops synthesizing, it cannot join the 3′ OH of the last added nucleotide with the 5′ phosphate of the abutting fragment. The resulting nick in the phosphodiester backbone is repaired by **DNA ligase**, which in *E. coli* uses energy gained by cleaving nicotinamide adenine dinucleotide (NAD) to create the phosphodiester bond (see **Fig. 7.18**). DNA ligase from eukaryotes and some other microbes uses ATP rather than NAD in this capacity.

A cleavage fragment of DNA Pol I, which can be made in the laboratory, containing DNA polymerase activity is shown with an associated DNA molecule in **Figure 7.19**. The figure illustrates DNA filling a crevice in the protein. The polymerase activity is located in the N terminus of the protein.

THOUGHT QUESTION 7.6 How fast does *E. coli* DNA polymerase synthesize DNA (in nucleotides per second), given that the genome is 4.6 million base pairs, replication is bidirectional, and the chromosome completes a round of replication in 40 minutes?



RNase H cleaves RNA at any point along the hybrid RNA-DNA section.

DNA Pol I fills the gap using 3′ OH end of DNA fragment.

DNA ligase repairs the phosphodiester nick.

Figure 7.18 RNase H removing the RNA primer. RNase H cleaves the RNA primer (blue). DNA polymerase I uses the preexisting 3′ OH end of the DNA fragment to fill the gap. Finally, DNA ligase repairs the phosphodiester nick using energy derived from the cleavage of NAD.

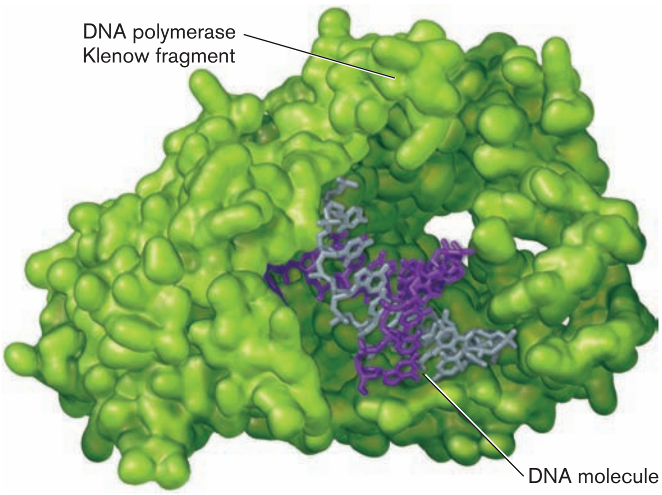


Figure 7.19 Active site of DNA Pol I. The DNA molecule fits into a molecular pocket of the polymerase. (PDB code: 1KLN)

DNA Replication Generates Supercoils

As template DNA is threaded through the replisome, the helicase continually pulls apart the two strands of the DNA helix. This causes the DNA ahead of the fork to twist, introducing positive supercoils. (Try this yourself. Twist two pieces of string together, staple one end of the pair to a piece of cardboard, and then pull the two strands apart from the free end. Notice the supercoiling that takes place beyond, or downstream of, the moving fork.) The increasing torsional stress in the chromosome could stop replication by making strand separation more and more difficult. What prevents the buildup of torsional stress is the DNA gyrase that is located ahead of the fork, removing the positive supercoils as they form.

Another topological question, noted earlier, is how DNA polymerase maneuvers through the cell. Although many descriptions of replication give the impression that the polymerase complex travels around the chromosome like a train along a track, DNA is actually fed through a stationary pair of replisomes (each a double Pol III complex) located at the cell membrane. This was shown by Katherine Lemon and Alan Grossman using *Bacillus subtilis*. The replisomes in this organism were each tagged with green fluorescent protein, and the location of the complex was monitored in replicating cells using fluorescence microscopy. If the replisomes moved like a train on a track, the polymerase-GFP protein would be found at different positions in each cell. Instead, however, in every replicating cell, replisomes were observed as distinct fluorescent foci located at or near midcell (**Fig. 7.20**). Cellular DNA stained with a blue fluorescent dye (DAPI) clearly occupied most of the cytoplasmic space.

Terminating Replication

Bidirectional replication of a circular bacterial chromosome results in the two membrane-associated replication machines attempting to replicate through the same DNA sequences 180° from the origin—that is, halfway around the chromosome. What tells the polymerases to stop? There are at least two and as many as six terminator sequences (*ter*) on the chromosome that polymerases enter but rarely, if ever, leave (**Fig. 7.21A**). One set of terminators deals with the clockwise-replicating polymerase, while the other set halts DNA polymerases replicating counterclockwise relative to the origin. A protein called Tus (terminus utilization substance) binds to these sequences and acts as a counter-helicase when it comes in contact with an advancing helicase (DnaB). The bound Tus protein effectively halts polymerase movement. Six terminator sites ensure that the polymerase complex does not escape and continue replicating DNA.

Once DNA polymerases have completed duplicating the chromosome and have been removed at the *ter* sites, the cell is still faced with what could be called a "knotty" problem. Because of the topology of the chromosome, the two daughter molecules will appear as a **catenane** of linked rings after replication (**Fig. 7.21B**). The cell resolves this structure using enzymes called

Replication forks moving clockwise are trapped by *terG*, *terF*, *terC*, and *terB*. Counterclockwise moving forks are trapped by *terA*, *terD*, and *terB*. **B.** Resolution of DNA replication catenanes. On the left is a linked chromosome catenane. The highlighted area is enlarged to the right. XerC and XerD catalyze a breaking and rejoining that passes the chromosomes through each other, resolving the link.

XerC and XerD that recognize a specific site (called *dif*) on both DNA molecules and catalyze a series of cutting and rejoining steps that essentially pass one molecule through the other. Once the two daughter chromosomes have resolved and move toward the poles, the cell can begin to divide, forming the cell septum.

THOUGHT QUESTION 7.7 Individual cells in a population of *E. coli* typically initiate replication at different times (asynchronous replication). However, depriving the population of a required amino acid can synchronize reproduction of the population. What happens is that ongoing rounds of DNA synthesis finish, but new rounds do not begin. Replication stops until the amino acid is once again added to the medium, an action that triggers simultaneous initiation in all cells; that is, reproduction of the population becomes synchronized. Why?

THOUGHT QUESTION 7.8 The antibiotic rifampin inhibits transcription by RNA polymerase, but not by primase (DnaG). What happens to DNA synthesis if rifampin is added to a synchronous culture?

www | DNA replication in archaea

TO SUMMARIZE:

- **Replication is semiconservative**, with newly synthesized strands lengthening in a 5′-to-3′ direction. It involves initiation, elongation, and termination.
- **Initiation of replication** occurs from a fixed DNA origin attached to the cell membrane. Initiation depends on the mass and size of the growing cell. It is controlled by the accumulation of initiator and repressor proteins and by methylation at the origin.
- **Elongation** requires that primase (DnaG) lay down an RNA primer, that DNA polymerase III act as a dimer at each replication fork, and that a sliding clamp keep DNA Pol III attached to the template DNA molecule.
- **The 3′-to-5′ proofreading** activity of Pol III corrects accidental errors during polymerization.
- **DNA ligase** joins Okazaki fragments.
- **Two replisomes, each containing a pair of DNA Pol III complexes**, are fixed at the membrane, and DNA feeds through them.
- **Termination** involves stopping replication forks halfway around the chromosome at *ter* sites that inhibit helicase (DnaB) activity.

- **Ringed catenanes** formed at the completion of replication are separated by the proteins XerC and XerD.

7.4 Plasmids and Bacteriophages

Two kinds of extragenomic DNA molecules can interact with bacterial genomes: **plasmids** and the genomes of bacteriophages, viruses that infect bacterial cells. Plasmid-encoded functions can contribute to the physiology of the cell, and in some cases the plasmid or phage DNA itself will integrate into the bacterial genome (see Section 9.2). Eukaryotic genomes and the genomes of eukaryote-specific plasmids and viruses are similarly subject to sharing of proteins and chromosomal interactions, such as insertions. Viruses of eukaryotes and their applications in genetic engineering are discussed in greater detail in Chapters 11 and 12.

Plasmids Replicate Autonomously within Cells

Plasmids are much smaller than chromosomes (**Fig. 7.22**) and are found in archaea and bacteria as well as in eukaryotic microbes. Plasmids are usually circular, and circular plasmids, like circular chromosomes, are typically negatively supercoiled. Replication of many of these extrachromosomal elements is not tied to chromosome replication. Each plasmid contains its own origin sequence for DNA replication, but only a few of the genes needed for replication. Thus, even when the timing of plasmid replication is not linked to that of the chromosome, many of the proteins used for plasmid replication are actually host enzymes. Which host proteins are used depends on the plasmid.

Plasmids can replicate in two different ways. Bidirectional replication, as described in **Figure 7.23A**, occurs in two directions simultaneously, while rolling-circle replication (**Fig. 7.23B**) is unidirectional. In rolling-circle replication, a replication initiator (RepA, encoded by a plasmid gene) binds to the origin of replication, nicks one strand, and holds on to one end (5′ PO_4) of it while the other end (3′ OH) serves as a primer for host DNA polymerase to replicate the intact, complementary strand. The RepA protein recruits a helicase that unwinds DNA, which becomes coated by single-strand binding proteins. As replication proceeds, the nicked strand progressively peels off until replication is complete. Then the two ends of the nicked single strand are rejoined by the Rep protein and released. A complementary strand is replicated by host enzymes to produce a double-stranded molecule. Although most known plasmids use one or the other strategy, a few can use either bidirectional or unidirection replication, depending on the cell circumstance.

The arrow points to the circular plasmid. **B.** Map of plasmid pBR322. This plasmid contains an origin of replication (*ori*) and genes encoding resistance to ampicillin (*amp*) and tetracycline (*tet*). The locations of three unique restriction sites are shown (*Hind*III, *Bam*HI, and *Pst*I).

If plasmids replicate autonomously, can cells easily lose their plasmids? Plasmids come equipped with self-preservation genes that help maintain the plasmid in the host (**Special Topic 7.2**).

Plasmids can ensure their inheritance by carrying genes whose functions benefit the host bacterium under certain conditions. For instance, bacterial plasmids can carry genes responsible for antibiotic resistance (discussed in Chapter 28). As long as the antibiotic is present in the environment, any cell that loses the plasmid will be killed or stop growing. Antibiotic resistance plasmids benefit bacteria, but they are a major problem for modern hospitals, where plasmids carrying multiple drug resistance genes are transmitted from harmless bacteria into pathogens. On the other hand, plasmids (such as pBR322) containing drug resistance genes are the workhorses of genetic technology and have benefited society tremendously.

Other kinds of host survival genes carried by plasmids include genes providing resistance to toxic metals,

Figure 7.23 Plasmid replication: bidirectional versus rolling circle. A. DNA replication begins at a fixed origin (*ori*) and proceeds bidirectionally. **B.** Replication begins at a fixed origin but only moves in one direction. As the polymerase moves, it displaces one strand as it replicates the other. At the end of a round, the polymerase releases the displaced strand as a single-stranded circle that is then replicated.

genes encoding toxins that aid pathogenesis, and genes encoding proteins that enable symbiosis. These will be discussed in later chapters. Most of the genes involved in the nitrogen-fixing symbiosis of *Rhizobium*, for example, are plasmid-borne. Far from being freeloaders, plasmids often contribute significantly to the physiology of an organism.

Plasmids Are Transmitted between Cells

Some plasmid molecules are self-transferable via conjugation, a process that involves cell-to-cell contact to move the plasmid from a donor cell to a recipient (as discussed in Section 9.2). Other plasmids are incapable of conjugation (nontransmissible). A third group can be transferred only if a self-transferable plasmid resides in the same cell. In this case, the conjugation mechanism produced by one plasmid will act on the other plasmid. Plasmids released from dead cells can also be taken up intact by some bacteria in a process called transformation. Finally, plasmid transmission in nature can occur by the accidental packaging of plasmids into bacteriophage head coats—in other words, by bacteriophage transduction (discussed in Section 9.2).

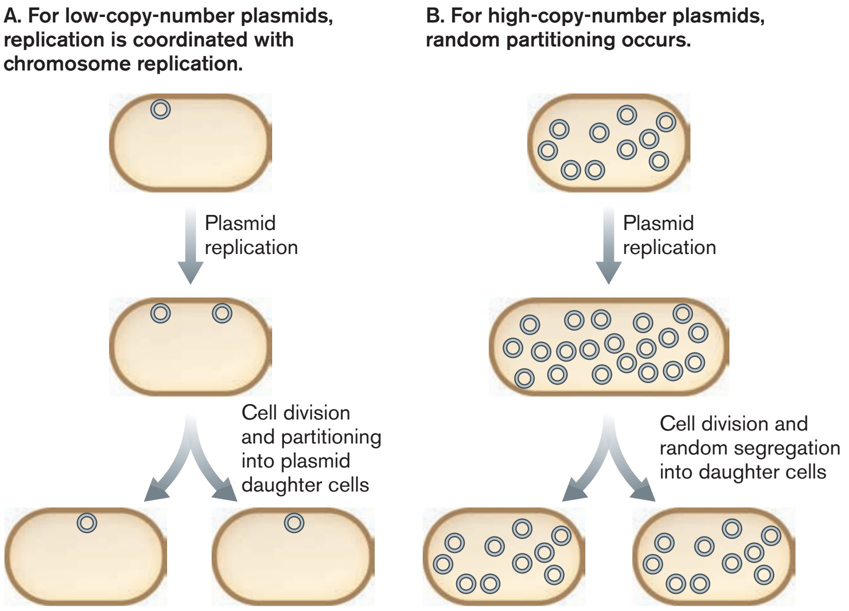
Replication Mechanisms of Bacteriophages

Bacteriophages show diverse mechanisms of DNA replication, which may differ considerably from those of cells. For instance, many phage genomes replicate unidirectionally rather than bidirectionally, and they may copy

Special Topic 7.2 Plasmid Partitioning and Addiction

By virtue of sheer numbers in a cell, *high-copy-number* plasmids ensure their inheritance into daughter cells through simple diffusion (**Fig. 1**). *Low-copy-number* plasmids, however, require dedicated partitioning mechanisms to guarantee that each daughter cell receives a copy prior to cell division.

Some enterprising plasmids even have addiction systems designed to kill cells that lose the plasmid. A typical addiction system includes a long-lived toxin and an antidote protein. The antidote is very labile and in need of constant synthesis if it is to neutralize the more stable toxin. Consequently, failure to inherit the plasmid means that the antidote can no longer be made. The antidote that remains will decay, leaving active toxin to kill the errant, plasmid-less cell. Why is this necessary? What happens if a cell division produces a cell with no plasmid? The cell without the plasmid may be at a competitive advantage for growth because maintaining a plasmid drains energy. Thus, the cells without plasmids could overgrow the plasmid-containing cells, eventually eliminating them from the population. Presence of an addiction molecule ensures that the plasmid is maintained in a population even if that plasmid does not provide any other selective advantage to the cell.



A. For low-copy-number plasmids, replication is coordinated with chromosome replication.
B. For high-copy-number plasmids, random partitioning occurs.

only one strand. Often a phage genome encodes specialized polymerase enzymes to conduct its own replication, coordinated with host components (see Section 7.3). Representative phage replication pathways are shown in **Figure 7.24**.

For example, the linear DNA duplex of phage T4 replicates bidirectionally from multiple origins using T4 gene products such as gene product 43, the T4 DNA polymerase. An interesting feature of T4 is that each capsid packs a linear DNA molecule containing redundant sequences at each end. Consequently, the genome is said to be terminally redundant. As indicated in Figure 7.24A, genes at one end of the packaged DNA are identical to genes at the other end. After the T4 DNA has replicated, it must be packaged into new capsids. The packaging apparatus, however, requires a long concatemer of DNA in which multiple genomes are joined end to end. The concatemer is made when the terminally redundant ends of individual copies of T4 DNA recombine to make a single DNA molecule (**Fig. 7.24A**). From the linear T4 DNA concatemer the individual genomes are packaged into head coats, then cleaved in such a way that 3% of each encapsidated DNA is redundant. Because each cleavage occurs farther along the genome, every T4 DNA molecule has a different terminal repeat. The genome is linear, but when the genes in a population of T4 phages are examined as a whole, the terminal repeats make the genome seem circular.

For other mechanisms of bacteriophage and viral genome replication, see Chapters 6 and 11.

TO SUMMARIZE:

- **Plasmids are autonomously replicating** circular or linear DNA molecules that are part of a cell's genome and can be transferred to other cells.
- **Plasmids replicate** by rolling-circle and/or bidirectional mechanisms.
- **Plasmids can be transferred** between cells.
- **Phage can replicate** by forming linear concatemers that are cut up to fill capsid heads. Some phage incorporate single-stranded DNA or RNA into their capsids.

Figure 7.24 Genome replication in bacteriophages. **A.** Phage T4 replicates by the rolling-circle method. Initially, the linear genome circularizes, then replicates as a linear concatemer. From the concatemer, the individual genomes are packaged into head coats, then cleaved. Because the phage head carries 103% of the genome, each encapsidated DNA contains an end-duplicated 3% of its genome. **B.** Phage lambda replicates its double-stranded DNA in two stages. In the first stage, each strand serves as a template for a complementary strand, replicated in opposite directions (bidirectional rope). In the second stage, rolling-circle replication generates a concatemer, which is precisely cleaved at *cos* sites.

7.5 Eukaryotic Chromosomes: Comparison with Prokaryotes

The chromosomes of eukaryotic microbes such as protists and algae have much in common with those of prokaryotes. Both consist of double-stranded DNA, and both usually replicate by bidirectional replication. Yet important differences are revealed as well—differences in genome structure. Eukaryotic chromosomes are linear, contained within a nucleus, and their replication involves the process of mitosis.

Eukaryotic Genomes Are Large and Linear

Overall, the genomes of eukaryotic nuclei are larger than those of bacteria, sometimes by several orders of magnitude (see Chapter 18). In addition, most eukaryotic chromosomes are linear, whereas most (though not all) bacterial chromosomes are circular. Eukaryotic chromosomes require segregation by mitosis, in order to ensure that each daughter cell receives the correct combination of daughter chromosomes.

Because their genomes are linear, eukaryotes require a special process to duplicate the chromosome ends, providing a primer for the lagging strand. The primer is provided by a special enzyme called telomerase. At each end of the chromosome (called a telomere) there often is not enough room on the lagging strand to add an appropriate RNA primer. So after each round of replication, the chromosome would be a little shorter and information would eventually be lost. Telomerase is actually a reverse transcriptase, an enzyme that reads RNA as a template to synthesize a complementary DNA molecule. Telomerase uses an intrinsic RNA (an RNA that is part of the enzyme) as a template to add DNA repeat sequences to the end of a lagging strand forming the telomere. The telomere allows for an RNA primer to be synthesized so that the end of the chromosome can be replicated. In this way, genetic information is not lost during division.

Telomerase may have evolved from the ancient progenitor cells that contained RNA rather than DNA genomes (see Section 17.2). For cells with RNA genomes to evolve modern chromosomes made of DNA, a reverse transcriptase must have been necessary. The reverse transcriptase may also be the evolutionary source of retroviruses (see Section 11.5).

Eukaryotic cells pack their DNA within the confines of a nucleus, using a series of proteins called **histones**. Histones are rich in arginine and lysine, and therefore, are positively charged, basic proteins that easily bind to the negatively charged DNA. The DNA becomes wrapped around the histones to form units called nucleosomes. For protection and condensation, all eukaryotic chromosomes are packaged by histones, proteins that play a regulatory role through methylation and acetylation. Bacteria, too, have DNA-packaging proteins, but they are more diverse and less essential for function (see Sections 3.5 and 7.2).

The detailed structure of the genomes of eukaryotes and prokaryotes reveal surprising differences (**Fig. 7.25**). The genome of the bacterium *E. coli* is packed with genes (green) encoding proteins or RNA molecules. These genes are separated by very little unused or noncoding DNA (purple) and with only an occasional mobile element, such as an insertion sequence, that can move from one DNA molecule to another. Most prokaryotic genes are organized in coordinately regulated operons such as *thrABC*, which encodes three enzymes needed to synthesize the amino acid threonine (see Section 10.1). In contrast, 95% of the human genome consists of noncoding sequences composed largely of regulatory sequences and the fossil genomes of ancient viruses. The coding genes are separated by large stretches of noncoding sequences and usually are not situated together in operons. Moreover, coding genes in the human genome are interrupted by **introns** (DNA within a gene that is not part of the coding sequence for a protein; shown as yellow in the figure) and ancient gene duplications that have decayed into nonfunctional, vestigial **pseudogenes** (orange). Bacteria also have pseudogenes, but they account for much less of the genome than in eukaryotes. The more rapid replication of bacteria causes pseudogenes to be lost more quickly.

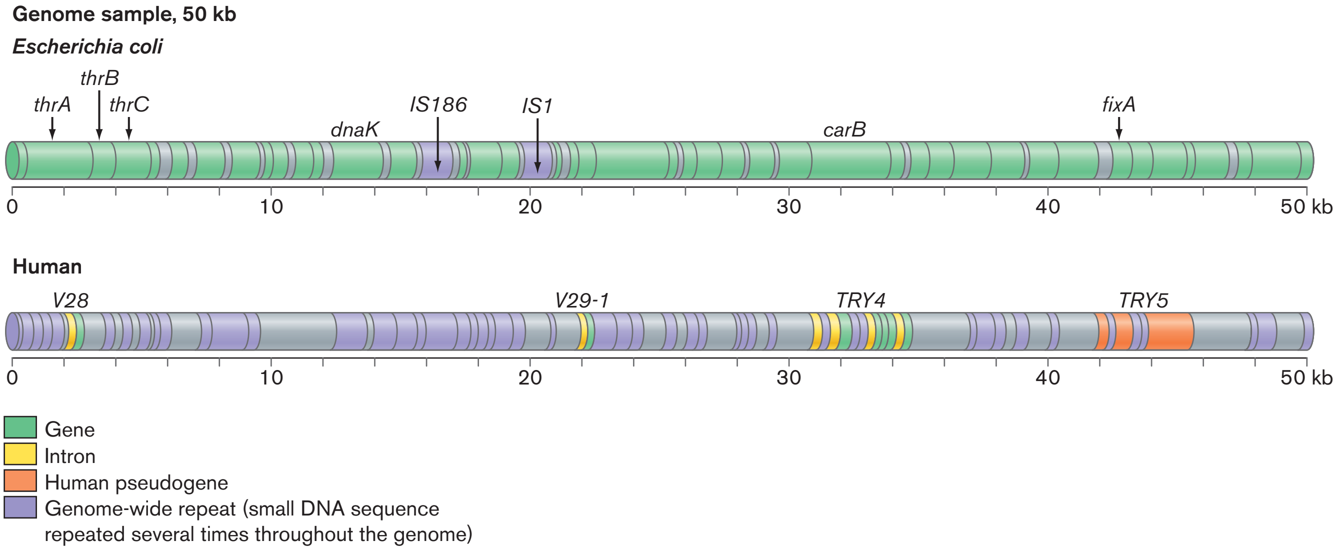

Figure 7.25 Genome structure in a prokaryote and in a eukaryote. The genome of the prokaryote *Escherichia coli* is packed with coding genes (green), with very little unused sequence between them (purple), only an occasional mobile element, such as an insertion sequence (IS). Most genes are organized in operons coordinately regulated by a single regulatory molecule such as *thrABC*. By contrast, the human genome consists of 95% noncoding sequences consisting largely of regulatory sequences and the decayed genomes of ancient viruses. The coding genes are separated by large stretches and usually are not situated together in operons. Moreover, coding genes are interrupted by introns (yellow). Ancient gene duplications have decayed into pseudogenes (orange).

The amount of noncoding DNA present in a eukaryote varies with the complexity of the eukaryotic species (for example, yeasts contain a much lower percentage of noncoding DNA than humans). It is believed that eukaryotes have retained noncoding DNA in their genomes because they rely heavily on it somehow for survival.

By themselves, promoters of eukaryotic genes have a very low activity and require enhancer DNA sequences to drive transcriptional activity. Enhancer sequences act at large distances from promoters, and scientists suspect that once enhancers became important, it was necessary to place enough DNA between them to reduce activation of other, unrelated but adjacent promotors.

Archaeal Genomes Combine Features of Bacteria and Eukaryotes

Like bacteria, archaea have polygenic operons, and their reproduction is predominantly asexual. Archaea are true prokaryotes in that their cells lack a nuclear membrane. On the other hand, in most species of archaea, the structures of the DNA-packing proteins, RNA polymerase, and ribosomal components more closely resemble those of eukaryotes. Even the DNA polymerase and the origin recognition sequence show greater similarity to those of eukaryotes. Finally, it should be noted that archaeal genomes encode certain unique components such as the metabolic pathway of methanogenesis. (For more on archaea, see Chapter 19.)

What experimental data allow us to make such comparisons? Overwhelmingly, we rely on new data from the growing number of microbial genomes sequenced. Comparison of genomes has revolutionized our understanding of evolutionary relationships among microbes.

We will now examine the tools of DNA sequence analysis that have made these studies possible. The most important of these tools—restriction mapping, DNA sequencing, and amplification by the polymerase chain reaction—actually harness the molecular apparatus used by bacteria to replicate or protect their own chromosomes.

TO SUMMARIZE:

- **Eukaryotic chromosomes** are always linear double-stranded DNA molecules that replicate by mitosis.
- A **reverse transcriptase** called telomerase is needed to finish replicating the ends of a eukaryotic chromosome.
- **Histones** (eukaryotic DNA-packing proteins) play a critical role in forming chromosomes.
- **Introns and pseudogenes** are noncoding DNA sequences that make up a large portion of eukaryotic chromosomes.
- **Archaeal chromosomes** resemble those of bacteria in size and shape, but archaeal DNA polymerases are more closely related to eukaryotic enzymes.

7.6 DNA Sequence Analysis

We have just described the core concepts of DNA structure, packaging, and replication. This knowledge is crucial to understanding genomics and the fundamentals of genomic analysis. It is now appropriate to discuss the basic techniques used to manipulate DNA. These include isolating genomic DNA from cells, snipping out DNA fragments with surgical precision, splicing them into plasmid vehicles, and reading their nucleotide sequences. These are the techniques that drove the genomic revolution.

DNA Isolation and Purification

The chemical uniformity of DNA means that simple and reliable purification methods can be used to isolate it. A variety of techniques are used to extract DNA from bacterial cells. The cells may be lysed using lysozyme to degrade the peptidoglycan of the cell wall, followed by treatment with detergents to dissolve the cell membranes. The next step is to remove most proteins by precipitating them in a high salt solution. These proteins are removed by centrifugation, and the cleared lysate containing DNA is passed through a column containing a silica resin that specifically binds DNA. The remaining proteins are washed out of the column because they do not stick, and the DNA is eluted with water. The DNA is then concentrated via alcohol precipitation (ethanol or isopropanol). DNA may be precipitated from aqueous solution by adding ethanol and salt because the charge density of the phosphates makes the molecule particularly insoluble in nonaqueous solvents. The precipitated DNA is then redissolved in water or a weak buffer. At this point, the extracted DNA can be examined with a variety of analytical tools.

Plasmid or chromosomal DNA molecules released from lysed cells can also be purified using a technique known as equilibrium density gradient centrifugation. (The principles of centrifugation are discussed in Chapter 3.) The density gradient is typically generated using a cesium chloride (CsCl) solution. Under high centrifugal force, the heavy Cs^+ atoms will increase in concentration towards the end of the tube, decreasing their concentration near the top. This forms a gradient at equilibrium ranging from the least dense at the top of the tube to the densest at the bottom. DNA molecules dissolved in the solution prior to centrifugation will migrate along the gradient according to each molecule's density. Adding the DNA-binding dye ethidium bromide to the mix will magnify these differences. Because the dye binds in between bases (intercalates), it binds more to linear DNA (such as fragmented chromosomal DNA) than it does to supercoiled molecular plasmids. The different molecules will stop moving down the gradient at different points where their apparent densities match the density of the Cs^+ gradient. No matter how long you spin, the bands stop at one density point, and they are extremely sharp. In this way, CsCl density gradient centrifugation differs from the sucrose gradient centrifugation, described in Chapter 3, where the gradient is prepared in a test tube *before* centrifugation. Besides isolating DNA molecules, CsCl density gradient centrifugation can be used to purify DNA/protein complexes and virus particles.

Restriction Enzyme Digestion

Although the method has largely been supplanted in recent years by PCR techniques (**Special Topic 7.3**), cloning genes for study typically required cutting the chromosome into distinct pieces, or fragments, that could be selectively "plucked" from the sea of other genes composing the chromosome. Fortunately, bacteria themselves provided a way to produce these small fragments (discussed in Section 9.2). The bacterial proteins involved are called **restriction enzymes**, which naturally function to clip the "foreign DNA" of invading plasmids and phages at specific points. Different species of bacteria use restriction enzymes that recognize different DNA sequences.

The most useful restriction enzymes for molecular biology recognize specific base sequences (usually four to six bases in length) in a DNA molecule and cleave both phosphodiester backbones at sites either near or within the center of the site. The cut may produce blunt ends or staggered ends; in staggered ends, the top strand is cut at one end of the site and the bottom strand cut at the other (**Fig. 7.26A**). Staggered ends are also called *cohesive ends* because the protruding strand of one of those ends can base-pair with complementary protruding strands from any DNA fragment cut with the same restriction enzyme, regardless of the source organism. This ability of cohesive ends from different organisms to base-pair forms the basis of recombinant DNA technology.

Figure 7.26 Bacterial DNA restriction enzymes. A. Target sequences of sample enzymes. The names of these enzymes reflect the genus and species of the source organism. For example, *Eco*RI comes from *Escherichia coli*. **B.** Agarose gel size analysis of *Eco*RI-restricted DNA fragments. M refers to marker fragments of known size. Smaller fragments move toward the bottom.

Notice in **Figure 7.26A** that each recognition sequence, also called a restriction site, is a **palindrome** in which the top and bottom strands read the same in the 5′-to-3′ direction. This is typical of the sequences recognized by one class of restriction enzymes (there are three general classes). But how do bacteria making these scissor-like DNA enzymes keep from destroying their own DNA? They protect themselves by producing a companion methylating enzyme that recognizes the same DNA sequence recognized by the restriction enzyme and methylates a base in both strands of the recognition sequence. The restriction enzyme cannot cut a site if either one or both of the strands are methylated. Thus, newly replicated double-stranded molecules are protected, since one strand, the template, remains methylated at all times. Phage DNA that originates from a cell with one type of restriction modification system will *not* be protected once it infects a cell with a different restriction modification system because the phage will not be methylated in the right places. As such, it faces a greater chance of destruction than of undergoing protective methylation.

Special Topic 7.3 The Polymerase Chain Reaction

A technique that relies on thermostable DNA polymerases isolated from thermophiles has revolutionized many fields, including biological research, medicine, and forensics. The technique is the **polymerase chain reaction (PCR)**, briefly described in Chapter 1. The basic PCR process, outlined in **Figure 1**, can produce over a millionfold amplification of target DNA. Using PCR, one can produce large quantities of a specific DNA sequence within a few hours. In this technique, specific oligonucleotide primers (usually between 20 and 30 bp) are annealed to known DNA sequences flanking the target gene. A thermostable DNA polymerase uses these primers to replicate the target DNA. Heat-stable DNA polymerases must be used in this process because the reaction mixture must be subjected to repeated cycles of heating to 95°C (to separate DNA strands so that they are available for primer annealing), cooling to 55°C (to allow primer annealing), and heating to 72°C (the optimum reaction temperature for the polymerase). The polymerase Taq, from the thermophile *Thermus aquaticus*, is often used for this purpose (polymerases from other thermophiles are also used). Because PCR reactions require 25–30 heating and cooling cycles, a machine called a thermocycler is used to reproducibly and rapidly deliver these cycles.

This basic PCR technique has been modified to serve many different purposes. Primers can be engineered to contain specific restriction sites that simplify subsequent cloning. **Cloning** is the process by which DNA from one source is spliced into DNA from another source. **Restriction sites** are small (4–8 bp) sequences that are recognized and cleaved by endonucleases called restriction enzymes. If the primers used for PCR are highly specific for a gene that is present in only one microorganism, PCR can be used to detect the presence of that organism in a complex environment, such as the presence of the pathogen *E. coli* O157:H7 in hamburger.

PCR has profoundly impacted human society. By making it possible to amplify the tiniest amounts of DNA contaminating a crime scene, PCR has changed our judicial system by providing conclusive evidence in court cases where no evidence would have existed previously. And there may come a day when individual human genomes are sequenced as a standard medical test—with profound ethical and societal implications. The hopes and fears raised by the invention of PCR-based genomic sequencing inspired the science fiction film *GATTACA*, directed by Andrew Niccol, depicting an imaginary future in which everyone's destiny is determined by his or her DNA sequence. This knowledge could impact which jobs are available to someone, whether insurance coverage can be withheld, and even whether two individuals can marry.

Figure 1 The polymerase chain reaction. 1. DNA template is heated to 95°C (30 seconds) to separate strands. 2. The reaction is cooled to 55°C for 30 seconds, which allows amplifying DNA primers to anneal. 3. Within seconds, the temperature is raised to 72°C, optimal for Taq polymerase activity. Polymerization is allowed to proceed for about 60 seconds, and then the strands are separated again at 95°C to prepare for another cycle. Each polymerization step increases (amplifies) the target sequence until, ultimately, only the fragment bounded by the primers is amplified. Thus, from a single DNA molecule, potentially 10^{30} copies of a fragment can be made.

Restriction enzymes from hundreds of bacteria are now commercially available for analyzing DNA. A few examples of such enzymes are shown in **Figure 7.26A**. Agarose gels can be used to analyze the DNA fragments obtained by treatment with these enzymes. In **Figure 7.26B**, each lane represents a different, homogeneous population of DNA molecules cut with the same restriction enzyme. Because DNA is negatively charged, all DNA molecules travel to the positive pole during electrophoresis. Pore sizes in the agarose are such that they allow small molecules to speed through the gel, while larger molecules take longer to move. Thus, DNA fragments in this gel separate on the basis of size—the smaller the fragment is, the farther it travels down the lane. The inserted DNA fragments were of different sizes and so travel different distances in the gel. The sum of the sizes of fragments in each lane yields the size of the original, intact, uncut molecule.

Cloning: The Birth of Recombinant DNA Technology

The ability to clone genes rests on several seemingly unrelated findings. The discovery of restriction enzymes in the late 1960s was initially considered interesting but esoteric, and its significance was grossly underestimated at the time. Only later would the full impact of these enzymes on biological research be realized. The beginning of the recombinant DNA revolution can be traced to 1972. It was known at that time that plasmids were small circular DNA molecules capable of independent replication in bacterial cells. Some of the known plasmids contained a single site for certain restriction enzymes. As already noted, many restriction enzymes generate cohesive ends that can base-pair with the ends of any DNA cut with the same enzyme.

The significance of these facts went unrecognized until Stanley Cohen, Herb Boyer, and Stanley Falkow were relaxing with colleagues in a Waikiki deli after a scientific meeting in 1972 (**Figs. 7.27A** and **B**). In something of a "eureka" moment, the scientists suddenly realized that it might be possible to use a restriction enzyme (such as *Eco*RI) to cut a piece of DNA from one organism's chromosome and graft it in vitro into a plasmid cut in a single place with the same enzyme (**Fig. 7.27C**). They also knew that DNA ligase (see earlier discussion) would seal the fragment to the plasmid and form a new artificial

Figure 7.27 Formation of recombinant DNA olecules. **A.** Stanley Cohen of Stanford University and **B.** Herbert Boyer of the University of California, San Francisco, two of the founders of recombinant DNA technology. **C.** A plasmid vector is cut with a restriction enzyme (*Eco*RI) that produces cohesive ends. The same enzyme is used to digest foreign DNA, producing a series of fragments all with identical cohesive ends. The cut vector and foreign DNA fragments are mixed. Cohesive ends of the foreign DNA and vector anneal to form a chimeric molecule containing two nicks. DNA ligase is used to seal the nicks and connect the phosphodiester backbones.

DNA molecule. This gene, as part of the recombinant molecule, could then be introduced into *E. coli* by transformation (discussed in Section 9.2) and be produced in large numbers through plasmid replication. Three months later, the strategy worked. This seminal work was published by Boyer and Cohen along with students Annie Chang and Robert Helling. Over the next decade, the technique became known as *gene cloning*, an immensely powerful technology that thrust biology into the genomic era.

WWW | Cloning strategies

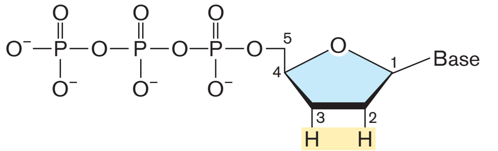
One problem with earlier cloning techniques is that *E. coli* plasmid origins will not function (that is, will not initiate replication) in most other bacterial species, but especially eukaryotes or archaea. This means that cloned genes from these groups of organisms could be studied only in *E. coli*. The problem with studying these foreign genes in *E. coli* is that the processing of RNA or proteins naturally carried out in the eukaryote, for instance, will not be possible in *E. coli* because *E. coli* does not possess those systems. Nor can function of these eukaryotic proteins be tested in the prokaryotic cell. The solution to these problems is to use a **shuttle vector**. A shuttle vector is a plasmid that contains a replication origin compatible with *E. coli* and a second origin that will allow the plasmid to replicate in an unrelated bacterial species, or in a eukaryote or archaeon. In this way, the cloned gene can be genetically manipulated in *E. coli* using well-characterized molecular protocols (that is, creating specific mutations) and then be reintroduced into the source organism to study function.

THOUGHT QUESTION 7.9 Knowing that *E. coli* possesses restriction enzymes that cleave DNA from other species, how is it possible to clone a gene from one organism to another without the cloned gene sequence being degraded?

THOUGHT QUESTION 7.10 PCR is a powerful technique, but one can easily contaminate a sample and amplify the wrong DNA—perhaps sending an innocent person to jail. What might you do to minimize this possibility?

DNA Sequencing Based on Sanger Dideoxynucleotides

Even with the development of gene cloning, our advance into the genomic age would not have been possible without a rapid way to sequence large pieces of DNA. The most commonly used DNA-sequencing method relies on the Sanger dideoxy strategy. Ingenious in its simplicity, the dideoxy method relies on the fact that the 3′ hydroxyl group on 2′-deoxyribonucleotides (shown in **Fig. 7.3A**) is absolutely required for a DNA chain to grow. Thus, incorporation of a 2′,3′-dideoxynucleotide (**Fig. 7.28**) into a growing chain prevents further elongation because without the 3′ OH, extension of the phosphodiester backbone is impossible.



Cannot form a phosphodiester bond with next incoming deoxynucleoside triphosphate (dNTP).

Figure 7.28 Dideoxy nucleotide. DNA nucleotides lack the 2′ OH group on ribose but retain the 3′ OH needed for DNA synthesis. Dideoxy nucleotides lack both the 2′ OH and the 3′ OH. Thus, the 5′ phosphate of a dideoxy nucleoside triphosphate can still form a phosphodiester bond to a growing chain but lacks the 3′ OH acceptor for a new incoming nucleotide.

The dideoxy method begins with a short (20–30-bp) oligonucleotide DNA primer molecule designed to anneal to the plasmid vector at a site immediately adjacent to the cloned insert to be sequenced. The mixture is first heated to 95°C to separate the DNA strands and then cooled, which allows the primer to bind. DNA polymerase can then build on this primer and synthesize DNA using the cloned insert as a template. A small amount of dideoxyadenosine triphosphate (dideoxy ATP) is included in the DNA synthesis reaction, which already contains all four normal deoxyribonucleotides. Because normal 2′-deoxyadenosine is present at high concentration, chain elongation usually proceeds normally. However, the sequencing reaction contains just enough dideoxy ATP to make DNA polymerase occasionally substitute the dead-end base for the natural one, at which point the chain stops growing. The result is a population of DNA strands of varying size, each one truncated at a different adenine position.

Now imagine using four different dideoxynucleotides corresponding to A, T, C, and G, with each dideoxy base tagged with a different-colored fluorescent dye (**Fig. 7.29A**▶). The result will be a series of different-sized strands tagged at their 3′ end with different colors, depending on the base incorporated. Analyzing the results of this reaction by electrophoresis in a single lane of a polyacrylamide gel will separate the various fragments based on their size. A laser and detector positioned at the bottom of the gel reads the individual fragments as they pass (**Fig. 7.29B**). Because we know the color of each tagged base, we can use a computer to print a series of colored peaks whose order corresponds to the template DNA sequence (**Figs. 7.29C** and **7.30**). Although the fig-

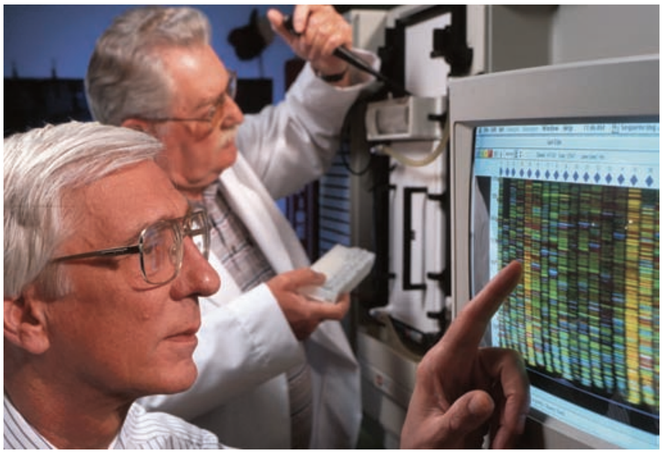
ure depicts a standard polyacrylamide slab gel, the rapid automated DNA sequencers used today for large-scale projects utilize small capillary tube gels.

Sequencing an Entire Genome

Sequencing a genome begins by indiscriminately cloning all the fragments of chromosomal DNA that have been randomly generated, either by restriction digestion (for small fragments) or by sonic breakage (for large pieces). The fragments can either be cloned into conventional plasmid vectors, which may only hold 40–50 kbp of insert DNA, or be cloned into super vectors known as bacterial artificial chromosomes (BACs) that can harbor inserts of 150–1,000 kbp. This random "shotgun" cloning approach must be done in such a way as to ensure overlapping cloned fragments. This is important when finally reassembling the DNA sequences read from various fragments into one contiguous sequence representing the entire chromosome.



Keith Weller, USDA

Figure 7.30 Rapid DNA sequencing using an automated DNA sequencer. Cletus Kurtzman inspects a yeast DNA sequence from a previous run while Larry Tjarks loads samples of new sequencing reactions at the National Center for Agricultural Utilization Research. The lanes on the screen represent the sequences of different DNA molecules.

NOTE: Sonication and some restriction enzymes generate blunt, rather than cohesive ends. These molecules can still be cloned into linearized plasmids that also contain blunt ends. However, the efficiency of cloning blunt end molecules is much lower than with cohesive ends.

Next, each clone is sequenced using primers that originate from a sequence in the vector. The vector provides a clear starting point and a known sequence to design a primer. Typically, 500–1,000 bases can be read using the Sanger sequencing technique previously described. New primers are then designed based on the previously read sequence, and the sequencing team continues to "walk" along the fragment until its sequencing is complete. An alternative to "walking" along the chromosome is to break large (greater than 5 kb) cloned fragments into many overlapping, smaller fragments, which are then subcloned into another plasmid vector. The entire sequence of the smaller subclones can usually be determined using the vector primers. It is important to remember that both complementary strands must be sequenced in order to verify a fragment's sequence and that the region should be sequenced at least two or three times.

Once the fragment sequences are verified, overlapping sequences from different fragments are identified using supercomputers and assembled in silico (in a computer) into **contigs**, which are contiguous sequences spanning several fragments. Ideally, each chromosome of a genome will assemble into a single contig. However, if some gaps remain between contigs, focused sequencing can span them.

Due to constantly improving technologies, the length of time it takes to sequence an entire genome has shortened remarkably over the past decade. It originally took many years to sequence the 4.6-million-bp genome of *E. coli*. Today it would take less than a month. The top DNA sequencing laboratories can sequence nearly 10 million bases per month.

How the information from sequences is mined will be discussed more in Chapter 8. Suffice it to say, many important discoveries have resulted from this technology. A particularly intriguing recent discovery was finding the entire genome of the bacterium *Wolbachia* (which infects 20% of the world's insect population) is embedded within the genome of *Drosophila*, the common fruit fly. The evolutionary implications of this are under intense investigation.

TO SUMMARIZE:

- **DNA restriction enzymes** used for DNA analysis cleave DNA at specific recognition sequences, which are usually 4–6 bp in length and produce either a blunt or a staggered cut.
- **Agarose electrophoresis** will separate DNA molecules based on their size.
- **Restriction enzyme digested DNA** molecules were first cloned into plasmids in the early 1970s.
- **The most commonly used DNA sequencing** technique (Sanger technique) uses nucleotides that lack both the 2′ OH and 3′ OH groups to terminate chain elongation.
- **Entire genomes** are sequenced by shotgun cloning of overlapping DNA fragments, each of which is sequenced. Overlapping regions are matched and joined by computer analysis until the entire genome is reconstructed.

Concluding Thoughts

We used to think of bacteria as simple, single-celled organisms. While they are single cells, they are far from simple. Complexity is evident in the elegant mechanisms they use to organize and replicate their genomes. The next three chapters will expand on this idea and discuss the way bacteria make proteins, regulate genes, exchange DNA, and, in the process, evolve. Knowing how a bacterial cell replicates and genetically controls the repertoire of available proteins and enzymes provides a unique perspective from which to study the physiology of microbial growth, explored in Part 3 of this textbook. Furthermore, understanding the bacterial genome allows us to explore the physiology of pathogenic as well as nonculturable organisms and gain greater insight into the evolutionary diversity of species that we will discuss in Part 4.

CHAPTER REVIEW

Review Questions

1. What is the difference between vertical and horizontal gene transmission?
2. Explain the structural types of bacterial genomes. What is a structural gene?
3. Describe the four functional levels of gene organization.
4. What are the differences between DNA and RNA?

5. Explain DNA supercoiling. Why is it important to microbial genomes?
6. Discuss the mechanisms of topoisomerases. What drug targets a topoisomerase?
7. What are the basic mechanisms involved in DNA replication?
8. How does the bacterial cell regulate the initiation of chromosome replication?
9. What is the gamma complex? Primase? DnaB? DnaC? DNA proofreading?
10. How is the problem of replicating both strands at a replication fork solved?
11. What is a catenane? What does it have to do with DNA replication?
12. Explain the polymerase chain reaction.
13. What is rolling-circle replication?
14. What is DNA restriction and modification? Why is it important to bacteria? Why is it important to forensic scientists?
15. Explain the basic technique of DNA sequencing.

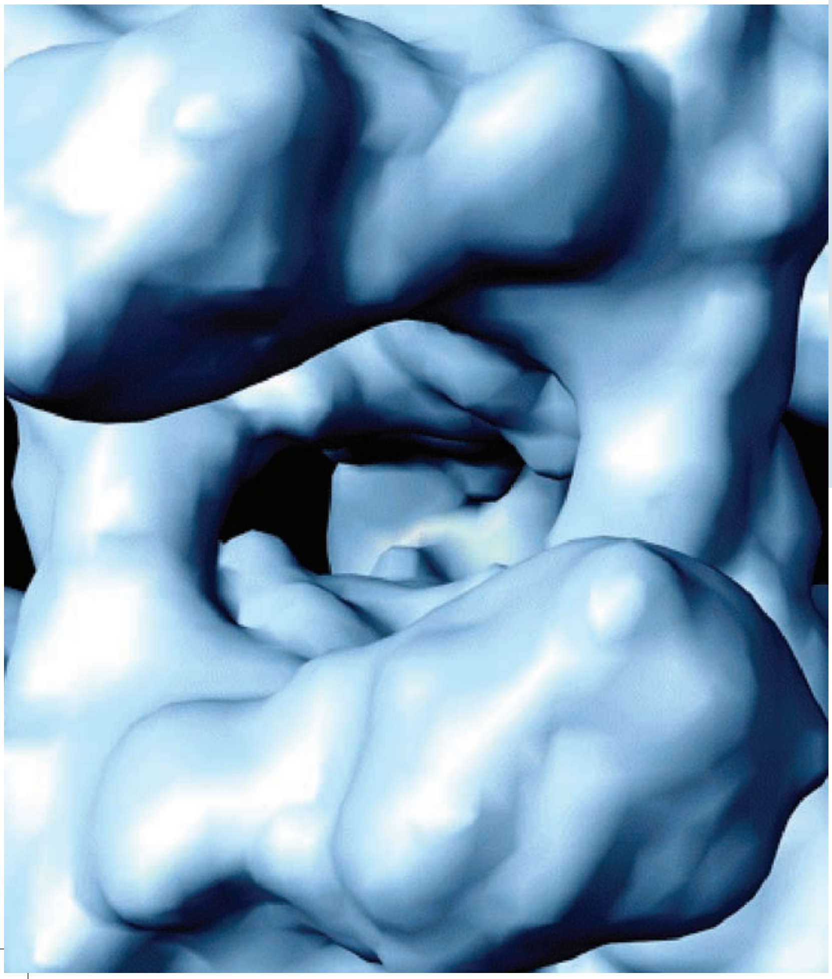
Chapter 8

Transcription, Translation, and Bioinformatics

8.1 RNA Polymerases and Sigma Factors
8.2 Transcription Initiation, Elongation, and Termination
8.3 Translation of RNA to Protein
8.4 Protein Modification and Folding
8.5 Secretion: Protein Traffic Control
8.6 Protein Degradation: Cleaning House
8.7 Bioinformatics: Mining the Genomes

The cell accesses the vast store of data in its genome through transcription, which is the reading of a DNA template to make an RNA copy, and translation, the decoding of RNA to assemble protein. The molecular machines that carry out these processes have been studied relentlessly, yet they still hold secrets.

After translation, each polypeptide must be properly folded and placed at the correct cellular or extracellular location. How does the cell do this? And what does the cell do with proteins it no longer needs? As we will discuss, elegant chaperone pathways help fold proteins; complex transport systems move proteins out of the cytoplasm; and regulated proteolytic systems properly dispose of unneeded or damaged proteins. What emerges is a picture of remarkable biomolecular integration, homeostatically controlled to maintain balanced growth and ensure survival.



The *Escherichia coli* DegP protein is a periplasmic protease that degrades misfolded proteins including "sentry" regulators that control certain stress responses. It has been hypothesized that unfolded polypeptides are threaded in an extended conformation into the cage to access the proteolytic sites. The image is a close-up view of the inner cavity of DegP. *Source*: Ahmad Jomaa, et al. 2007. *Journal of Bacteriology* 189:706; © 2007, American Society for Microbiology. All Rights Reserved.

By 1960, it was clear that the genetic code was embedded in DNA, but the code itself remained a mystery, as was the mechanism by which the code produced protein. RNA was a suspected, but unproven, intermediate. Marshall Nirenberg and Heinrich Matthaei, a postdoctoral student of Nirenberg's at the National Institutes of Health, set out in 1959–1960 to design a cell-free system (a cell lysate of *E. coli*) to test the hypothesis (**Fig. 8.1A**). Key to their investigation was the use of synthetic RNA molecules containing simple, known, repeated sequences such as poly-A (consisting only of adenylic acid), poly-U (polyuridylic acid), poly-AAU, and poly-AAAAU. These RNA molecules were tested in a cell-free protein-synthesizing system to see if the repetitive sequence might direct incorporation of a specific amino acid into a protein. Each synthetic polynucleotide was tested in the presence of a radiolabeled amino acid. If the radioactive amino acid was incorporated into a polypeptide, the polypeptide would also be radioactive. On the morning of May 27, 1960, the results of experiment 27Q indicated that the poly-U RNA specified the assembly of radioactive poly-phenylalanine. It was the first break in the genetic code.

Figure 8.1 Many scientists contributed to understanding the genetic code. **A.** Heinrich Matthaei (left) and Marshall Nirenberg (right) were first to crack the genetic code. An early hand-drawn model of what would eventually be known as translation is behind them. **B.** Maxine Singer, a key contributor to the genetic code experiments, also helped develop guidelines for recombinant DNA research.

Nirenberg reported the result at a conference in Moscow at the height of the Cold War. News that Nirenberg's poly-U experiment had determined the first "word" of the genetic code was an international media event. In January 1962, the *Chicago Sun-Times* announced: "No stronger proof of the universality of all life has been developed since Charles Darwin's *The Origin of Species* . . . In the far future, the . . . hereditary lineup will be so well known that science may deal with the aberrations of DNA . . . that produce cancer, aging, and other weaknesses of the flesh." This statement was truly prophetic, for understanding the genetic code was the first step in discovering the basis of many genetic diseases. For his work, Nirenberg, along with Har Gobind Khohara (who developed methods for making synthetic nucleic acids) and Robert Holley (who solved the structure of yeast transfer RNA), won the 1968 Nobel Prize in Physiology or Medicine. Maxine Singer, who also played an important role in deciphering the genetic code by synthesizing the RNA molecules used in the Nirenberg experiments, became a leader in developing guidelines for recombinant DNA research (**Fig. 8.1B**).

Since Nirenberg's breakthrough, we have learned a tremendous amount about genes and proteins and, in this electronic age, we can use the information in ways never before possible. A new discipline called bioinformatics uses powerful computer technologies to store and analyze gene and protein sequences. Bioinformatic programs can compare a new gene sequence with hundreds of thousands of known genes. These comparisons help predict for any given microbe what genes are present, what proteins are made, and even what food it consumes. Patterns in DNA sequences across species also allow us to pose new questions about microbial life, disease, and evolution.

In this chapter, we use *E. coli* as a paradigm to explore the way microbes interpret the nucleotide sequence of DNA and convert it to proteins. From there we look at what the cell does with those proteins once they are made. Specific proteins are targeted for movement into the periplasm, while other proteins must be inserted into membranes. We also show how damaged proteins are selectively degraded. We conclude with bioinformatics, now an essential tool of the new microbiology. Chapters 9 and 10 then discuss how microbes respond to their environment by controlling the expression of their genes.

8.1 RNA Polymerases and Sigma Factors

To survive and reproduce, every cell needs to form proteins using the information encoded within DNA. Chromosomal DNA is large and cumbersome, so the first step in the process is to make multiple copies of the information in snippets of RNA that can move around the cell and, like disposable photocopies, be destroyed once the encoded protein is no longer needed. This copying of the DNA to RNA is called **transcription**. Much of what we have learned about transcription has come from studying *E. coli*. However, bioinformatic analyses indicate that the mechanisms and components of transcription in other bacterial species are similar to those characterized in *E. coli*.

RNA Polymerase Transcribes DNA to RNA

An enzyme complex called RNA polymerase, also known as DNA-dependent RNA polymerase, carries out the process of transcription, making RNA copies (called **transcripts**) of a DNA template. The DNA **template strand** specifies the base sequence of the new complementary strand of RNA. Transcription involves (1) initiation, which is the binding of RNA polymerase to the beginning of the gene, followed by melting of the helix and synthesis of the first nucleotide of the RNA; (2) elongation, the sequential addition of ribonucleotides from nucleoside triphosphates; and (3) termination, in which sequences at the end of the gene trigger release of the polymerase and the completed RNA molecule.

RNA polymerase in bacteria consists of a "core polymerase," which is a protein complex containing the *essential* components required for elongation of the RNA chain, plus a **sigma factor**, a protein needed only for initiation of RNA synthesis, not for its elongation. Core polymerase plus sigma factor together are called "holoenzyme."

Core RNA polymerase is a complex of four different subunits: two alpha (α) subunits, one beta (β) subunit, and one beta-prime (β′) subunit for every core enzyme (**Fig. 8.2**). The beta-prime subunit contains the Mg^{2+}-containing catalytic site for RNA synthesis, as well as sites for the ribonucleotide and DNA substrates and the RNA products. The three-dimensional structure of RNA polymerase resembles a hand, whose "fingers" consist of the beta and beta-prime subunits (**Fig. 8.3**). DNA fits into a cleft formed by the beta and beta-prime subunits (**Fig. 8.2**). The alpha subunit assembles the other two subunits into a functional complex and communicates through physical "touch" with

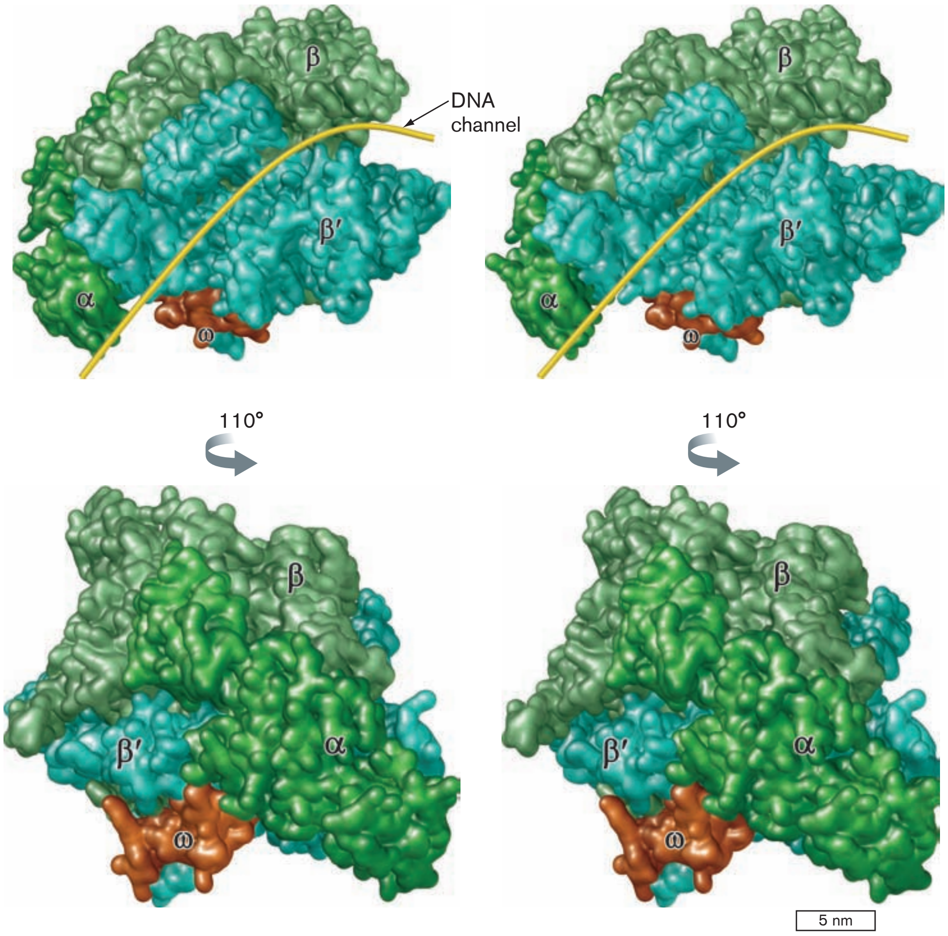

Figure 8.2 Subunit structure of core RNA polymerase. Two stereo-image views of RNA polymerase. The channel for the DNA template is shown by the yellow line. The molecule is rotated as shown. Subunits are color-coded. Omega is a subunit of unclear function sometimes associated with RNA polymerase. To view the stereo-images, place a piece of cardboard vertically between the two images. Position your eyes on opposite sides of the cardboard and force them to focus behind the images. The images will merge and produce a 3-D image. (PDB code: 1HQM) *Source*: Robert D. Finn, Elena V. Orlova, Brent Gowen, Martin Buck, and Marin van Heel. 2000. *Escherichia coli* RNA polymerase core and holoenzyme structures. *EMBO J.* 19(24):6833–6844.

various regulatory proteins that can bind DNA. The resulting protein-protein communications instruct RNA polymerase in what to do after binding DNA.

Promoter binding. Where does a gene begin and end? The helical structure of a DNA sequence appears largely homogeneous compared to proteins, which bend and fold in complex ways. In fact, without sigma factor, the core RNA polymerase binds and releases DNA at random. Yet there must be a mechanism that tells RNA polymerase where a gene starts, because random transcription is extremely wasteful.

The proteins responsible for guiding RNA polymerase to genes are the sigma (□) factors (see **Fig. 8.3B**). A sigma factor binds RNA polymerase through the alpha subunit and then helps the core enzyme detect a specific DNA sequence, called a **promoter**, which signals the beginning of a gene. We will discuss how sigma recognizes a promoter later.

A single bacterial species can make several different sigma factors, with each sigma factor helping core RNA polymerase find the start of a different subset of genes. However, a single core polymerase complex can bind only one sigma factor at a time. By acting as a sort of "seeing-eye" protein, sigma factors help RNA polymerase recognize different classes of promoter sequences. The specific sigma factor used to initiate transcription of a given gene will vary, depending on the gene and on the environmental signals needed to initiate transcription of that gene. However, regardless of which sigma factor is used, core RNA polymerase is required for all gene transcription.

Sigma factors regulate major physiological responses. Individual sigma factors coordinately control genes involved in nitrogen metabolism, flagellar synthesis, heat stress, starvation, sporulation, and many other physiological responses. So far, over 100 sigma factor genes have been sequenced from numerous species. While they all have different amino acid sequences, they also show sequence similarities that make them recognizable as sigma factors. The DNA sequence recognized by a given sigma factor can be determined by comparing known promoter sequences of different genes whose expression requires the same sigma. The DNA sequence similarities seen when comparing these different promoters defines a **consensus sequence** likely recognized by the sigma factor (**Fig. 8.4A**). A consensus sequence consists of the most likely base (or bases) at each position of the predicted promoter. Note that while the promoter is a dsDNA sequence, convention is to present the promoter as the ssDNA sequence of the sense strand, which matches the RNA product sequence.

The best consensus sequences are based on a large set of promoters that use the same sigma factor, or other regulator. Some positions in a consensus sequence are highly conserved—that is, the same base is found in that position in every promoter. Other, less conserved positions can be occupied by different bases. Few promoters will actually have the most common base at every position. Even highly efficient promoters usually differ from the consensus at one or two positions.

Microbes are guarded by an array of protein sensors that continually sample the internal and external environments. These sensors "look" for chemical deficiencies or dangers and, when triggered, direct the cell to increase synthesis or decrease destruction of the appropriate sigma factor. Accumulation of a specialty sigma factor dislodges other sigma factors from core polymerase and redirects RNA polymerase to the promoters of genes whose products can best solve the problem sensed. Regulation of multiple genes by a single sigma factor enables the cell to coordinately control those genes simply by regulating when a given sigma factor accumulates (Section 10.4). This control is critical to survival in constantly changing environments.

THOUGHT QUESTION 8.1 If each sigma factor recognizes a different promoter, how does the cell manage to transcribe genes that respond to multiple stresses, each involving a different sigma factor?

Every cell has a "housekeeping" sigma factor that keeps essential genes and pathways operating. In the case of *E. coli* and other gram-negative rod-shaped bacteria, that factor is sigma-70, so named because it is a 70-kilodalton (kDa) protein (its gene designation is *rpoD*). Genes recognized by sigma-70 all contain similar promoter consensus sequences consisting of two parts. The DNA base corresponding to the start of the RNA transcript is called nucleotide +1 (+1 nt). Relative to this landmark, the consensus promoter sequences are characteristically centered at –10 and –35 nt before the start of transcription (see **Fig. 8.4**). Other sigma factors typically recognize different

consensus sequences at one or both of these positions (or at nearby locations in some cases); or they shape the overall polymerase complex to bind the promoter.

How do sigma factors, or any other DNA-binding protein for that matter, recognize specific DNA sequences when the DNA is a double helix? The phosphodiester backbone is quite uniform, and the bases appear inaccessible owing to base pairing. Recognition of DNA sequences is possible, however, because the alpha-helical portions of DNA-binding proteins recognize base side groups (noncovalent binding) that protrude from the base into the major and minor grooves of DNA. **Figure 8.5A** illustrates how portions of sigma-70 from *E. coli* wrap around DNA allowing certain parts of the protein to fit into DNA grooves.

A key to understanding how sigma factors recognize different promoters is their structure. Based on amino acid sequence comparisons, sigma factors generally contain four highly conserved regions (**Figs. 8.5A** and **B**). Part of region 2 of the sigma-70 family recognizes –10 sequences, while region 4 recognizes the –35 sites. A part of region 1 helps separate the DNA strands in preparation for RNA synthesis. The structure of the holoenzyme RNA polymerase complex positioned at a promoter is shown in **Figure 8.5C**.

THOUGHT QUESTION 8.2 With respect to two different sigma factors with different promoter recognition sequences, predict what would happen to the overall gene expression profile in the cell if one sigma factor were artificially overexpressed? Could there be a detrimental effect on growth?

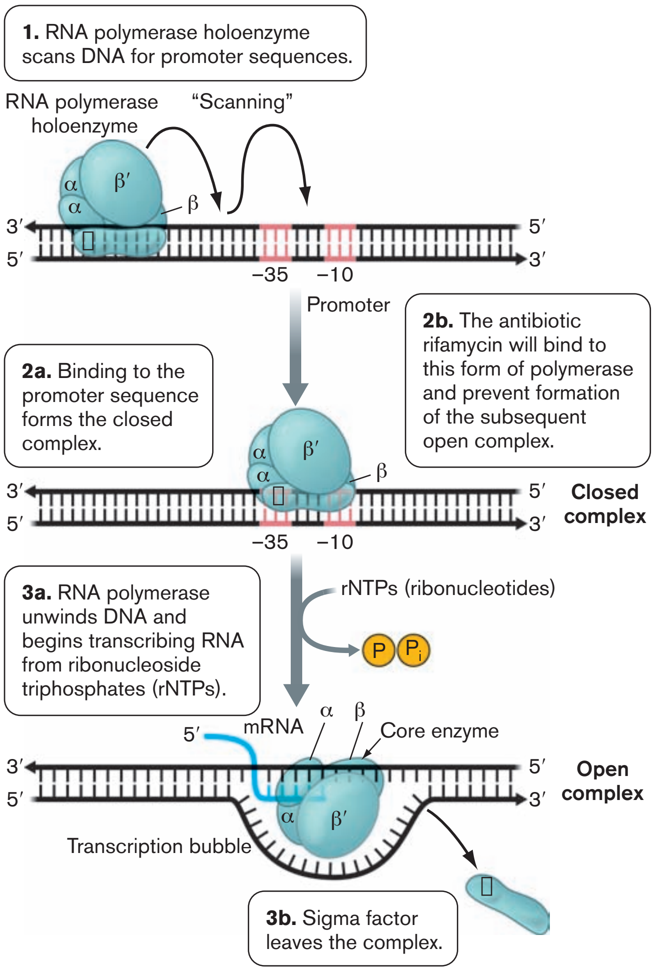
TO SUMMARIZE:

- **RNA polymerase holoenzyme** consisting of core RNA polymerase and a sigma factor executes transcription of a DNA template strand.
- **Sigma factors** help core RNA polymerase locate consensus promoter sequences near the beginning of a gene. The sequences identified and bound by *E. coli* sigma-70 are located –10 and –35 bp upstream of the transcription start site.
- **Dynamic changes in gene expression** result when the relative levels of different sigma factors change.

8.2 Transcription Initiation, Elongation, and Termination

Sigma binding is the first step of transcription initiation. Once the promoter has been activated by binding with its sigma factor, RNA polymerase completes the process of initiation, in which the closed RNA polymerase complex becomes an open complex. In elongation, the RNA chain is extended, followed by termination, in which the RNA polymerase comes apart from the DNA.



1. RNA polymerase holoenzyme scans DNA for promoter sequences.

2a. Binding to the promoter sequence forms the closed complex.

2b. The antibiotic rifamycin will bind to this form of polymerase and prevent formation of the subsequent open complex.

3a. RNA polymerase unwinds DNA and begins transcribing RNA from ribonucleoside triphosphates (rNTPs).

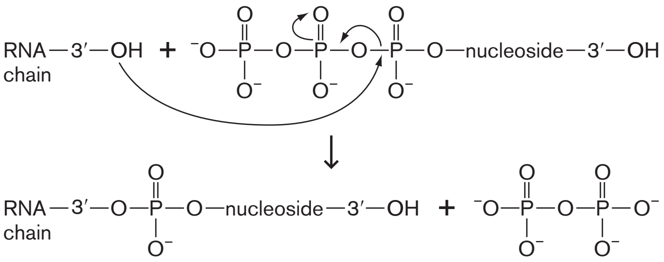
3b. Sigma factor leaves the complex.

Figure 8.6 Transcription initiation.

Initiation of Transcription

RNA polymerase constantly scans DNA for promoter sequences (**Fig. 8.6**, step 1). It binds DNA loosely and comes off repeatedly. Once bound to the promoter, RNA polymerase holoenzyme forms a loosely bound, closed complex with DNA, which remains annealed and double-stranded (that is, unmelted) (step 2). To successfully transcribe a gene, this closed complex must become an open complex through the unwinding of one helical turn, which causes DNA to become unpaired in this area (step 3). After promoter unwinding, RNA polymerase in the open complex becomes tightly bound to DNA. Region 1 of the sigma factor is important for DNA unwinding, as is a "rudder" complex in β′ that separates the two stands (shown in **Fig. 8.7A**).

The open complex form of RNA polymerase begins transcription. The first ribonucleoside triphosphate (rNTP) of the new RNA chain is usually a purine. It base-pairs to the DNA template designated position +1, marking the start of the gene. As the enzyme complex moves along the template, subsequent NTPs diffuse through a channel in the polymerase and into position at the DNA template (see **Fig. 8.7B**). After the first base is in place, each subsequent ribonucleoside triphosphate transfers a nucleoside monophosphate to the growing chain while releasing a pyrophosphate:



$$\underset{\text{chain}}{\text{RNA}}-3'-\text{OH} + {}^{-}\text{O}-\underset{\text{O}^-}{\overset{\text{O}}{\text{P}}}-\text{O}-\underset{\text{O}^-}{\overset{\text{O}}{\text{P}}}-\text{O}-\underset{\text{O}^-}{\overset{\text{O}}{\text{P}}}-\text{O}-\text{nucleoside}-3'-\text{OH}$$

$$\downarrow$$

$$\underset{\text{chain}}{\text{RNA}}-3'-\text{O}-\underset{\text{O}^-}{\overset{\text{O}}{\text{P}}}-\text{O}-\text{nucleoside}-3'-\text{OH} + {}^{-}\text{O}-\underset{\text{O}^-}{\overset{\text{O}}{\text{P}}}-\text{O}-\underset{\text{O}^-}{\overset{\text{O}}{\text{P}}}-\text{O}^-$$

The energy released by cleaving the rNTP triphosphate groups (phosphoric anhydride bond) is used to create the phosphodiester link to the growing polynucleotide chain.

As seen in **Figure 8.7**, the β′ subunit forms part of the pocket, or cleft, in which the DNA template is read. Another part of the β′ cleft is involved in hydrolyzing ribonucleoside triphosphates. Deep at the base of the cleft is the active site of polymerization, defined by three evolutionarily conserved aspartate residues that chelate (that is, bond with) two magnesium ions (Mg^{2+}). As we saw for DNA polymerases, these metal ions play a key role in catalyzing the polymerization reaction.

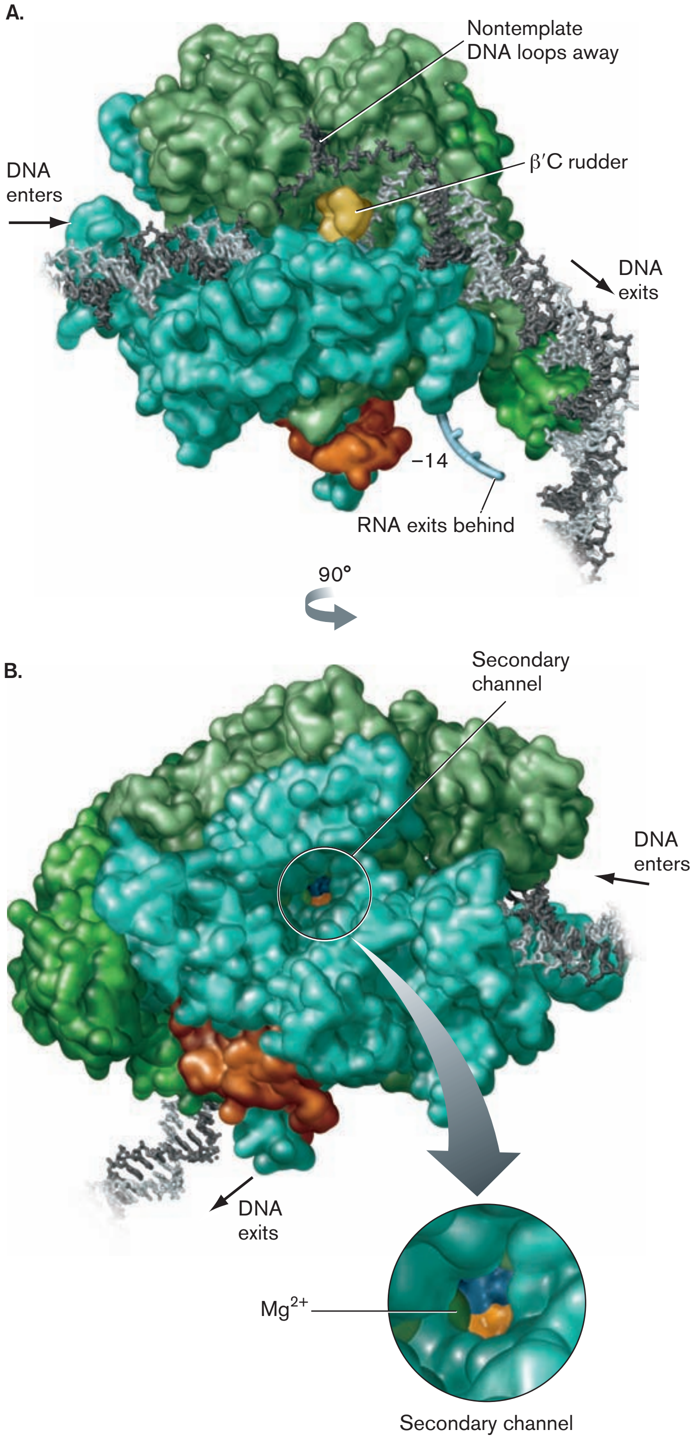


Figure 8.7 Three-dimensional view of transcription by *Thermus aquaticus* (Taq) RNA polymerase showing DNA, RNA, and the position of the rudder. The process is shown from two different angles. Transcription (polymerase movement on the DNA) is going from right to left in panel A and the opposite in panel B. Color-coded molecular surfaces are as follows: beta subunit, green; beta G flap in red, beta-prime C rudder in gold; alpha and omega, not seen in this view; the DNA template (template strand, purple; nontemplate strand, gray); and the RNA transcript (blue). The directions of the entering downstream DNA and exiting upstream DNA are indicated (black arrows). **A.** A view perpendicular to the main active site channel, which runs roughly horizontal. Parts of the protein structure are colored. **B.** In this view, the structure is rotated 90° relative to view (A). With the entering DNA removed for clarity, Mg^{2+} is seen in the catalytic site; the secondary channel where nucleotides (orange) enter and a part of the RNA strand (blue) are also seen. (PDB codes: 1L9Z, 1K8J) *Source*: A. Seth A. Darst. 2001. Bacterial RNA polymerase. *Current Opinion in Structural Biology* 11:155–162.

Elongation of RNA transcripts. The sigma factor remains associated with the transcribing complex until about nine bases have been joined; then it dissociates (see **Fig. 8.6**). The newly liberated sigma factor can then reassociate with an unbound core RNA polymerase to direct another round of promoter binding. Meanwhile, the original RNA polymerase continues to move along the template, synthesizing RNA at approximately 45 bases per second. The unwinding of DNA ahead of the moving complex forms a 17-bp transcription bubble. Because of this unwinding, positive supercoils are formed ahead of the advancing bubble. These positive supercoils are removed by enzymes that return the DNA to its normal negative supercoiled state (see Section 7.2).

Termination of transcription. We have learned how RNA polymerase recognizes the beginning of a gene and transcribes RNA, but how does it know when to stop? Again, the secret is in the sequence. All bacterial genes use one of two known transcription termination signals. One termination mechanism, called **Rho-dependent**, relies on a protein called Rho and an ill-defined sequence at the 3′ end of the gene that appears to be a strong pause site. Pause sites are areas of DNA that slow or stall RNA polymerase movement. Some pause sites occur within the gene's **open reading frame (ORF)**, the part of a gene that actually encodes a protein, to allow time for the ribosome to catch up to a transcribing RNA polymerase (discussed in Section 8.3). The transcription termination pause site, however, is located after the ORF, beyond the translation stop codon, because if transcription were to cease before the ribosome reaches the translation stop codon, an incomplete protein would be made. Rho factor binds to an exposed region of RNA after the ORF at GC-rich sequences that lack obvious secondary structure. This is the transcription terminator pause site. Rho monomers assemble as a hexamer around the RNA (**Fig. 8.8A**). Then, like a raft pulled to shore by winding a rope around a piling, Rho pulls itself to the paused RNA

Figure 8.8 Transcription termination.

polymerase by wrapping downstream RNA around itself via an intrinsic ATPase activity. Once Rho touches the polymerase, an RNA-DNA helicase activity built into Rho appears to unwind the RNA-DNA heteroduplex, which releases the completed RNA molecule and frees the RNA polymerase.

The second type of termination event, called **Rho-independent**, occurs in the absence of Rho or any other protein cofactors. Rho-independent termination requires a GC-rich region of RNA roughly 20 bp upstream from the 3′ terminus as well as four to eight consecutive uridine residues at the terminus. The GC-rich sequence contains complementary bases and forms an RNA stem, or **stem loop**, a structure that "grabs" RNA polymerase, causing it to pause (**Fig. 8.8B**). While the polymerase is paused, the DNA-RNA duplex is weakened because the poly-U, poly-A base pairs at the 3′ terminus contain only two hydrogen bonds per pair and are usually weak (that is, easier to melt). The melting of the hybrid molecule releases the transcript and halts transcription. The pause in polymerase movement, and thus transcription, is important to prevent the formation of tighter base pairing downstream of the UA region.

Antibiotic Resistance Helped Reveal Components of RNA Synthesis Machines

How did scientists determine the details of RNA and protein synthesis? The processes were observed in cell-free systems. For example, transcription and translation were observed in the test tube using purified RNA polymerase and ribosomes. In addition, the various protein subunits of RNA polymerase were separated from each other and mixed together again to make an active complex.

One particularly clever strategy was based on the genetics of antibiotic resistance. We now know that many antibiotics target specific components of the bacterial transcription and translation machinery. However, organisms, such as *E. coli* mutate at low frequency to become resistant to a given antibiotic. The resistance mutation often affects the part of the RNA or protein synthesis machine that binds to the antibiotic. The effect is a decreased affinity of that altered protein for the antibiotic.

The subunits that conferred resistance to particular antibiotics were determined in cell-free systems. For example, rifamycin is an antibiotic that inhibits transcription (**Special Topic 8.1**). To determine which RNA polymerase subunit was targeted by the drug, RNA polymerases from rifamycin-sensitive and -resistant strains were purified, the component parts of the polymerase were separated, and then a chimeric RNA polymerase was reassembled using all but one of the protein subunits from the sensitive strain. The missing subunit was supplied by the resistant strain and the polymerase preparation tested in vitro for an ability to make RNA in the presence of rifamycin. This will happen only when the subunit conveying resistance has been added—in this case, the beta subunit. Subsequent in vitro assays and X-ray crystallography used this information to learn more about the enzymatic mechanism of this subunit.

Different Classes of RNA Have Different Functions

Now that we have shown how RNA is synthesized, it is important to note that not all RNA molecules are translated to protein. Six known classes of RNA are made. Each

Table 8.1 Classes of RNA in *E. coli*.[a]

RNA class	Function	Number of types	Average size	Approx. half-life	Unusual bases
mRNA (messenger RNA)	Encodes protein	Thousands	1,500 nt	3–5 minutes	No
rRNA (ribosomal RNA)	Synthesizes protein	Three	5S, 120 nt; 16S, 1,542 nt; 23S, 2,905 nt	Hours	Yes
tRNA (transfer RNA)	Shuttles amino acids	27 typeset (86 genes)	80 nt	Hours	Yes
sRNA (small RNA)	Controls translation, controls transcription	20–30	<100 nt	Variable	No
tmRNA (properties of transfer and messenger RNA)	Frees ribosomes stuck on damaged mRNA	Roughly one per species	300–400 nt	3–5 minutes	No
Catalytic RNA	Carries out enzymatic reactions (e.g., RNase P)	??	Varies	3–5 minutes	No

[a] Six major classes of RNA exist in all bacteria. They differ based on their function in the cell, the number of types, average sizes, half-lives, and whether they contain modified bases.

is designed for a different purpose (**Table 8.1**). RNA molecules that encode proteins are called **messenger RNA (mRNA)**. Molecules of mRNA average 1,000–1,500 bases in length but can be much longer or shorter, depending on the size of the protein they encode. Another class of RNA forms the scaffolding on which ribosomes are built and is called **ribosomal RNA (rRNA)**. As will be discussed later, rRNA also forms the catalytic center of the ribosome. **Transfer RNA (tRNA)** molecules ferry amino acids to the ribosome. A unique property of rRNA and tRNA is the presence of unusual modified bases not found in other types of RNA.

The fourth important class of RNA is called **"small RNA" (sRNA)**. Molecules of sRNA do not encode proteins but are used to *regulate* the stability or translation of specific mRNAs into proteins. As will be discussed later in more detail, all mRNA molecules contain untranslated leader sequences that precede the actual coding region. Complementary sequences within some of these RNA leader regions snap back on themselves to form double-stranded stems and stem loop structures that can obstruct ribosome access and limit translation. The regulatory sRNAs are thought to disrupt or stabilize intrastrand stem structures by base-pairing to key regions within the mRNA molecule.

The final two classes of RNA are **tmRNA**, which has properties of both tRNA and mRNA, and **catalytic RNA**. Catalytic RNA is usually found associated with proteins in which the enzymatic (catalytic) activity actually resides in the RNA portion of the complex rather than in the protein.

RNA Stability

Once released from RNA polymerase, most prokaryotic mRNA transcripts are doomed to a short existence owing to their degradation by various intracellular RNases. This is especially true of transcripts that encode proteins (mRNA). The rationale for this is that the cell must be prepared to react rapidly to a changing environment, quickly halting synthesis of superfluous or even detrimental proteins. An effective way to do this is to rapidly destroy the mRNAs that encode those proteins. Rapid mRNA degradation makes it necessary to continually transcribe those genes as long as the need for their products exists.

RNA stability is measured in terms of half-life, which is the length of time the cell needs to degrade half the molecules of a given mRNA species. The average half-life for mRNA is 1–3 minutes but can be as little as 15 seconds. Other RNAs can be fairly stable, with half-lives of 10–20 minutes or longer. However, different kinds of RNAs differ drastically with respect to stability. The mRNAs are usually unstable compared with rRNAs and tRNAs, which contain modified bases less susceptible to RNase digestion. These more stable RNA molecules have half-lives of hours.

TO SUMMARIZE:

- **A closed complex** occurs on initial binding of RNA polymerase to promoter DNA.
- **Opening (melting) of the DNA** strands produces a "bubble" of DNA around the polymerase and forms the open complex.

- **Rho-dependent and Rho-independent** mechanisms mediate transcription termination.
- **Half-lives of RNA** species vary within the cell.
- **Messenger RNA** molecules encode proteins.
- **Ribosomal RNA** are stable molecules found in ribosomes and contain unusual modified bases.
- **Transfer RNA** are stable molecules that bind amino acids and contain modified bases.
- **Small RNA** molecules can regulate gene expression, have catalytic activity (catalytic RNA), or function as a combination of tRNA and mRNA (tmRNA).

8.3 Translation of RNA to Protein

Once a gene has been copied into mRNA, the next stage is **translation**, the decoding of the RNA message to synthesize protein. An mRNA molecule can be thought of as a sentence in which triplets of nucleotides, called **codons**, represent individual words, or amino acids (**Fig. 8.9**). Ribosomes are the machines that read the language of mRNA and convert, or translate, it to protein. Numerous steps are involved in translation, the first of which is the search by ribosomes for the beginning of an RNA coding region. Because the code consists of triplet codons, a ribosome must start translating at precisely the right base (in the right frame) or the product will be gibberish. Before we discuss how the ribosome finds the right reading frame, let's review the code itself and the major players in the translation process.

The Code and tRNA Molecules

When learning a new language, we need a dictionary that converts words from one language into the other, in this case from RNA to protein. Through painstaking efforts of Marshall Nirenberg and colleagues, the molecular code was broken, and it was found that each codon (a triplet of nucleotides) represents an individual amino acid. Remarkably, and with few exceptions, the code operates universally across species. (Some exceptions: UGA is normally read as a stop codon but encodes tryptophan in vertebrate mitochondria, *Saccharomyces*, mycoplasmas; and *Candida albicans* read CUG for serine instead of leucine.) On examining the code presented in **Figure 8.9**, we can see that most amino acids have multiple codon synonyms. Glycine, for example, is translated from four different codons, leucine from six, whereas methionine and tryptophan each have only one

Often, single letter abbreviations for amino acids are used to convey protein sequences, Ala (A); Arg (R); Asn (N); Asp (D); Cys (C); Gln (Q); Glu (E); Gly (G); His (H); Ile (I); Leu (L); Lys (K); Met (M); Phe (F); Pro (P); Ser (S); Thr (T); Trp (W); Tyr (Y); Val (V).

Special Topic 8.1 Antibiotics That Affect Transcription

To be useful in medicine, all antibiotics need to meet two fundamental criteria: They must kill or retard the growth of a pathogen, and they must not harm the host. Antibiotics used against bacteria, for instance, must *selectively* attack features of bacterial targets not shared with eukaryotes. Many antibiotics possess highly specific modes of action, binding to and altering the activity of one specific "machine" of one type of cell. Thus, the quest to discover how antibiotics worked ultimately revealed the molecular mechanics of life.

One example of this is the antibiotic rifamycin B (**Fig. 1A**), produced by the actinomycete *Streptomyces mediterranei* (**Fig. 1B**). Rifamycin B selectively targets bacterial RNA polymerase. Rifamycin binds to the bacterial RNA polymerase beta subunit near the Mg^{2+} active site (**Fig. 1C**) and sterically blocks phosphodiester bond formation during initiation but does not prevent RNA polymerase from binding to promoters and does not inhibit complexes already transcribing DNA (that is, elongation). The semisynthetic derivative of this drug, rifampin, is used for treating tuberculosis and leprosy and is given to contacts (family members or roommates) of individuals with bacterial meningitis caused by *Neisseria meningitidis*.

codon. Because more than one codon can encode the same amino acid, the code is said to be degenerate or redundant. Notice that in almost every case, synonymous codons differ only in the *last* base. How the cell handles this degeneracy (redundancy) in the code will be explained later.

Only 61 out of a possible 64 codons specify amino acids. Four of these act as codons that can mark the beginning of the protein "sentence." In order of preference, they are AUG (90%), GUG (8.9%), UUG (1%), and CUG (0.1%). Due to their inefficiency in starting translation, the use of a rare start codon, such as CUG, limits the translation of any ORF in which they are found. Although these **start codons** are used to begin all proteins, they are not restricted to that role; they also encode amino acids found in the middle of

Actinomycin D (**Fig. 2**) is another antibiotic produced by a *Streptomyces* species. Its phenoxizone ring is a planar structure that "squeezes," or intercalates, in between GC base pairs within DNA. The side chains then extend in opposite directions along the minor groove (see **Fig. 2B**). Because it mimics a DNA base, actinomycin D blocks the elongation phase of transcription; but because it binds any DNA, it is not selective for prokaryotes. It can be used to treat human cancers because cancer cells replicate rapidly, but has severe side effects due to its inhibition of DNA synthesis in normal cells. (Further discussion of antibiotics can be found in Chapter 27.)

coding sequences. Consequently, there must be another mRNA feature that signifies whether an AUG codon, for example, marks the start of a protein or resides internally, where it codes for an amino acid (discussed below).

The other three triplets (UAA, UAG, and UGA), however, are equally important, for they tell the ribosome when to stop reading a gene sentence. Called **stop codons**, they trigger a series of events to be described later that dismantle ribosomes from mRNA and release a completed protein.

DHU (or D) is dihydroxyuracil, which only occurs in this loop; TΨC are thymine, pseudouracil, and cytosine bases that occur as a triplet in this loop **C.** Three-dimensional structures. The DHU and TΨC loops are named for the modified nucleotides that are characteristically found there. The anticodon loop binds to the codon, while the acceptor end binds to the amino acid. (PDB code: 1GIX)

The decoder (or adaptor) molecules that convert the language of RNA (codons) to the language of proteins (amino acids) are the tRNAs. Their job is to travel through the cell and return to the ribosome with amino acids in tow. Approximately 80 bases in length, a tRNA laid flat appears as a cloverleaf with three loops (**Figs. 8.10A** and **B**). In nature, however, the molecule folds into a characteristic "boomerang-like" three-dimensional structure (**Fig. 8.10C**). The very bottom or middle loop of all tRNA molecules (as depicted in **Figs. 8.10B** and **C**) harbors an **anticodon** triplet that base-pairs with codons in mRNA (**Fig. 8.11**). As a result, this loop is called the anticodon loop. Notice that codon and anticodon pairings are aligned in an antiparallel manner. Most tRNA molecules begin with a 5′ G, and all end with a 3′ CCA, to which amino acids attach (see **Figs. 8.10** and **8.11**). Because of this, the 3′ end of the molecule is called the acceptor end.

Transfer RNA molecules contain a large number of unusual, modified bases, which accounts for the strange letter codes seen in **Figure 8.10A** (for example, D, M, Y, and T). Some of the odd bases used are diagrammed in **Figure 8.12**. For example, wybutosine (with the symbol Y) has three rings instead of the two found in a normal purine. During transcription of the tRNA genes, normal, unmodi-

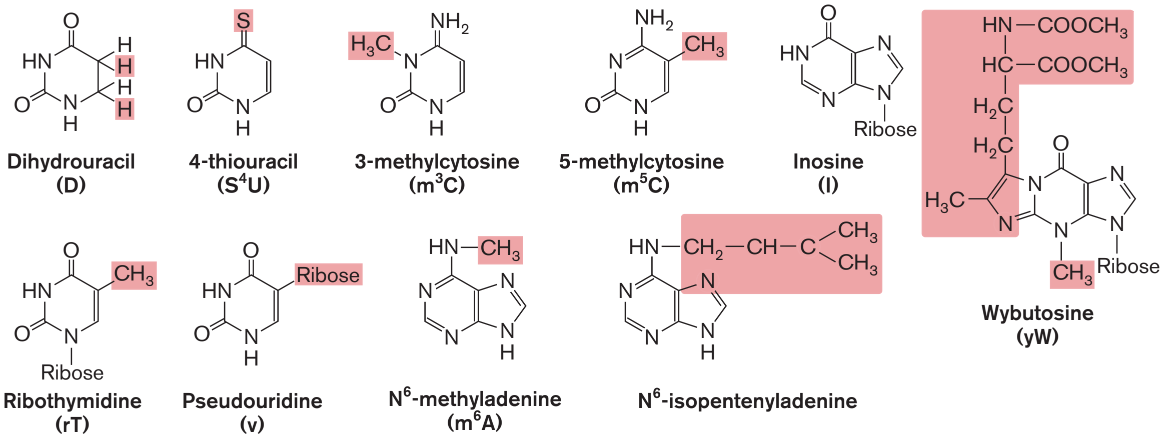

Figure 8.12 Modified bases present in tRNA and rRNA molecules. Modifications are shown in red.

fied bases are incorporated, but some of these are modified later by specific enzymes. The remarkable stability of tRNA molecules is explained, in part, by these unusual bases because they are poor substrates for RNases.

When looking at the cloverleaf structure of tRNA, two of the loops are named after modifications that are invariently present in those loops. One is called the TPC (or TΨC) loop because this loop in every tRNA has the nucleotide triplet thymidine, pseudouridine (Ψ), and cytidine. The other loop always contains dihydroxyuridine and is called the DHU loop. These loops are recognized by the enzymes that match tRNA to the proper amino acid.

As noted previously, the code is redundant in that many amino acids have codon synonyms. Redundancy occurs primarily in the third position of the codon (for example, UUU and UUC both encode phenylalanine). This is the result of a "wobble" in the first position of the anticodon, which corresponds to the third position of the codon (remember, as with DNA, base-pairing between RNA strands is antiparallel). The wobble is due in part to the curvature of the anticodon loop and to the use of an unusual base (inosine) at this position in some tRNA molecules. The wobble structure allows one anticodon to pair with several codons differing only in the third position.

Aminoacyl-tRNA Transferases Attach Amino Acids to tRNA

When a tRNA GCG anticodon, for instance, pairs with a CGC codon, the ribosome has no way of checking that the tRNA is attached (that is, charged) to the "correct" amino acid (arginine in this case). Consequently, each tRNA must be charged with the proper amino acid *before* it encounters the ribosome. How are amino acids correctly matched to tRNA molecules and affixed to their 3′ ends? The charging of tRNAs is carried out by a set of enzymes called **aminoacyl-tRNA transferases**. There are generally 20 of these "match and attach" proteins in the cell, one for each amino acid. Some bacteria, however, have only 18, choosing instead to modify already charged glutamyl-tRNA and aspartyl-tRNA by adding an amine to make glutamine and asparagine derivatives. Each aminoacyl-tRNA transferase enzyme has a specific binding site for its cognate (matched) amino acid. Each enzyme also has a site that recognizes the target tRNA and an active site that joins the carboxyl group of the amino acid to the 3′ OH (class II synthetases) or 2′ OH (class 1 synthetases) of the tRNA by forming an ester (**Fig. 8.13**).

The specificity of the aminoacyl-tRNA transferase is based on recognition of the anticodon loop as well as other features of the tRNA structure such as the TΨC and DHU loops. It is very important not only that each enzyme recognize its own tRNA but that it does not bind to any other tRNA. Thus, each tRNA has its own set of interaction sites that only match the proper aminoacyl-tRNA transferase.

The Ribosome, a Translation Machine

The decoding process of the ribosome may be compared to a language translation machine that converts one language to another. The ribosome can be viewed as translating the language of the mRNA code into sensible protein sequences that conduct the activities of the cell. Ribosomes are composed of two complex subunits, each of which includes rRNA and protein components. In prokaryotes, the subunits are named 30S and 50S for their "size" in Svedberg units. A Svedberg unit reflects the rate at which a molecule sediments under the centrifugal force of a centrifuge (discussed in Chapter 3). Within the living cell, the two subunits exist separately but come together on mRNA to form the translating 70S ribosome (**Fig. 8.14**). Note that Svedberg units are not directly additive, since they represent a rate of sedimentation, not a weight.

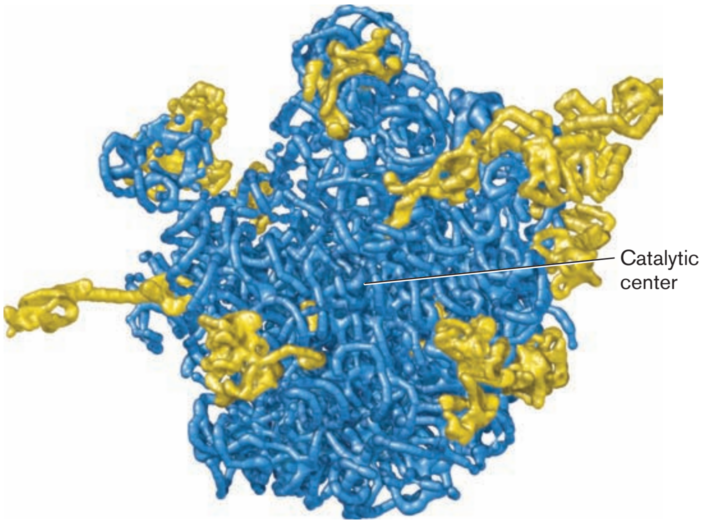
The smaller, 30S subunit (900,000 Da) contains 21 ribosomal proteins (named S1–S21; S = small) assembled around one 16S rRNA molecule. The 50S subunit (1.6 million Da) consists of 31 proteins (designated L1–L34; three numbers were not used; L = large) formed around two rRNA molecules (5S and 23S). **Figure 8.15** presents a three-dimensional spatial arrangement of rRNA and protein in the 50S subunit. Note that the majority of the ribosome is RNA.

The typical *E. coli* cell has approximately 18,000 ribosomes. The ribosome is a molecular machine, whose production, together with that of other translation components, can take up 40% of the energy of a growing bacterium. How does such a complex molecular machine get built? Assembly of the ribosome starts with the transcription of ribosomal RNA genes (DNA), sometimes referred to as rDNA. Although there are only three forms of rRNA



Catalytic center

Figure 8.15 RNA: protein interfaces in the large (50S) ribosome subunit. rRNA is in blue, proteins are gold. (PDB code: 1GIY)

in a prokaryotic cell (16S, 23S, and 5S), many microbes possess multiple copies of the genes encoding them. Arranged together as packaged sets on the chromosome, the 16S, 23S, and 5S rRNAs are initially transcribed as a single RNA molecule from a common DNA promoter, as illustrated in **Figure 8.16**.

In the initial RNA transcript, there are also leaders, spacers, and trailer sequences that often contain tRNA sequences. This polycistronic message is the starting point from which the ribosomes are built. A **cistron** is a name used to define a functional unit of RNA; a **polycistronic** RNA is a single RNA molecule that contains information from several contiguous genes. In a carefully choreographed series of steps, the rRNA precursor molecule is surgically processed by various RNases that trim away excess RNA. (The RNA stem structures represented in the figure are specifically required substrates for some RNases.) Although shown as forming two-dimensional loops in **Figure 8.17**, the rRNA molecules actually form complex, three-dimensional folded structures. As with tRNA molecules, many bases in rRNA are enzymatically modified during processing to enhance the molecule's rigidity and stability.

Simultaneous with rRNA transcription and processing, the ribosomal proteins begin to assemble, finding their places nestled in the secondary rRNA structures (see **Fig. 8.17**). Ribosomal proteins bind sequentially in waves, the first wave providing new binding sites for a second wave of different proteins. Thus, the ribosome is built by precise, timed molecular interactions that occur between RNA sequences, between RNA and protein, and between protein and protein.

THOUGHT QUESTION 8.5 Synthesis of ribosomal RNAs and ribosomal proteins causes a major energy drain on the cell. How might the cell regulate synthesis of these molecules when growth rate slows as a result of amino acid limitation?

Figure 8.16 Processing of ribosomal RNA and tRNA. A. The genes encoding rRNAs in *E. coli* exist in operons that include several tRNA genes. *E. coli* contains seven such operons in its chromosome, all of which make the same rRNA molecules but differ in which tRNA molecules are present. **B.** Processing of precursor rRNA molecules. Specific RNases cleave the transcript at precise places to release 16S, 23S, and 5S rRNA and the interspersed tRNA molecules.

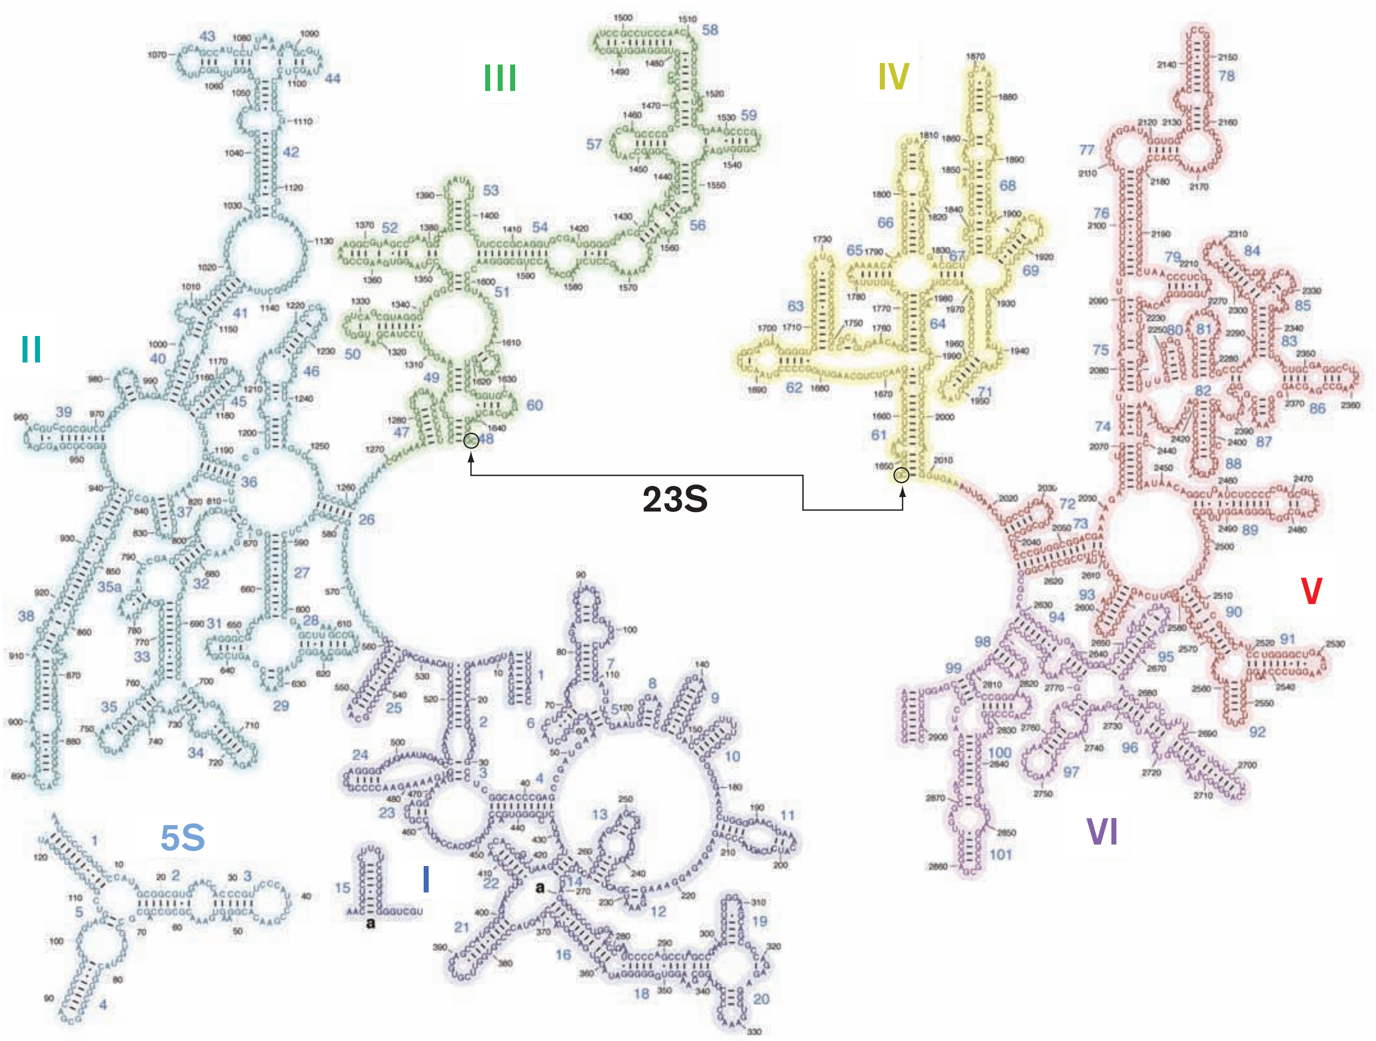

Figure 8.17 Secondary structure of the 5S and 23S rRNA. Note the many double-stranded hairpin structures that fold into domains (roman numerals). Nucleotides are numbered in black; stem structures are numbered in blue. During the building of the ribosome, proteins bind to specific sites on the RNA molecule. The proteins bind to some of the secondary and tertiary rRNA structures and help form the key tertiary 23S structure. Domains where various ribosomal proteins bind are indicated by different colors. The 23S RNA is split where indicated to provide space for all secondary structures.

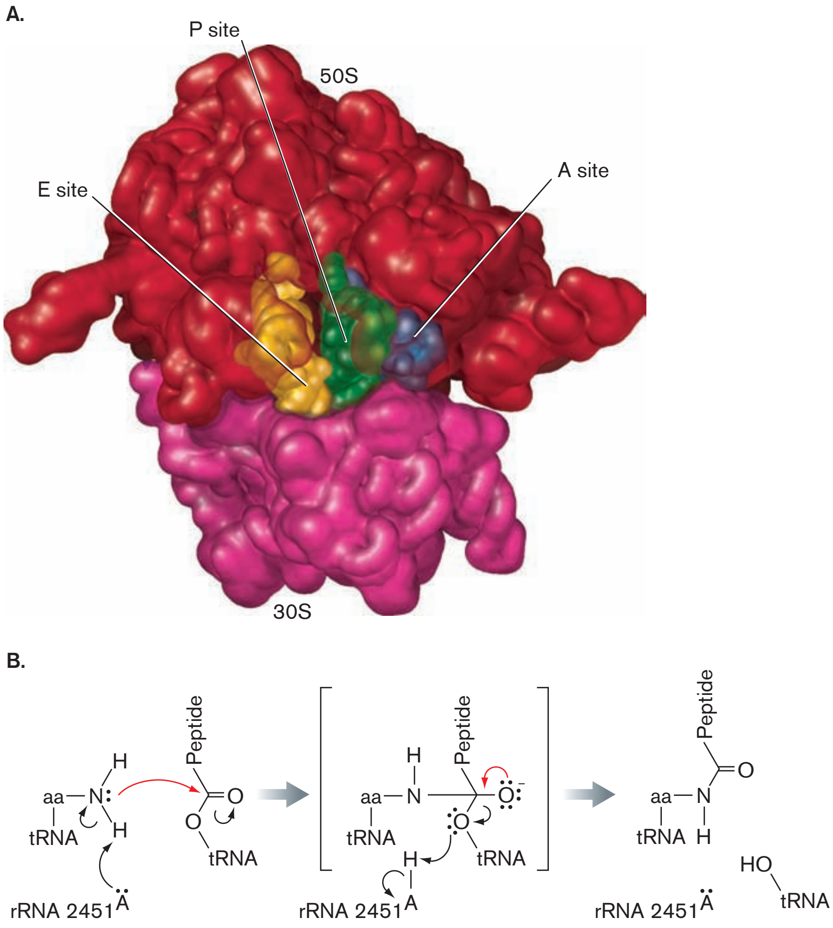
The 70S ribosome harbors three binding sites for tRNA (**Fig. 8.18A**). During translation, each tRNA molecule moves through the sites in an assembly-line fashion, first entering at one site, then moving progressively through the others before being jettisoned from the ribosome. The first position is the aminoacyl-tRNA **acceptor site (A site)**, which binds an incoming aminoacyl-tRNA. The growing peptide is attached to tRNA berthed in the **peptidyl-tRNA site (P site)**. Lastly, a tRNA recently stripped of the polypeptide is located in the **exit site (E site)**.

The Ribosome Is a Ribozyme

The ribosome's specialty is to make the peptide bonds that stitch amino acids together. This is carried out by a remarkable enzymatic activity called **peptidyltransferase**, present in the 50S subunit. Contrary to expectation, the peptidyltransferase activity resides not in ribosomal proteins, but in the rRNA. Peptidyltransferase is actually a **ribozyme** (an RNA molecule that carries out catalytic activity), and it is part of 23S rRNA highly conserved across all species. Proteins surrounding this active center offer structural assistance to ensure that the RNA is folded properly. The catalytic mechanism of peptide bond formation appears to involve a key adenine residue within the 23S rRNA molecule (**Fig. 8.18B**).

The sequences of ribosomal RNAs from all microbes are very similar, in large part because rRNA plays an important catalytic role in the activities of ribo-



1. By accepting a proton from the amino group of an aa-tRNA, the adenine at position 2451 facilitates nucleophilic attack of this amino group on the carbonyl carbon of the peptidyl-tRNA.

2. The tetrahedral oxyanion intermediate removes a proton from A2451 and loses the uncharged tRNA to complete the formation of a new peptide bond.

Figure 8.18 Binding of tRNA. **A.** X-ray crystallographic model of *Thermus aquaticus* ribosome with associated tRNAs. 50S is red, 30S is violet, and tRNAs in the A, P, and E sites are purple, green, and gold, respectively. (PDB codes: 1GIX, 1GIY) **B.** Proposed general acid-base mechanism for peptidyltransferase. Adenine at position 2451 on 23S rRNA receives a proton from the amino group in an amino acyl (aa)-tRNA. This allows the amino nitrogen to launch a nucleophilic attack on the carbonyl carbon of the peptidyl-tRNA, forming a tetrahedral intermediate. The oxyanion then accepts a proton from A2451, forming a new peptide bond and an uncharged tRNA.

somes. But there are differences in rRNA sequences that increase in relation to the evolutionary distance between species. As a result, rRNA serves as a molecular clock that measures the approximate time since two species diverged.

How Do Ribosomes Find the Right Reading Frame?

Every mRNA has three potential reading frames, depending on which base the ribosome happens to start with. Having a one in three chance of randomly picking the right frame on the template, a ribosome that chooses the wrong frame would produce proteins with totally different amino acid sequences. In addition, a shifted reading frame often generates an inadvertent stop codon that prematurely terminates the peptide; thus, the translated protein would not even have the right length. So how does the ribosome find the right frame?

The key is that each mRNA contains additional sequences upstream of the segment that encodes protein. Upstream, untranslated leader RNA plays a critical role in directing the prokaryotic ribosome to the right place. The upstream leader RNA contains a purine-rich sequence with the consensus 5′-AGGAGGU-3′ located four to eight bases upstream of the start codon in *E. coli*. This upstream sequence is called the **ribosome-binding site** or **Shine-Dalgarno sequence** after the scientists who discovered it in 1974, Lynn Dalgarno and her student John Shine (Australian National University). The Shine-Dalgarno site is complementary to a sequence at the 3′ end of 16S rRNA (5′-ACCUCCU-3′), found in the 30S ribosomal subunit. Binding of mRNA to this site positions the start codon precisely in the ribosome P site, ready to pair with an N-formylmethionyl-tRNA.

NOTE: Eukaryotic ribosomes have a different mechanism for finding the start codon. They generally start translating at the first AUG after the 5′ cap. The 5′ cap is a 7-methylguanosine added post-transcriptionally to the 5′ end of eukaryotic mRNA molecules. The normal role of the cap is thought to be as a signal to transport RNA out of the nucleus and/or to stabilize mRNA.

Although Dalgarno and Shine predicted the importance of the ribosome-binding site in 1974, experimental evidence that this mRNA region truly bound 16S rRNA was lacking. The evidence was supplied in 1975 by Joan

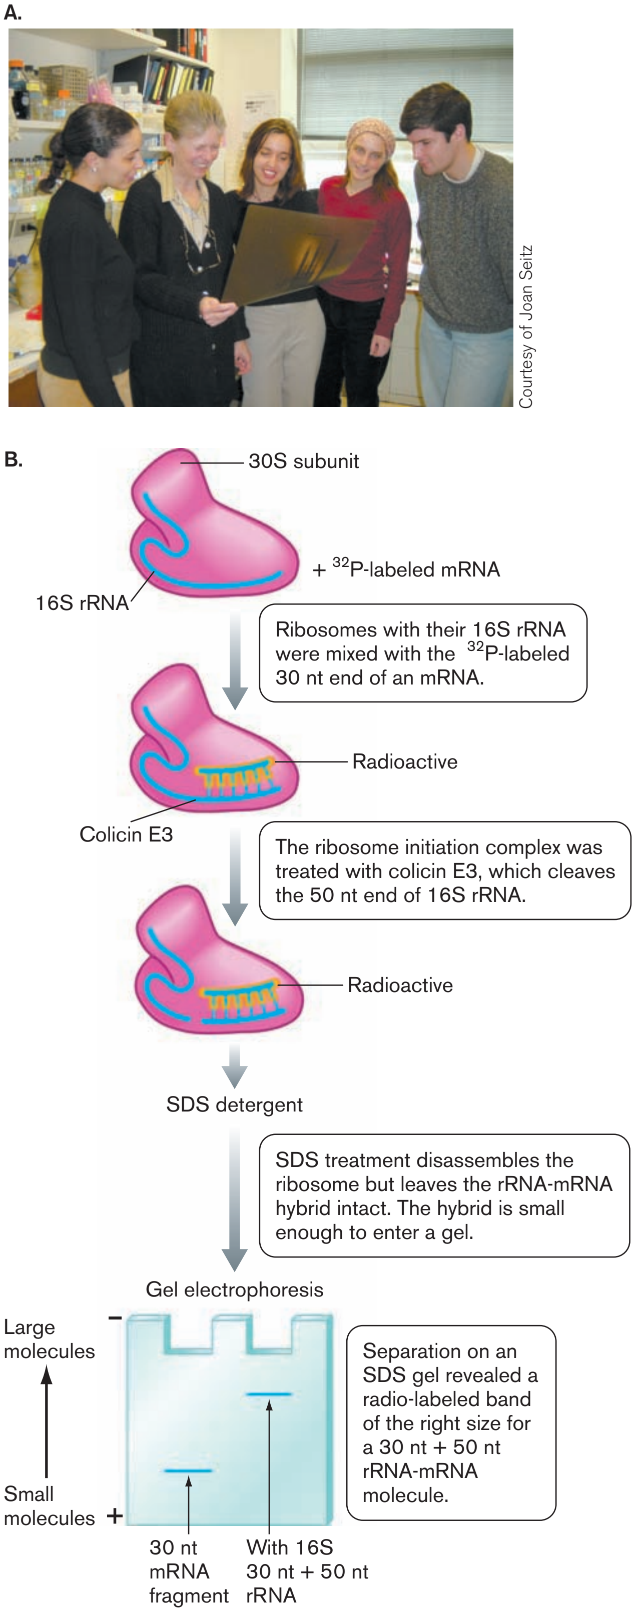
Steitz in an elegant yet simple experiment (**Fig. 8.19A**). A radioactive, 30-nt, ^{32}P-labeled RNA fragment was taken from the 5′ end of an mRNA molecule and added to ribosomes. The 5′ end of the mRNA is where the initiation sequences should be. Steitz then treated the ribosome initiation complex with colicin E3, a toxin made by some bacteria as a defense against others. Colicin E3 cleaves the large 16S rRNA molecule once, about 50 nt from the 3′ end, to yield a small, manageable piece that would easily enter a gel. The ribosomal proteins were then peeled away using the detergent SDS (sodium dodecyl sulfate), and the mixture was subjected to electrophoresis through a polyacrylamide gel to separate different RNA bands by size. The gel was dried and placed onto X-ray film to visualize the RNA bands. SDS does not disrupt RNA-RNA interactions; consequently, if the 3′ end of 16S rRNA oriented the mRNA message for translation by binding to the 5′ end of the mRNA, a 50-nt + 30-nt (rRNA-^{32}P labeled mRNA fragment) hybrid molecule would exist and, based on its size, travel to a specific position in the gel. When the film was developed, the radioactive band was exactly where Steitz predicted a 50 nt–30 nt hybrid should be (**Fig. 8.19B**).

The Three Stages of Protein Synthesis

Like transcription, peptide synthesis is a three-step process. Once the ribosome has been properly positioned on the message, peptide synthesis can begin. Peptide synthesis has three phases: initiation, which brings the two ribosomal subunits together, placing the first amino acid in position; elongation, which sequentially adds amino acids as directed by the mRNA transcript; and termination. Note that there are several steps in the process that can be inhibited by certain antibiotics (**Special Topic 8.2** on page 281).

Initiation of translation. In bacteria, initiation of protein synthesis requires three small proteins called initiation factors (IF1, IF2, and IF3). In archaea (for example, *Methanococcus jannaschii*), initiation is much more complex, involving six different IF proteins. For simplicity, we will limit discussion to the process in bacteria, such as *E. coli*.

IF3 first brings mRNA and the 30S ribosome subunit together, allowing the ribosome-binding site to find its complementary site on 16S rRNA (**Fig. 8.20**). Next, IF1 binds and blocks the A site. IF2 bound to GTP then escorts the initiator N-formylmethionyl-tRNA (f-met-tRNA) to the start codon located at what will be the P site. N-formylmethionyl-tRNA binds to all start codons and is the only aminoacyl-tRNA to bind directly to the P site. Once the initiator tRNA is in place, IF3 is released. The 50S subunit then docks to the 30S subunit, GTP is



Courtesy of Joan Seitz

Ribosomes with their 16S rRNA were mixed with the ^{32}P-labeled 30 nt end of an mRNA.

The ribosome initiation complex was treated with colicin E3, which cleaves the 50 nt end of 16S rRNA.

SDS treatment disassembles the ribosome but leaves the rRNA-mRNA hybrid intact. The hybrid is small enough to enter a gel.

Separation on an SDS gel revealed a radio-labeled band of the right size for a 30 nt + 50 nt rRNA-mRNA molecule.

2. IF2 interacts with initiator tRNA.

3. f-Met tRNA binds to start codon.

4. Association of initiator tRNA with 30S mRNA releases IF3 and allows IF1 to bind.

50S subunit enters complex.

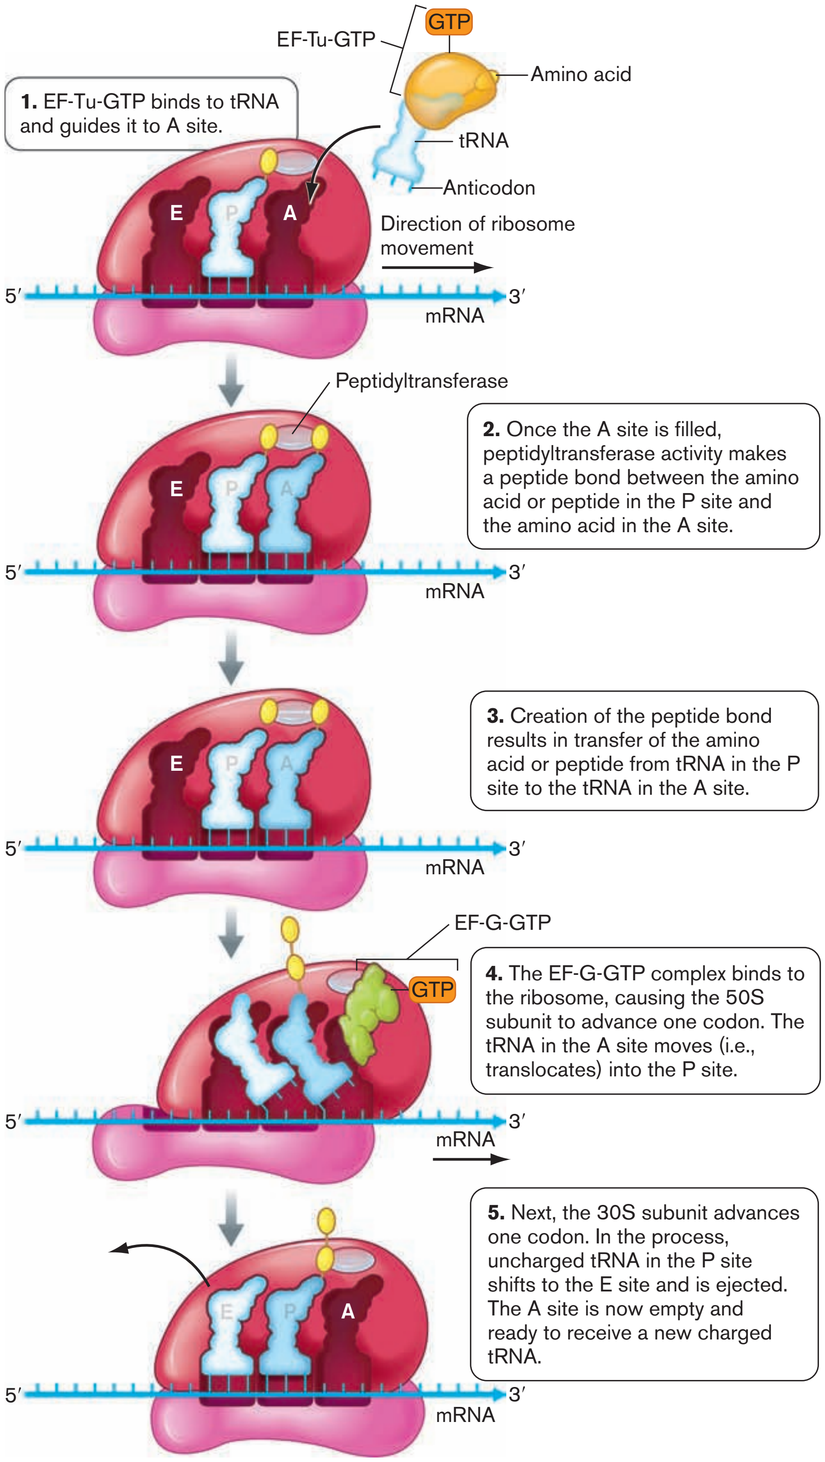
50S binding to 30S complex and GTP hydrolysis releases IF1 and IF2.

Figure 8.20 **Translation initiation.** See text for details.

hydrolyzed, and IF1 and IF2 are released. The ribosome is now "locked and loaded."

Elongation of the peptide. Elongation involves repetition of three basic steps: an aminoacyl-tRNA binds to the A, or acceptor, site; peptide bond formation occurs between the new amino acid and the growing peptide prepositioned in the P site; and the message must move by one codon (**Fig. 8.21**). First, an elongation factor (EF-Tu) associates with GTP to form a complex (EF-Tu-GTP) that binds to free, charged aminoacyl-tRNAs (except for the initiator tRNA). Sequences within the 50S rRNA recognize features of the EF-Tu-GTP-aminoacyl-tRNA complex, guiding it into the A site (**Fig. 8.21**, step 1). Correct selection of tRNA is guided in large part by codon-anticodon pairing, but conformational changes sensed by various ribosomal proteins customize the fit. If the fit is not perfect, the tRNA is rejected.

Once an aminoacyl-tRNA is in the A site (step 2), a peptide bond is formed between the amino acid moored there and the terminal amino acid linked to tRNA in the



1. EF-Tu-GTP binds to tRNA and guides it to A site.

2. Once the A site is filled, peptidyltransferase activity makes a peptide bond between the amino acid or peptide in the P site and the amino acid in the A site.

3. Creation of the peptide bond results in transfer of the amino acid or peptide from tRNA in the P site to the tRNA in the A site.

4. The EF-G-GTP complex binds to the ribosome, causing the 50S subunit to advance one codon. The tRNA in the A site moves (i.e., translocates) into the P site.

5. Next, the 30S subunit advances one codon. In the process, uncharged tRNA in the P site shifts to the E site and is ejected. The A site is now empty and ready to receive a new charged tRNA.

Figure 8.21 Elongation of peptide.

P site (step 3). Simultaneously, a GTP is hydrolyzed and the resulting EF-Tu-GDP is expelled. Peptide bond formation effectively transfers the peptide from the tRNA in the P site to tRNA in the A site. Finally, for protein synthesis to continue, the ribosome must advance by one codon, which moves the peptidyl-tRNA from the A site into the P site, leaving the A site vacant. The process, called **translocation**, involves another elongation factor, EF-G, associated with GTP. EF-G-GTP binds to the ribosome, GTP is hydrolyzed, and the 50S subunit

ratchets ahead on the message by one codon (step 4). The 30S subunit then follows (step 5). This maneuver opens up the A site, moves the peptidyl-tRNA into the P site, and slides uncharged tRNA into the E (exit) site. The next aminoacyl-tRNA that enters the A site creates a conformational change in the ribosome that telegraphs through to the E site and ejects the uncharged tRNA.

Figure 8.22⏯ presents a three-dimensional rendering of EF-Tu and EF-G cycling on and off the ribosome. Note that both factors bind to the same site. This reflects a structural similarity (or molecular mimicry) between EF-G-GTP and the EF-Tu-GTP-aminoacyl-tRNA complex. Because both factors bind to the same site, they cannot do so simultaneously, so they must cycle on and off the ribosome sequentially. **Figure 8.23**⏯ illustrates the path of mRNA into the ribosome

Figure 8.23 **Orientation of tRNA molecules within the ribosome and tracks of mRNA and nascent polypeptide.** Note that the mRNA travels along the 30S subunit, and the growing peptide exits from a channel formed in the 50S subunit. (PDB codes: 1GIX, 1GIY) ⏯

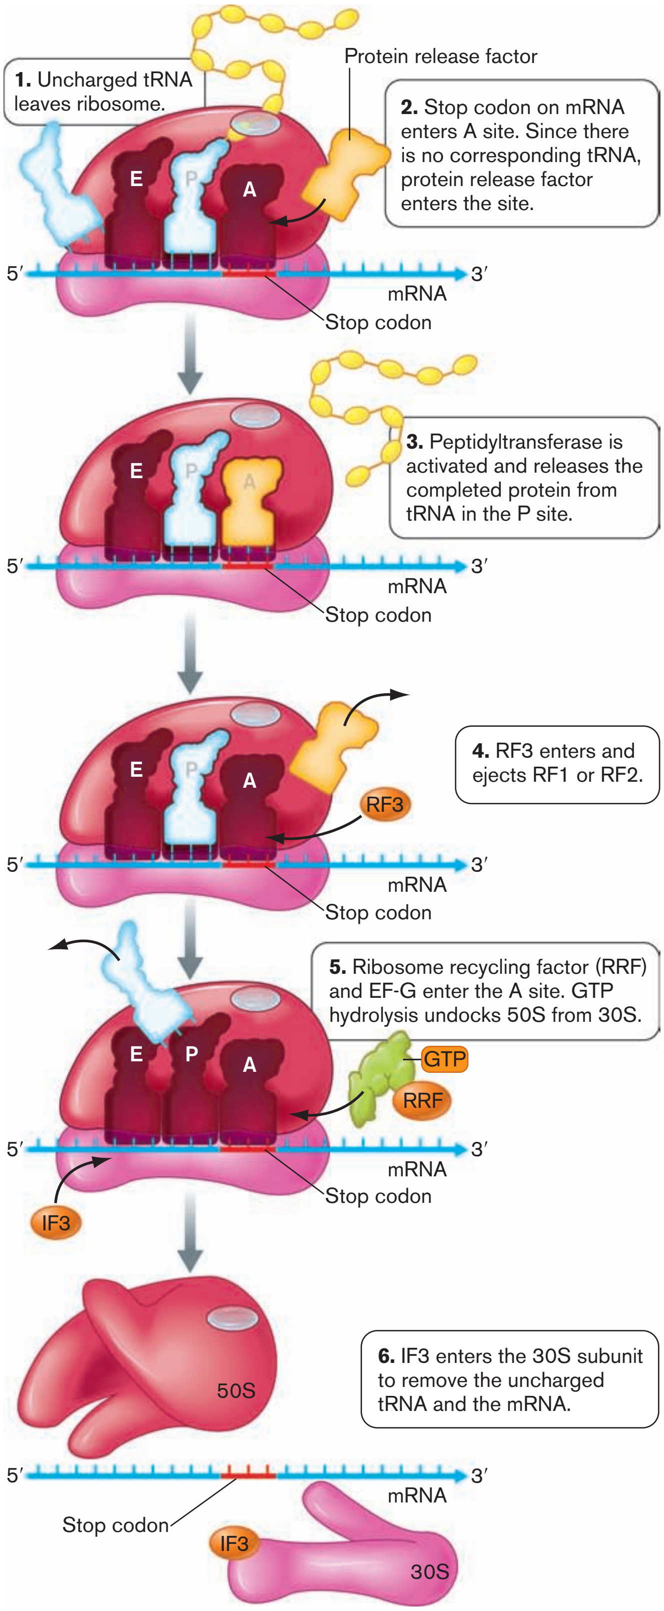
and the nascent (that is, incomplete) peptide emerging from it. While this process seems incredibly complex, the ribosomes of *E. coli* manage to link together 16 amino acids per second.

Termination of translation. Eventually, the ribosome arrives at the end of the coding region, but not the end of the RNA. As noted previously, the end of the coding region is marked by one of three stop codons. Formation of the last peptide bond and the subsequent translocation of mRNA leads to ejection of tRNA in the E site (**Fig. 8.24**⏯, step 1) and brings the stop codon into the A site (**Fig. 8.24**, step 2). No tRNA binds, but one of two **release factors** (RF1 or RF2) will enter and activate the peptidyltransferase (step 2). This cuts the bond tethering the completed peptide to tRNA in the P site (step 3).

With the protein released, the ribosome must disassemble. RF3 causes RF1 or RF2 to depart the ribosome (step 4). Then ribosome recycling factor (RRF), along with EF-G, binds at the A site, and an accompanying GTP hydrolysis undocks the two ribosomal subunits (step 5). IF3 then reenters the 30S subunit to replace the remaining uncharged tRNA and mRNA (step 6). The liberated ribosomal subunits are now free to diffuse through the cell, ready to bind yet another mRNA and begin the translation sequence anew.

THOUGHT QUESTION 8.6 While working as a member of a pharmaceutical company's drug discovery team, you have found that a soil microbe snatched from the jungles of South America produces an antibiotic that will kill even the most deadly, drug-resistant form of *Enterococcus faecalis*, which is an important cause of heart valve vegetations in bacterial endocarditis. Your experiments indicate that the compound stops protein synthesis. How could you more precisely determine the antibiotic's mode of action?

Many genes in bacterial chromosomes are arranged and transcribed in tandem and produce a polycistronic mRNA (see Section 7.2). It should be remembered that the beginning of each gene in a polycistronic mRNA carries its own ribosome-binding site. This means that different ribosomes can bind simultaneously to the start of each cistron within a polycistronic mRNA.



1. Uncharged tRNA leaves ribosome.

2. Stop codon on mRNA enters A site. Since there is no corresponding tRNA, protein release factor enters the site.

3. Peptidyltransferase is activated and releases the completed protein from tRNA in the P site.

4. RF3 enters and ejects RF1 or RF2.

5. Ribosome recycling factor (RRF) and EF-G enter the A site. GTP hydrolysis undocks 50S from 30S.

6. IF3 enters the 30S subunit to remove the uncharged tRNA and the mRNA.

Figure 8.24 **Translation termination.** The completed protein is released and the ribosome subunits are recycled. ⏯

Special Topic 8.2 Antibiotics That Affect Translation

Streptomycin (**Fig. 1A**), a well-known member of the aminoglycoside family of antibiotics, is produced by a species of *Streptomyces*. The drug targets bacterial small ribosomal subunits by binding to a region of 16S rRNA that forms part of the decoding A site and to protein S12, a protein critical for maintaining the specificity of codon-anticodon binding. At high concentrations, streptomycin binds to the 30S-mRNA-tRNA initiation complex and prevents binding of the 50S subunit. It stops the initiation of translation. At low concentrations, translation can go on, but the A site becomes "sloppy," permitting illicit codon-anticodon matchups that result in a mistranslated protein sequence. Bacteria usually become resistant to streptomycin by spontaneously mutating the S12 gene (*rpsL*), although mutations in 16S rRNA can also prevent binding. The altered S12 protein maintains function but will not bind streptomycin. Some bacteria gain resistance by acquiring an aminoglycoside phosphotransferase that modifies streptomycin so that it cannot bind to its target. Additional mechanisms are discussed in Chapter 27. Other therapeutically important aminoglycosides include gentamicin, kanamycin, and amikacin.

Tetracycline (**Fig. 1B**) also targets the 30S ribosomal subunit, but instead of preventing formation of the 70S complex (as with streptomycin), it outright prevents binding of aminoacyl-tRNA to the A site and stops protein synthesis. It binds to 16S rRNA, right above the A site for incoming tRNA. Resistance to tetracycline can be conferred by an efflux transport system that effectively removes the antibiotic from the bacterial cell. Genes encoding this resistance are usually carried on mobile genetic elements like plasmids that can be passed from cell to cell (see Section 9.2). Other resistance mechanisms are described in Chapter 27.

Another species of *Streptomyces* produces chloramphenicol (**Fig. 1C**), which attacks the 50S subunit. It binds to 23S rRNA at the peptidyltransferase active site and inhibits peptide bond formation. Resistance to this drug involves the ability to synthesize an enzyme, chloramphenicol acetyltransferase, that destroys chloramphenicol activity by modifying the chemical.

Erythromycin, made by *Streptomyces erythrens*, is one of a large group of related antibiotics called macrolides whose hallmark is a large lactone ring of 12–22 carbon molecules (**Fig. 1D**). They all affix themselves to the 50S subunit by binding to protein L15 and 23S rRNA in the peptidyltransferase cavity. This triggers an abortive translocation step that evicts peptidyl-tRNA from the P site while preventing peptide bond formation. In some organisms, mutational alterations in L15 decrease macrolide binding and confer resistance to these drugs. Other microbes reduce erythromycin binding by methylating the relevant area of 23S rRNA using an enzyme produced from another mobile genetic element.

Other translation targeting antibiotics interfere with mRNA binding to the ribosome (kasugamycin), prevent translocation by targeting EF-G (fusidic acid), or use **molecular mimicry** to trick peptidyltransferase into action without having a bonafide tRNA in the A site (puromycin). We chronicle the discovery and use of antibiotics more completely in Chapter 27.

Prokaryotic Transcription and Translation Are Coupled

Ribosomes bind to the 5′ end of mRNA and begin translating protein even before RNA polymerase has finished transcribing the mRNA (**Fig. 8.25**). This is called coupled transcription and translation. Transcriptional-translational coupling in prokaryotes provides an opportunity to use translation as a means of regulating transcription, a process that is explained further in Chapter 10.

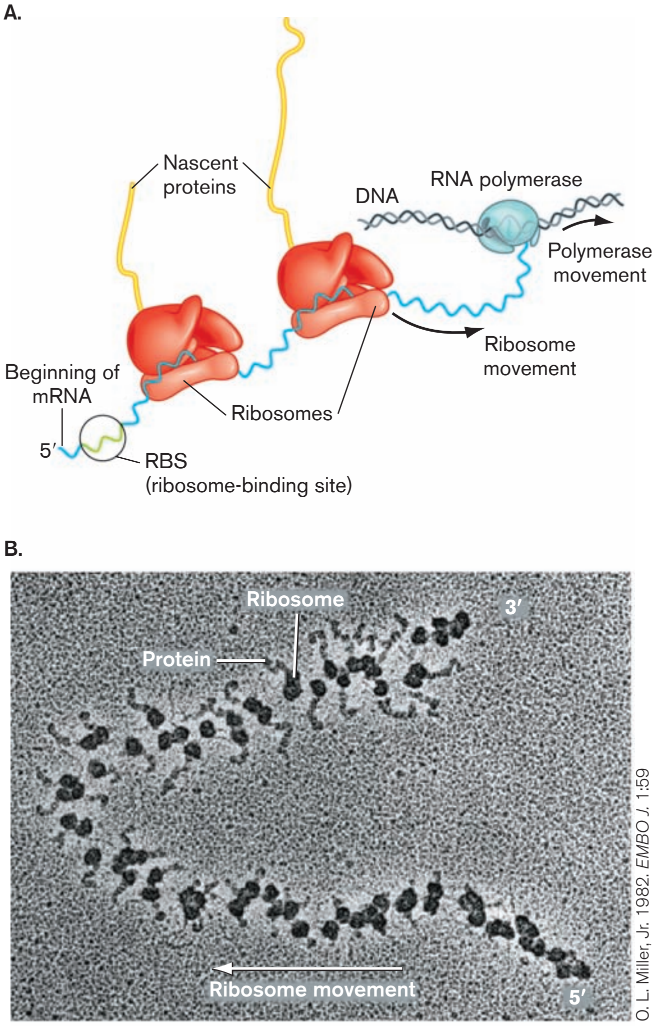
Eukaryotic microbes, on the other hand, use separate cellular compartments to carry out most of their transcription and translation. They transcribe genes in the nucleus and, after splicing and other forms of processing, transport mRNA to the cytoplasm, where the majority of translation occurs. However, a small amount of translation is carried out in the eukaryotic nucleus, where it is also coupled to transcription.

In prokaryotes, coupled transcription and translation presents a potential problem. Ribosomes generally travel along mRNA more slowly than mRNA is generated by RNA polymerase, so RNA polymerase can potentially scoot ahead of the ribosome and leave large tracts of RNA unprotected and susceptible to nucleases. Unintentional cleavage of the RNA between the ribosome and polymerase would separate the two macromolecular machines and destroy the message. The cell handles this problem by modulating transcriptional speed. The rate of RNA synthesis averages about 45 nt per second, which roughly equals the average rate of translation (16 amino acids per second). However, these speeds are not constant. For example, RNA polymerase pauses momentarily at sites rich in GC content (GC base pairs, with three hydrogen bonds, are harder to melt than AT pairs with only two hydrogen bonds). Once sigma factor exits the transcription complex, proteins called NusA and NusG enter the complex and can actually lengthen the pause in RNA polymerase activity to allow time for the trailing protein-synthesizing ribosome to catch up to the polymerase. Pausing allows the ribosome to follow RNA polymerase closely and protect the RNA.

THOUGHT QUESTION 8.7 How might one gene code for two proteins with different amino acid sequences?

THOUGHT QUESTION 8.8 Why involve RNA in protein synthesis? Why not translate directly from DNA?

THOUGHT QUESTION 8.9 Codon 45 of a 90-codon gene was changed into a translation stop codon. This produced a shortened, truncated protein. What kind of mutant cell could produce a full-length protein from the gene *without* removing the stop codon?



O. L. Miller, Jr. 1982. *EMBO J.* 1:59

Figure 8.25 Coupled transcription and translation in prokaryotes. A. Ribosomes attach at mRNA ribosome-binding sites and start synthesizing protein before transcription of the gene is complete. **B.** Electron micrograph of a polysome (ribosome is 21 nm across). Several ribosomes may translate a single mRNA molecule at the same time. This structure is called a polysome. The beginning (5′ end) of the mRNA is to the right (at the arrow), and the 3′ end is to the left. Note that the synthesized protein molecule grows longer and longer the closer the ribosome gets to the 3′ end of the mRNA. The protein molecule is most clearly seen at the end of the mRNA (to the upper right).

Unsticking Stuck Ribosomes: tmRNA and Protein Tagging

Sometimes an RNase will shear off the 3′ end of a message, removing the stop codon before the translation is complete. What happens after a ribosome has finished translating this damaged mRNA molecule? Without a stop codon, there is nothing to trigger ribosome release when the ribosome reaches the end of the message. So the ribosome is stuck at the end of the mRNA with a peptidyl-tRNA in the ribosome P site.

The answer to this problem is a translation rescue molecule, the previously mentioned tmRNA, which has the properties of both tRNA and mRNA. One end of the tmRNA molecule has an attached amino acid and a folded structure that resembles a tRNA. This aminoacyl end acts like tRNA, entering the unoccupied ribosome A site where a peptide bond then forms between the stalled polypeptide (in the P site) and the emergency amino acid on the tmRNA. Another section of the tmRNA is then read as mRNA, which adds a tag of 12 or so amino acids to the now dislodged peptide (SsrA in **Fig. 8.26A**). These amino acids, called a proteolysis tag, predestine the protein for destruction. A stop codon present in tmRNA triggers peptide release and ribosome disassembly. A helper protein (SspB) recognizes the proteolysis tag and brings the useless aberrant polypeptide to the ClpXP protease (discussed shortly) for degradation. **Figure 8.26B** shows this process for tmRNA from *E. coli*.

TO SUMMARIZE:

- **Triplet nucleotide codons** in mRNA encode specific amino acids. **tRNA molecules** interpret the genetic code and bring specific amino acids to the A (acceptor) site in the ribosome.
- **Specific codons** mark the beginning and end of a gene, but the Shine-Dalgarno sequence in mRNA located before the start codon helps the ribosome find the correct reading frame in the mRNA.
- **Initiation of protein synthesis** in bacteria requires three initiation factors that bring the ribosomal subunits together on an mRNA molecule.
- **Peptidyltransferase** activity of the ribosome is carried out by ribosomal RNA, not protein. **Elongation of translation** occurs when the ribosome ratchets one codon length along the mRNA.
- **Translation terminates** upon reaching a stop codon. The ribosome pauses because it cannot find an appropriate tRNA, and a release factor enters the A site and triggers peptidyltransferase activity. This frees the completed protein from tRNA in the A site.
- **Ribosome release factor** and EF-G bind to the A site to dissociate the two ribosomal subunits from the mRNA.
- **Transcription and translation** in prokaryotes are coupled.
- **RNA polymerase pauses** during transcription to allow the slower translating ribosomes to stay close. This minimizes exposure of mRNA to degradative cellular enzymes.
- **tmRNA** rescues ribosomes stuck on damaged mRNA that lacks a stop codon.

8.4 Protein Modification and Folding

For many proteins, translation is not the last step in producing a functional molecule. Cell function often requires that a protein be modified *after* translation to achieve an appropriate three-dimensional structure or to regulate the activity of the protein. There are many ways of modifying the primary, secondary, or tertiary structure of proteins after the primary protein sequence has been assembled by the ribosomes.

Protein Structure May Be Modified after Translation

Completed proteins released from the ribosome contain N-formylmethionine at the N-terminus (as previously described). With some proteins, the N-formyl group is surgically removed from the N terminus with methionine deformylase, leaving methionine. Alternatively, methionyl aminopeptidase will remove the whole amino acid. It is of interest to note that N-formylmethionine (f-Met) peptides are produced only by bacteria and mitochondria, not by archaea or by cytoplasmic ribosomes of eukaryotes. Therefore, during the immune response, white blood cells detect N-formyl-Met (f-Met) peptides as a sign of invading bacteria or of necrotic (dying) host cells releasing mitochondria. The f-Met peptides are detected at incredibly low concentrations, around 10^{-12} M.

Some proteins undergo other types of processing in which acetyl groups or AMP can be attached to change their functions, and proteolytic cleavages may either activate or inactivate a protein. Examples of modified bacterial enzymes include glutamine synthetase (adenylylation), isocitrate dehydrogenase (phosphorylation), and a variety of ribosomal proteins (acetylation). These groups directly regulate enzyme activity (glutamine synthetase and isocitrate dehydrogenase) or alter tertiary structure (ribosomal proteins).

Proteins Must Be Correctly Folded

Christian Anfinsen (1916–1995) won the Nobel Prize in 1972 for demonstrating that for some proteins, folding is governed solely by the protein itself. In other words, the optimal three-dimensional structure of a protein is determined solely by the linear sequence of amino acid residues. But three decades later, other scientists discovered that folding of many proteins requires assistance from other proteins. These helper proteins are called **chaperones** (or chaperonins). Chaperones associate with target proteins during some phase of the folding process, then dissociate, usually after folding of the target protein is completed. Although there is some specificity, a

given chaperone can help fold many different types of proteins.

The major chaperone family in most species includes GroEL (60 kDa), GroES (10 kDa), DnaK (70 kDa), and trigger factor (48 kDa). Because their levels in *E. coli* increase in response to high temperature stress, these chaperones were originally named **heat-shock proteins (HSPs)** and are, in fact, more resistant to heat denaturation than the average protein. Representatives of these chaperones are found in all species. As a result, DnaK examples throughout nature are called HSP70s, and GroEL homologs are called HSP60s. Chaperones increase in response to heat stress because they are needed to help refold heat-damaged proteins.

The GroEL and GroES chaperones form a stacked ring with a hollow center (**Figs. 8.27** and **8.28**). The chaperoned protein fits inside. The small capping protein GroES controls entrance to the chamber (**Fig. 8.28A**). Cycles of ATP binding and hydrolysis cause conformational changes within the chamber that can reconfigure target proteins. DnaK (HSP70) chaperones have a very different structure (**Fig. 8.28B**). They do not form rings like the GroEL and GroES chaperones, but can clamp down on a peptide to assist folding. Proteins emerging from a prokaryotic ribosome enter a folding pathway that involves a hierarchy of these chaperones.

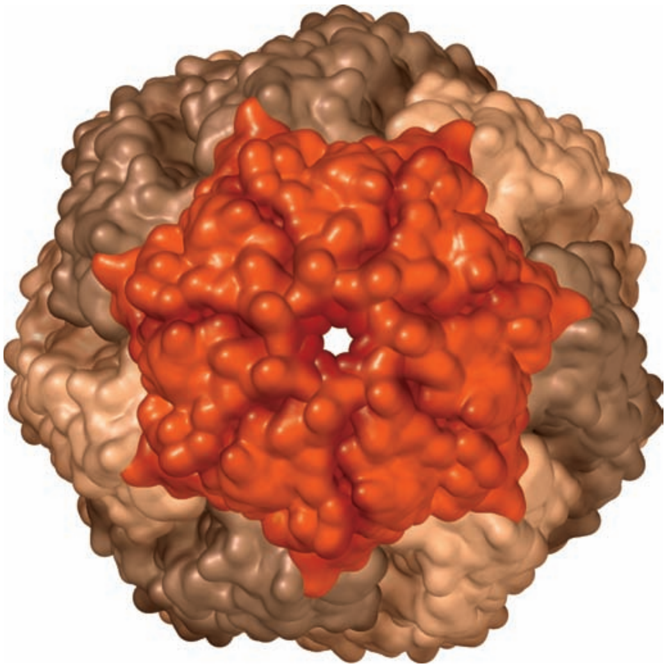

Figure 8.27 Top view of the GroEL-GroES complex of *E. coli*. The heat-shock chaperone-10 (equivalent to GroES) is shown in red, which is tacked on a GroEL ring. The chaperoned protein fits inside the open hole. (PDB code: 1PCQ)

TO SUMMARIZE:

- **Protein modifications** are made after translation.
- **The N-terminal amino acid** (N-formylmethionine) can be removed by methionine deformylase.
- **An inactive precursor protein** can be cleaved into a smaller active protein, or other groups can be added to the protein (for example, phosphate or AMP).
- **Chaperone proteins** help translated proteins fold properly.

8.5 Secretion: Protein Traffic Control

Microorganisms, especially gram-negative bacteria, face an intriguing challenge in delivering proteins to different target locations in the cell. Recall that gram-negative microbes are surrounded by two layers of membrane (the inner membrane, or cell membrane, and an outer membrane) between which lies a periplasmic

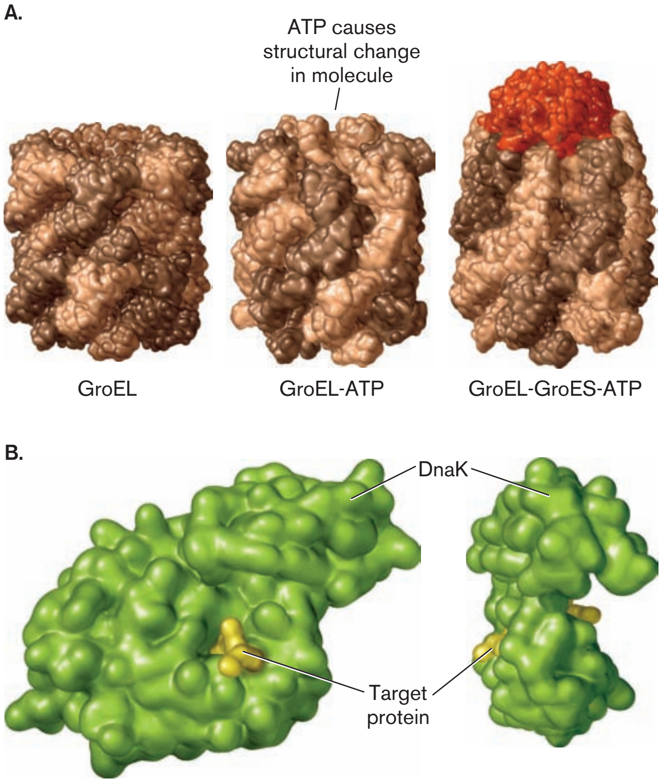

Figure 8.28 GroEL-GroES and DnaK (HSP70) structures. **A.** Three-dimensional reconstructions of GroEL, GroEL-ATP, and GroEL-GroES-ATP from cryo-EM. The GroES ring is seen as a disk above GroEL. (PDB codes: 1SS8, 2C7E, 1PCQ) **B.** DnaK clamping down on a peptide (yellow). (PDB code: 1DKX)

space (see Section 3.4). Many proteins are specifically destined for one or another of these cell compartments. Other proteins are secreted completely out of the cell into the surrounding environment (for example, hemolysins that lyse red blood cells). But how do these diverse proteins know where to go? Protein traffic out of the cell is directed by an elaborate set of **protein secretion systems**. Each system selectively delivers a set of proteins originally made in the cytoplasm to various extracytoplasmic locations.

The term *secretion* is used to describe movement of a protein out of the cytoplasm. There are protein secretion systems that move proteins to the periplasm, others that move proteins to the outer membrane, and still others that deliver proteins across both of the membranes and into the surrounding environment. An added complication of protein export is that periplasmic proteins are usually delivered unfolded into the periplasm and require another set of chaperones to fold properly in this cell compartment.

Protein Export Out of the Cytoplasm

Proteins destined for the bacterial cell membrane or envelope regions (periplasm, outer membrane, or extracellular spaces) require special export systems. These systems manage to move hydrophilic proteins through one or more hydrophobic membrane barriers. Proteins meant for the inner membrane (for example, cytochromes) are tagged, as part of the open reading frame, with very hydrophobic N-terminal **signal sequences** of 15–30 amino acids. Signal sequences tether nascent proteins to the membrane and confer conformations that allow the proteins to melt into the fabric of the membrane. Inner membrane proteins also contain hydrophobic transmembrane spanning regions (20–25 amino acids) that aid in this insertion process. These hydrophobic regions are important because they are compatible with the hydrophobicity of the membrane itself. A nutrient transport protein often has 12 such membrane-spanning regions, which weave back and forth across the membrane.

One special export system begins with a complex called the **signal recognition particle (SRP)**, which targets proteins for inner membrane insertion. A second export mechanism uses a protein called trigger factor for proteins destined for the periplasm. (Trigger factor was mentioned earlier as a chaperone.) These two protein traffic pathways converge on a general secretion complex composed of three proteins, collectively called the **SecYEG translocon**, embedded in the cell (inner) membrane.

Protein Export to the Cell Membrane

The pathway leading proteins to the inner (cell) membrane begins with SRP. In *E. coli*, SRP consists of a 54-kDa protein Ffh complexed with a small RNA molecule (*ffs*). SRP binds to the signal sequences of integral cell membrane proteins as they are being translated (**Fig. 8.29**⏯) and halts further translation in the cytoplasm. The nascent protein with its paralyzed nontranslating ribosome is delivered to the membrane-bound protein FtsY, where translation resumes. The partially translated protein is now subject to one of two fates: It may be cotranslationally inserted directly into the cell membrane, meaning that the protein is inserted even as it is still being translated. Alternatively, the protein may be completely synthesized, after which it is delivered to the

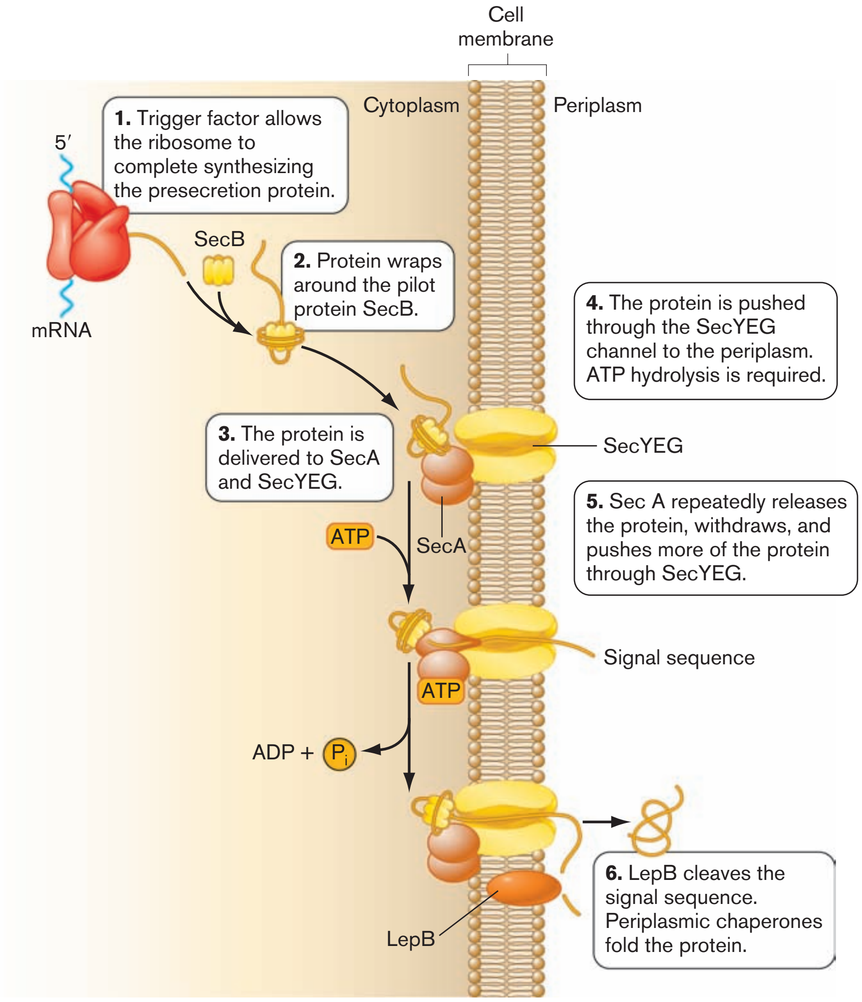
Figure 8.29 **SRP and cotranslational export.** A ribosome "paralyzed" by SRP does not resume translating protein until encountering FtsY in the membrane. Translation can then recommence. Some proteins designated for integral membrane location are inserted directly (top). Other integral membrane proteins, and proteins destined for the periplasm, are inserted or secreted via the Sec system (bottom). ⏯

SecYEG translocon for insertion. The route to membrane insertion that occurs depends on the protein.

Protein Export to the Periplasm: The Sec-Dependent General Secretion Pathway

The periplasm contains important proteins that bind nutrients for transport into the cell and other proteins that carry out enzymatic reactions. For example, one form of superoxide dismutase (SOD), an enzyme that degrades superoxide, is a periplasmic protein in *Salmonella enterica* and other gram-negative bacteria. Many periplasmic proteins, such as SOD and maltose-binding protein (which imports the sugar maltose), are delivered to the periplasm by a common pathway called the general secretion pathway.

There are several steps in the general secretion pathway. First, the peptide is completely translated in the cytoplasm (**Fig. 8.30**, step 1). The completed presecretion protein is then captured by a piloting protein called SecB (step 2 and **Fig. 8.31**) and delivered in an unfolded state to SecA, a protein peripherally associated with the membrane-spanning SecYEG translocon (step 3). SecB discourages folding in the cytoplasm. This assists in secretion because sliding an unfolded protein through a membrane is far easier than trying to deliver a folded one.



1. Trigger factor allows the ribosome to complete synthesizing the presecretion protein.

2. Protein wraps around the pilot protein SecB.

3. The protein is delivered to SecA and SecYEG.

4. The protein is pushed through the SecYEG channel to the periplasm. ATP hydrolysis is required.

5. Sec A repeatedly releases the protein, withdraws, and pushes more of the protein through SecYEG.

6. LepB cleaves the signal sequence. Periplasmic chaperones fold the protein.

Figure 8.30 **SecA-dependent general secretion pathway.**

The SecA ATPase appears to act like a plunger (step 4). It inserts deep into the SecYEG channel, shoving about 20 amino acids of the target export protein into the channel. ATP hydrolysis causes SecA to release the protein and withdraw (step 5). At this point, SecA can bind fresh ATP, rebind the target protein, and reinsert, pushing another 20 amino acids through. Proteins needed in the periplasm have cleavable signal sequences at their amino-terminal ends. Immediately following translocation into the periplasm, periplasmic signal peptidases (LepB is one of several examples in *E. coli*) snip off the amino-terminal signal sequence of the protein. This allows release of the mature protein into the periplasm (step 6). Signal peptidases will not, however, cleave signals from proteins destined to stay embedded within the membrane (integral membrane proteins).

Periplasmic proteins delivered by the Sec system arrive unfolded and inactive. Because the folding chaperones mentioned earlier are cytoplasmic, periplasmic proteins need another set of dedicated periplasmic chap-

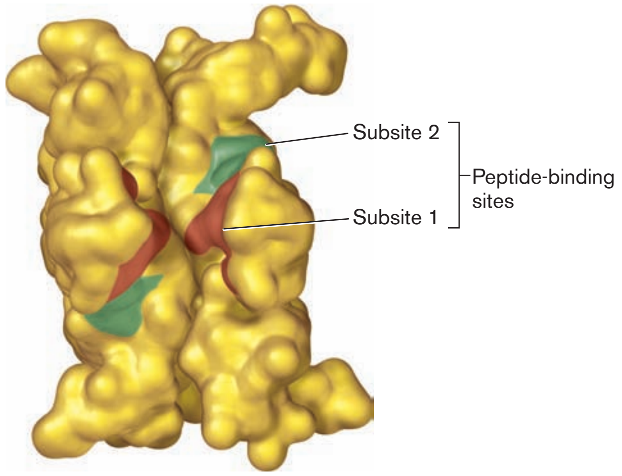


Figure 8.31 **Proposed peptide-binding channel of SecB.** The exposed surfaces encompassing the two proposed peptide-binding subsites are highlighted. The presecretion protein is wrapped around these sites in SecB. (PDB code: 1FX3)

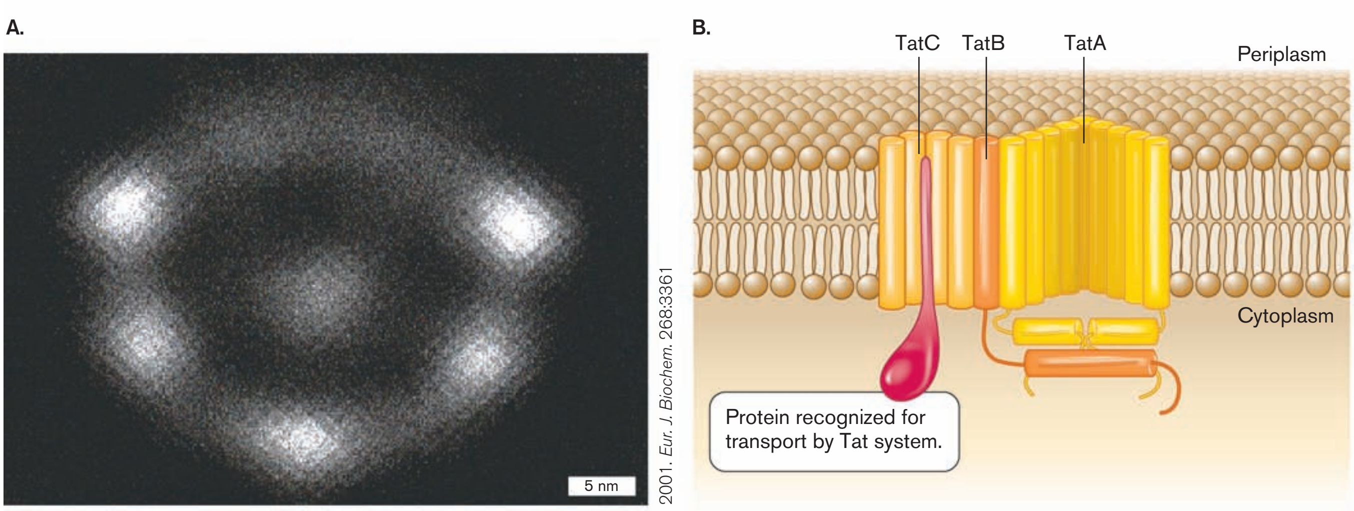
erones to guide their tertiary folding. Another problem with periplasmic proteins is that the oxidizing environment of aerobic cells can oxidize cysteines within a protein and produce inappropriate cysteine disulfide bonds that destroy enzyme function. Special periplasmic disulfide reductases are required to reverse these S—S bonds and form two SH groups. Many periplasmic proteins, however, need certain disulfide bonds to be active. The periplasm also contains a disulfide bond catalyst (DsbA) to make those bonds.

Eukaryotic microbes such as the yeast *Saccharomyces cerevisiae* also possess secretion systems that move proteins to the membrane and beyond. However, the eukaryotic Sec systems are more complex and are evolutionarily



2001. *Eur. J. Biochem.* 268:3361

Figure 8.32 The twin arginine translocase. A. A negative stain electron microscopic image of the purified TatAB complex. **B.** A commonly accepted model for the Tat protein translocase, which includes proteins TatA, TatB, and TatC.

Table 8.2 Comparison of mechanisms that secrete proteins across the outer membrane.[a]

Type	Mechanism	Structure	Location of protein substrate	Location of secretory signals	Number of components
I	Coupled to TolC	ABC type	Cytoplasm	N terminus, not cleaved	3
II	Extending and contracting	Pilus-like structure	Periplasm	Cleaved N terminus for Sec-dependent transport	12–16
III	Injecting proteins directly into host eukaryotic cell cytoplasm	Syringe, related to flagella biogenesis	Cytoplasm	None	20
IV	Conjugation-like	Multicomponent	Some are cytoplasmic and are moved directly to outside of cell; others use Sec system to get to periplasm first	None	8 or 9
V	Autotransport	Self-transporting channel in outer membrane formed by C-terminal domain	Periplasm	N terminus, cleaved	1

[a] The five classes are grouped on the basis of their structure. Types II, III, and IV are evolutionarily related to mechanisms that assemble pili (type II) or flagella (type III) or that carry out conjugation (type IV). Some systems pick up protein substrates from the cytoplasm and transport them across both membranes. Substrates for other systems are collected in the periplasm. Substrates also differ as to the presence of N-terminal signal sequences.

distinct from bacterial Sec systems. Archaea secretion systems are actually more similar to those of eukaryotes.

Export of Prefolded Proteins to the Periplasm

In a dramatic departure from Sec-dependent transport systems, some proteins like TorA, a component of an anaerobic respiratory chain, can be transported fully folded across the membrane to their periplasmic destination. These proteins contain the amino acid motif RRXFXK within their N-terminal signal sequence (R is shorthand for arginine, F is phenylalanine, and X stands for any amino acid). This sequence, called the twin arginine motif because it begins with two arginines, targets the protein to the membrane-bound **twin arginine translocase (TAT)**, a transport protein that ships fully folded proteins across the cell membrane to the periplasm (**Fig. 8.32**). Whereas Sec-dependent transport is ATP driven, the TAT system is powered by proton motive force (see Chapters 4 and 12).

Journeys through the Outer Membrane

For many reasons, bacteria need to export proteins completely out of the cell and into their surrounding environment. Some exported proteins digest extracellular peptides for carbon and nitrogen sources, whereas others act as free-floating toxins that bind and kill host cells. Still others are injected directly into eukaryotic cells by pathogenic or symbiotic microbes to commandeer host metabolic processes. Five elegant secretion systems, identified as type I–type V, have evolved to ship these proteins out of the cell (**Table 8.2**). A few start with the Sec system just to get the protein into the periplasm, where dedicated outer membrane systems take over and complete export. Other systems provide nonstop service, delivering the protein directly from the cytoplasm to the extracellular space. The diversity of system design is impressive. It is the result, in some instances, of selective evolutionary pressures appropriating established cell processes (for example, pilus assembly). This occurs through the accidental duplication of one set of genes followed by random mutations that innovatively redesign the duplicated set for a new purpose. We know this because the footprints of genetic divergence have been left behind in the DNA sequence. Type I secretion will be described here. Other systems will be covered during the discussion of pathogenesis in Chapter 25.

Type I Protein Secretion

Chapter 4 describes the family of ATP-binding cassette (ABC) influx transporters whose signature is an amino acid motif that binds ATP. Similar ABC transporters function in the opposite direction to export various toxins, proteases, and lipases, as well as antimicrobial drugs (multidrug efflux transporters). These ABC transporters are the simplest of the protein secretion systems and make up what is called type I protein secretion (one example is the Hly system that secretes hemolysin; **Fig. 8.33**). Type I systems all have three protein components, one of which contains an ATP-binding cassette. One component is an outer membrane channel, the second is an ABC protein at the inner membrane, and the third is a periplasmic protein lashed to the inner membrane.

Proteins secreted through type I systems never contact the periplasm because they pass through a continu-

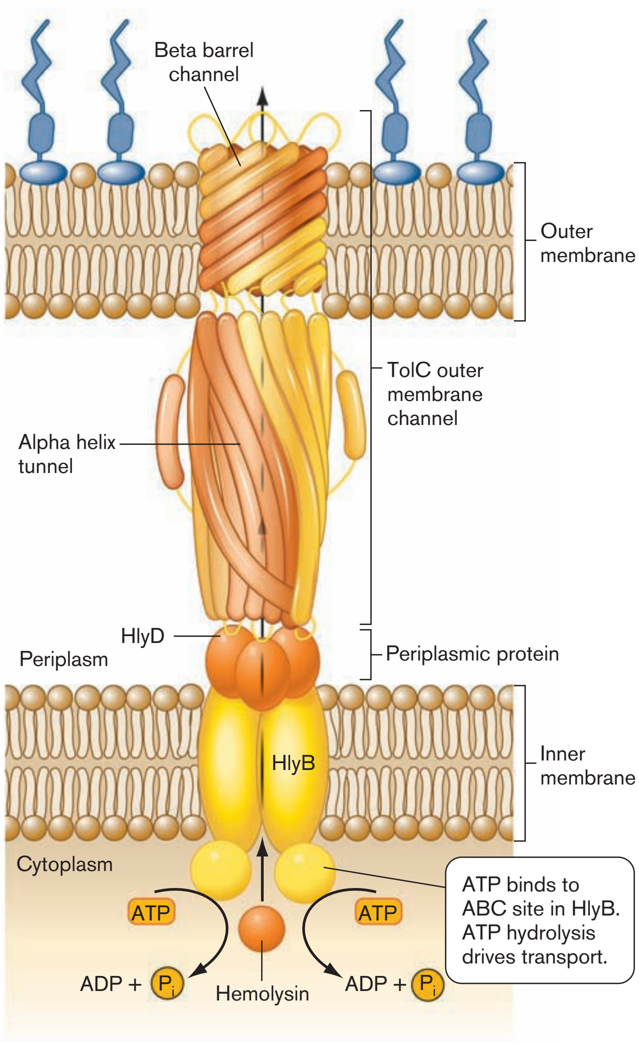


Figure 8.33 Type I secretion, the Hly ABC transporter. Hemolysin (HlyA) is transported directly from the cytoplasm into the extracellular medium through a multicomponent ABC transport system. The HlyB and D proteins are dedicated to HlyA transport. TolC is shared with other transport systems. ous channel that extends from the cytoplasm to the outer membrane. The inner membrane and periplasmic subunits are generally substrate specific, but numerous ABC export systems share the channel protein TolC. TolC is an intriguing protein composed of a beta-barrel channel embedded in the outer membrane and an alpha-helix tunnel spanning the periplasm. **Figure 8.34** illustrates how the tunnel might open and close. The type I transport shown in **Figure 8.33** exports a hemolysin (HlyA) from *E. coli* that lyses red blood cell membranes. HylB and HylD are the ABC and periplasmic components, respectively.

Four other protein secretion systems are briefly summarized in **Table 8.2**. Some move proteins directly from the cytoplasm to the outside, similar to the type I system, while others pick up proteins deposited in the periplasm by the Sec system. It is important to note that they all play important roles in microbial pathogenesis and are more fully discussed in Chapter 25.

WWW | Chaperone-assisted protein folding

TO SUMMARIZE:

- **Special protein export mechanisms** are used to move proteins to the inner membrane, the periplasm, the outer membrane, and the extracellular surroundings.
- **N-terminal amino acid signal sequences** help target membrane proteins to the membrane.
- **The general secretory system** involving the SecYEG translocon can move unfolded proteins to the inner membrane or periplasm.
- **Signal recognition protein (SRP)** pauses translation of a subset of proteins that will be placed into the membrane.
- **SecB** binds to certain proteins that will eventually end up in the periplasm. SecB protein pilots these unfolded proteins to the SecYEG translocon.
- **The twin arginine translocase** can move a subset of folded proteins across the inner membrane and into the periplasm.
- **Type I secretion systems** are ATP-binding cassette (ABC) mechanisms that move certain secreted proteins directly from the cytoplasm to the extracellular environment.

8.6 Protein Degradation: Cleaning House

What happens when a cell no longer needs a specific protein—or when a cell synthesizes a protein with incorrect amino acids? These useless or disabled proteins must be degraded to maintain cellular health. In addition, because cellular needs are constantly changing, proteins no longer needed can produce deleterious effects on the cell. This is particularly true of regulatory proteins, whose concentrations must change with time or in response to alterations in the cellular condition.

Many normal proteins contain degradation signals called **degrons** that dictate the stability of a protein. The **N-terminal rule** describes one type of degron. The rule states that the N-terminal amino acid of a protein directly correlates with its stability. For example, proteins beginning with arginine, lysine, or phenylalanine experience a short half-life (2 minutes or less), while proteins with aspartic acid, glutamic acid, or cysteine in the lead position enjoy a much longer half-life (more than 10 hours). Why this correlation exists is not clear.

Abnormally folded proteins are recognized by proteases in part because regions that are normally buried within the protein's three-dimensional structure become exposed. The protein is progressively degraded into smaller and smaller pieces by a series of these proteases. Initial cuts usually involve ATP-dependent endoproteases like Lon protein or ClpP followed by digestion with tripeptidases and dipeptidases. Endopeptidases cleave proteins somewhere within the sequence but not from the ends of the sequence. Many peptidases use ATP hydrolysis to help unfold the target protein prior to digestion. Unfolding is necessary for the protein to slide into a barrel-shaped protease such as ClpAP, ClpXP, or the 28S proteasome of eukaryotic microbes (**Fig. 8.35**). Proteasomes are protein-degrading organelles of eukaryotes. The protein-degrading enzymes are classified as serine, cysteine, or threonine proteases, based on the key residue in their active sites.

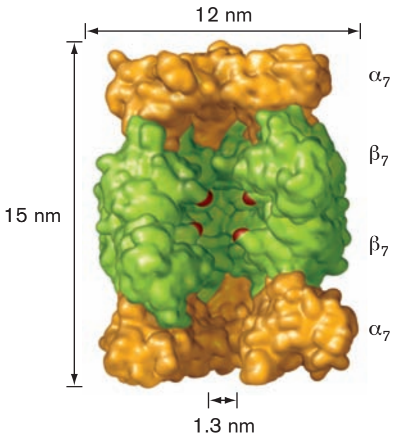

Figure 8.35 Protein degradation machines. Predicted structure of the 20S proteasome from the methanoarchaeon *Methanosarcina thermophila*. The active sites involved in peptide bond cleavage are indicated in red. (PDB code: 1G0U)

There is a striking resemblance between prokaryotic and eukaryotic ATP-dependent proteases (**Fig. 8.36**). The core particle of the eukaryotic proteasome contains 2 copies of 14 different proteins assembled in four stacked rings, each containing 7 proteins (heteroheptameric). The core particle is capped at the top and bottom by the regulatory particles, also made from 14 proteins that are different from those in the core. Six of those proteins are ATPases, while others recognize a ubiquitin peptide tag (see later) placed on doomed proteins. The purpose of this cap is to unfold the target protein and inject it into the 20S proteasome barrel. Archaea also contain a proteasome, but it comprises 14 copies of 2 different proteins assembled in four stacked rings, each containing 7 proteins (homoheptameric). Unlike eukaryotic proteasomes, there is no regulatory particle, and substrate proteins are not ubiquitinated (see **Special Topic 8.3**).

Bacteria contain **Clp proteases**, which contain a proteolytic core made of two homoheptameric rings of the protein ClpP. These proteases also have interchangeable homohexameric ATPase caps made of ClpX, ClpA, ClpB, or ClpC, each of which recognizes different substrates. The accessory proteins recognize and present different substrate proteins to the ClpP protease and thereby regulate which proteins are degraded. **Figure 8.36** shows a side-by-side comparison of the bacterial Clp proteases and the eukaryotic 26S proteasome.

How Do Cells Cope with Stress-Damaged Proteins?

Microbes are constantly exposed to environmental insults such as high temperature or pH extremes that damage proteins and cause them to misfold. As an energy cost-saving device and to prevent interruption of protein func-

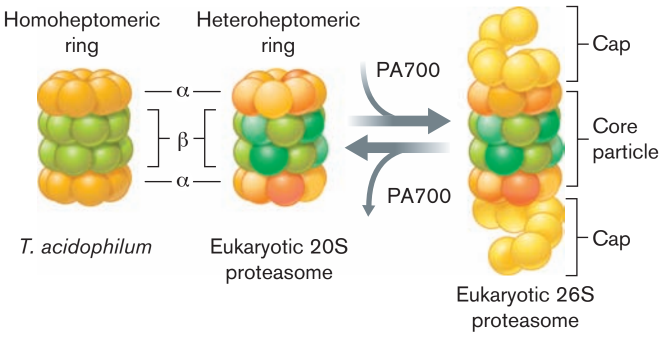

Figure 8.36 Proteolysis degrading machines from prokaryotes and eukaryotes. Structural comparison of the 20S proteasome from an archeaon (*Thermoplasma acidophilum*), a eukaryote, and the 26S eukaryotic proteasome.

Special Topic 8.3 Ubiquitination: A Ticket to the Proteasome

In eukaryotes, protein degradation occurs through organelles called proteasomes. However, proteins are not degraded randomly; they are targeted to the proteasome by the carrier protein **ubiquitin (Ub)**, a small, 76-amino-acid protein found only in eukaryotic organisms. Among eukaryotes, ubiquitin is highly conserved and found ubiquitously throughout the cell (hence its name). Following ATP hydrolysis, Ub is attached (conjugated) to proteins through a covalent bond between glycine at the C-terminal end of Ub and the side chains of lysine on target proteins. Single Ub molecules can be conjugated to proteins, but more commonly, Ub chains are attached. Ubiquitination of proteasomal substrate proteins is performed by a complex system of three enzymes, ubiquitin-activating (E1) enzyme, ubiquitin-conjugating (E2) enzyme, and substrate recognition protein (E3 enzyme) (**Fig. 1**).

Ubiquitination controls protein turnover by closely regulating the degradation of specific proteins. But what determines if a protein gets marked by Ub? Several factors are involved. First, ubiquitination can be triggered when a substrate recognition protein encounters an N-degron (already discussed) or a PEST sequence, a short stretch of about eight amino acids enriched with proline (P), glutamic acid (E), serine (S), and threonine (T). Other signals buried in the hydrophobic core can do the same thing if they are exposed to the surface when the protein is abnormal or partially unfolded.

The 26S proteasome is the structure that actually carries out degradation. Without Ub, proteins interact with the proteasome, but quickly dissociate. The role of Ub in degradation is to stabilize the interaction between proteasomes and their target substrate proteins. This increases the likelihood that the proteasome will degrade the protein.

Figure 1 Protein degradation and ubiquitin. Most proteins that are degraded by 26S proteasomes are tagged for destruction by the addition of polyubiquitin chains. Ubiquitin is a small 76-amino-acid protein that is highly conserved in eukaryotic cells. Ubiquitination of proteasomal substrate proteins is performed by a complex system consisting of ubiquitin activating (E1) enzymes, ubiquitin-conjugating (E2) enzymes and substrate recognition proteins (E3 enzymes).

tion, injured proteins go through a kind of triage process that evaluates whether they are salvageable or must be destroyed before they can endanger the cell. Chaperones constantly hunt for misfolded (or otherwise damaged) proteins and attempt to refold them. But if the protein is released from a chaperone and remains misfolded, it can, by chance, either reengage the chaperone or bind a protease that destroys it (**Fig. 8.37**). This fold-or-destroy triage system is essential if a microbe is to survive environmental stress.

TO SUMMARIZE:

- **All proteins** are eventually degraded.
- **The N-terminal rule** is one type of degradation signal (degron) that marks the half-life of a protein (how long it takes 50% of the protein to degrade).
- **ATP-dependent proteases** such as Lon or ClpP usually initiate degradation of a large protein.
- **Ubiquitination** marks eukaryotic proteins for degradation by the proteasome (see **Special Topic 8.3**).

Figure 8.37 **Protein folding versus degradation triage pathways.** The figure depicts what can happen to a newly synthesized protein. However, a protein that unfolds as a result of environmental stress (for instance, heat) will undergo the same triage process.

- **Damaged proteins** randomly enter chaperone-based refolding pathways or degradation pathways until the protein is repaired or destroyed.

8.7 Bioinformatics: Mining the Genomes

We have just described how the information within a genome is deciphered by the cell to produce proteins. But the experiments described cannot be performed in the vast majority of microbes, which are unculturable. In Chapter 7, we discussed how we can quickly and efficiently sequence entire genomes (see Section 7.6). This knowledge, combined with our understanding of protein structure (amino acid sequences) and the relationships between protein structure and function, has brought us to the postgenomic era. We can now call on the vast store of information gathered over the last century to make predictions about the genetics and physiology of microbes even when we cannot grow them in the laboratory. The following sections reveal how these predictions are made.

Annotating the Genome Sequence

Chapter 7 explained how the DNA sequence of a genome is obtained. Knowing the sequence is just a first step; meaningful information comes from **annotation** of the DNA sequence—that is, understanding what the sequence means. Annotation is analogous to identifying separate sentences and words in an unknown language. For most languages, you would look for punctuation marks like periods or exclamation points to identify sentences and then scan for blank spaces between letters to signify the beginning and end of a word. You may not initially know what the sentence says, but defining what makes a sentence is the first step.

Annotation of a DNA sequence includes finding the start and stop sites of genes, as well as predicting the function of the gene product. Computers use established rules to mark potential genes—open reading frames (ORFs). Then similarities are sought between the deduced amino acid sequences of those ORFs and the sequences of proteins with known functions. Similarities are used to infer the function of the unknown ORF. Genes encoding transfer RNA and ribosomal RNAs do not encode proteins but can be identified because of the conservation of these sequences across vast phylogenetic distances. The results of annotation can be represented in many different forms. **Figure 8.38** shows a commonly used method of presenting the results, a circular display map—in this case of the *Mycoplasma mycoides* genome—with genes color-coded by predicted function.

Since 1998, the complete genomes of over 225 microbial species have been published, and many others have been partially sequenced. This wealth of information has spawned a new discipline called **bioinformatics** dedicated to comparing genes of different species. Data from bioinformatics enable scientists to make predictions about an organism's physiology and evolutionary development, even if the organism cannot be grown in the laboratory. The magnitude of this achievement, and of the job ahead, can be appreciated if we recall that fewer than 1% of microorganisms can be cultured. Bioinformatics has forever changed how the science of microbiology is conducted.

WWW | Sequenced Genomes

Computer Analysis and Web Science

Lengthy DNA sequences are analyzed by computer programs such as ORFfinder. The program uses the universal genetic code to deduce all possible protein sequences that could be formed in all reading frames on RNA molecules transcribed from either direction on the chromosome (**Fig. 8.39A**). An open reading frame (ORF), the equivalent of a sentence in our analogy, is defined

1.211.703 bp

Figure 8.38 Circular display map of the *Mycoplasma mycoides* genome (1,211,703 bp). Color code indicates gene clustering by function. The two outer rings represent genes transcribed from different DNA strands. The innermost circle uses peaks to show GC content levels above or below 50%.

as a DNA sequence that can potentially encode a string of amino acids of minimum length—say, for example, 50 residues. The 50 residues of the ORF could encode a 5,500-Da (5.5-kDa) protein, since the average weight of an amino acid is 110 Da. Each ORF begins with a translation start codon (usually ATG or, more rarely, GTG or TTG). A translation start codon marks where ribosomes start to read a messenger RNA molecule. An ORF ends with a termination codon (in the DNA, these are TAA, TAG, or TGA), which, as UAA, UAG, and UGA in RNA, signals the ribosome to stop translation. Additionally, the computer can identify an ORF by looking for potential ribosome-binding sites upstream of the start codon, but these ribosome-binding sites may differ between species, so finding one is not essential to declaring the presence of an ORF.

While the preceding methods work for prokaryotes, identifying ORFs in eukaryotes is more difficult. In eukaryotes, most genes contain **introns** (long noncoding sequences that occur in the middle of genes), as do the initial mRNA products produced from those genes (**Fig. 8.39B**). The vast majority of known prokaryotic genes do not contain introns. Introns serve several regulatory functions in eukaryotes that determine whether a protein product is made. However, the eukaryotic cell must use special splicing mechanisms to remove the intron sequences and rejoin the protein-encoding sequences, called **exons**, of the mRNA prior to translation. (In eukaryotic organisms, the mRNA transcribed directly from DNA is thus called the **preliminary mRNA transcript** or **pre-mRNA**; the "final" mRNA transcript is produced when the introns have been spliced out.) Because there are few identifying sequence characteristics that mark an intron, extremely sophisticated computer analysis is needed to determine where to remove introns in order to derive the ORF coding sequence of a eukaryotic gene.

Once an ORF is identified, computers use mathematical algorithms to determine whether the protein predicted by the ORF resembles any other protein deposited in the worldwide databases or, even better, resembles proteins of known function. By "resemble" we mean that the query protein possesses amino acid sequences that are identical or functionally similar to those found in other proteins. In a functionally similar sequence, certain amino acids are replaced by similar amino acids—for example, isoleucine for leucine. We know from consider-

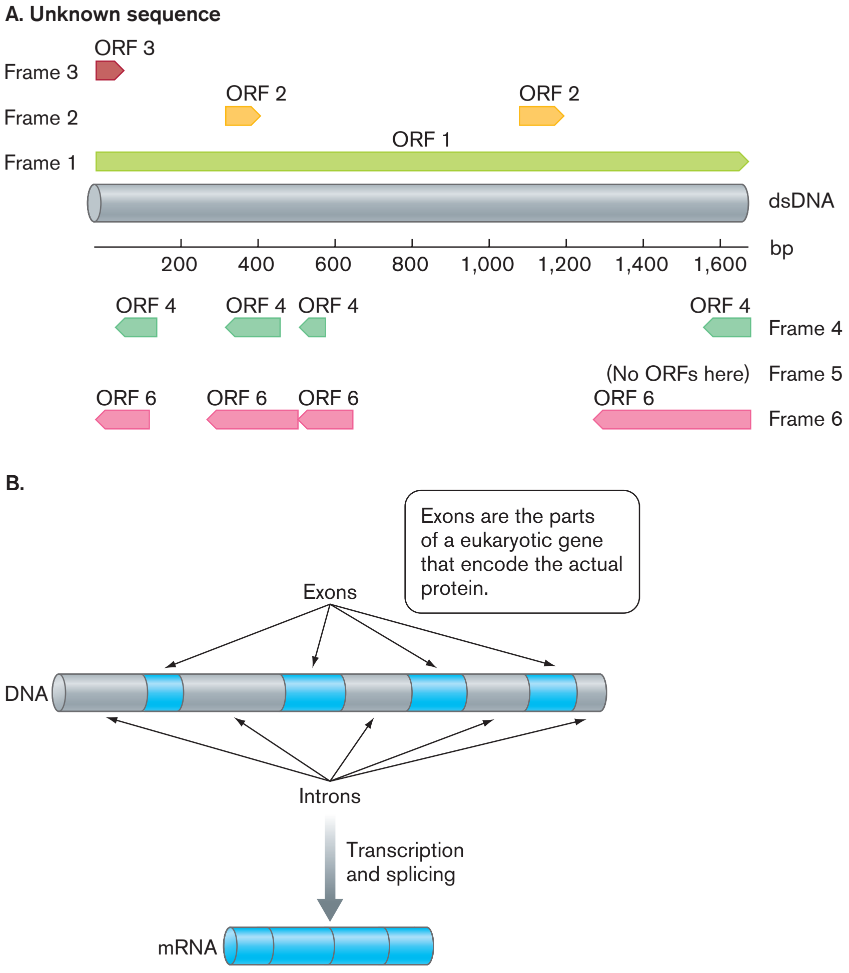

Figure 8.39 Predicting open reading frames (ORFs) in a DNA sequence. **A.** Each predicted ORF in this 1,600-bp bacterial sequence begins with an AUG or GUG (potential translation start codons in mRNA) and ends with a translation terminator codon. The computer can translate in all six reading frames (3 on top strand, 3 on bottom strand). Determining which is the real ORF requires additional information, such as potential ribosome-binding sites and transcriptional start site. **B.** In eukaryotes, finding ORFs is complicated by the presence of noncoding DNA sequences called introns. The actual ORF (exons) is disrupted by introns, which must be spliced out of the primary RNA message before the final mRNA leaves the nucleus.

able experimental precedent that proteins with the same function, regardless of species, usually have critical amino acid sequences in common because they evolved from the same ancestral sequence. Sequences common to two different protein or DNA molecules are called homologous sequences.

Figure 8.40 shows a sequence alignment between eight examples of dihydrolipoamide dehydrogenases from different species and illustrates how this alignment was used to partially characterize the function of a virulence gene in an important pathogen. Ordinarily, dihydrolipoamide dehydrogenase is integrally important to the tricarboxylic acid cycle, which extracts energy and carbon from carbohydrate food sources. Note the highlighted areas in the figure; these represent regions of identity or similarity at similar positions. Identity means the same amino acid is present in each protein, whereas similarity means that chemically related amino acids are substituted (for example, valine is substituted by the similar leucine, or glutamate is substituted by aspartate). Also notice that the top sequence in the figure is an unknown ORF from the *Streptococcus pneumoniae* genome, an organism that causes pneumonia. The computer program flagged the sequence similarities between this unknown ORF and the known proteins shown in the figure. Based on that homology, the ORF was deduced to encode a dihydrolipoamide dehydrogenase, a prediction confirmed by mutating the gene and by looking directly for the biochemical activity. However, *S. pneumoniae* are strictly fermentative organisms that do not have a complete TCA cycle. Nevertheless, deleting the gene decreased virulence of this pathogen in a mouse model, suggesting an important function for the enzyme unrelated to the TCA cycle. In this and many other instances, bioinformatics provides important insights into microbial physiology.

Alignments can be done either with base sequences in DNA or with protein sequences deduced from the DNA sequence. Because of the degeneracy of the code, however, it is usually easier to pick up evolutionary relationships between genes from distantly related species by comparing their protein products rather than the DNA sequence. Remember, one amino acid can be encoded by more than one DNA codon. So a DNA strand (nontemplate) encoding the peptide Ala-Leu-Ser could be 5′ GCU CCU UCC or 5′ GCA CCG UCA. It is easier to see the homology using the deduced peptide. On the other hand, not all genes encode proteins.

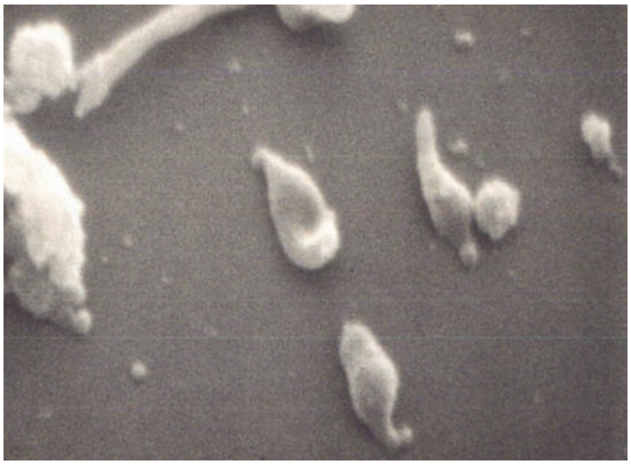
Figure 8.40 Multiple sequence alignment. The program CLUSTALW (available online) was used to align the amino acid sequence of dihydrolipoamide dehydrogenases from *Streptococcus pneumoniae* C08 ORF with selected orthologs from other known species (only a portion of the alignment is shown). These proteins are called orthologs because they have similar sequences and carry out the same biochemical reaction. Top sequence in each tier is a different portion of the C08 sequence. Amino acid sequences of over 51% similarity are shaded. Highly conserved residues where at least five residues are the same or similar amino acids are shaded yellow. Very highly conserved residues where at least seven out of eight are identical are shaded brown. Deletions (sequences missing in one or more orthologs) are indicated as dots.

Special Topic 8.4 What Is the Minimal Genome?

Defining life is more than a philosophical exercise. Attempts to address the topic have touched almost every scientific discipline. From a genetic viewpoint, we could try to define what makes life by determining the minimum number of genes needed to sustain the life of a cell. Mycoplasmas, bacteria that lack cell walls, have long been viewed as minimal organisms. (Viral DNA is not considered to represent a minimal genome because viruses are not cells and are incapable of independent growth and reproduction.) The *Mycoplasma* species with the smallest genome is *Mycoplasma genitalium* (**Fig. 1**), whose chromosome encodes a mere 480 proteins, compared with over 4,000 for *E. coli*. The small size of the *M. genitalium* genome is thought to reflect its parasitic lifestyle. For example, the many genes required to synthesize amino acids, make cell wall components, and run a citric acid cycle have been lost from this organism, presumably because the host cell supplies these products.

Based on this finding should we conclude that 480 genes is the minimum needed to sustain cellular life? Any effort to define such a minimum depends on what we define as "living." How can we know which, if any, of the 480 genes "enhance" life rather than being absolutely essential? Removing even nonessential genes can reduce the fitness of an organism and result in its eventual extinction. For example, microbes with small genomes often have a slower growth rate than their relatives with larger genomes and exhibit a greater dependence on outside assistance. At some point during genome reduction, the ability to maintain active cultures will become impossible. That point may differ, however, depending on the environment. Environmental factors will dictate whether a given gene is essential for survival. For example, a fish requires gills to live; humans do not. Thus, the evolutionary niche occupied by a microbe will influence which genes are retained in its genome. An organism that lives in acidic environments will require genes whose products will protect the cell against low pH. Those genes are dispensable to an organism that grows only at neutral pH.



K. Frantz, A. Albay, and K. Bott, U. of North Carolina, Chapel Hill

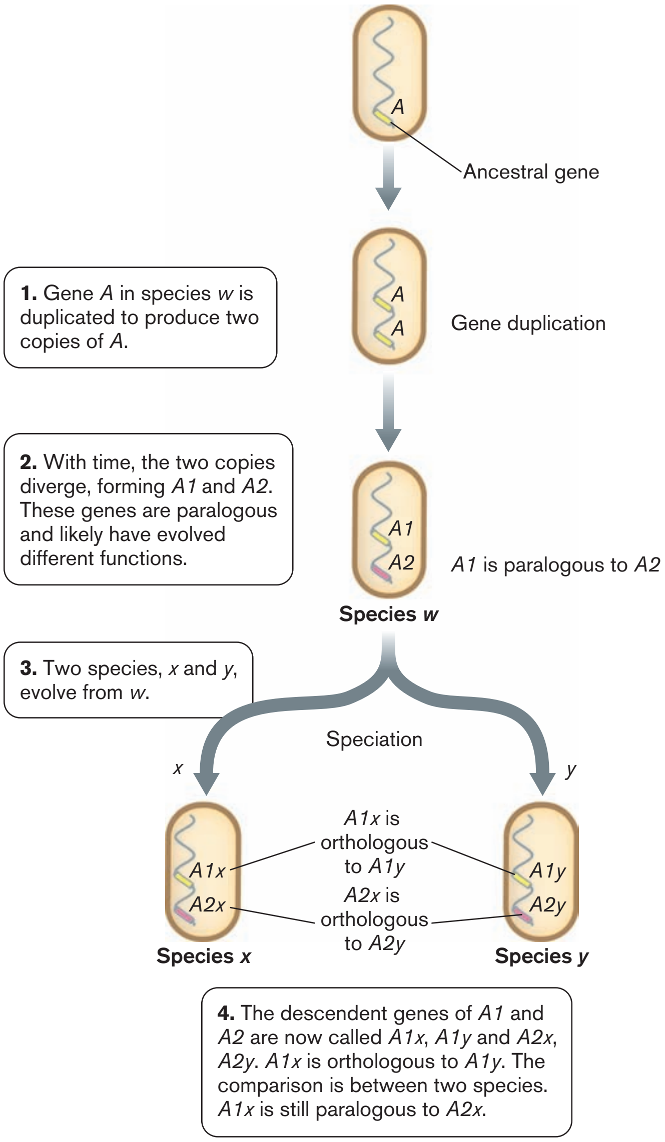
Figure 1 ***Mycoplasma genitalium*.** Scanning electron micrograph.

In experiments to determine the minimal genome required to support growth of *M. genitalium*, scientists have used transposon mutagenesis, a technique in which pieces of DNA (transposons) are inserted into the the cell's DNA to disrupt gene function (described in Section 9.6). This technique makes it possible to randomly knock out genes and see which ones could be neutralized without losing cell viability. Based on a statistical treatment of their results, these investigators concluded that 129 genes appeared dispensable (they could be knocked out and the cell would still grow). This does not mean that the minimal genome is 351 genes, since it is impossible to know if any of the paralogous genes present among the 129 dispensables might carry out identical (redundant) functions such that losing one or the other would not affect viability. However, losing both simultaneously would be lethal.

It is sobering to realize that one-third of the 351 essential genes in *M. genitalium* are of undefined function. It brings into question a basic assumption held by many that the fundamental mechanisms of life have, for the most part, been recognized. On the other hand, it may be that many of those 100 or so genes with unannotated function encode activities that are well characterized in other organisms but are simply not recognized by sequence as being orthologs in *M. genitalium*. Some may be specialized for colonization or parasitism. Whether these genes encode unknown fundamental life processes or not, there is much to be done before claiming a clear understanding of the simplest cell. The clearest solution to determining the minimum number of genes required to support life would to be to build a genome from scratch in the test tube, place it into a cell whose genome had been excised, and then see if that cell can survive.

Prime examples are the genes encoding stable ribosomal RNA molecules. The DNA sequences for these ribosomal RNAs are highly conserved across species, and their similarities reveal homology even between the three ancestral kingdoms of bacteria, archaea, and eukarya.

> **NOTE:** Do not confuse template and nontemplate strands of DNA for a given gene. The template strand, read 3′-to-5′ by RNA polymerase, is transcribed to make the 5′-to-3′ RNA transcript. The nontemplate DNA strand, also called the sense strand, has the *same* sequence as the RNA transcript, with the substitution of T's for U's.



1. Gene *A* in species *w* is duplicated to produce two copies of *A*.

2. With time, the two copies diverge, forming *A1* and *A2*. These genes are paralogous and likely have evolved different functions.

3. Two species, *x* and *y*, evolve from *w*.

4. The descendent genes of *A1* and *A2* are now called *A1x*, *A1y* and *A2x*, *A2y*. *A1x* is orthologous to *A1y*. The comparison is between two species. *A1x* is still paralogous to *A2x*.

Figure 8.41 **Paralogous versus orthologous genes.** An ancestral gene can undergo a duplication to evolve an orthologous or paralogous gene.

Homologs, Orthologs, and Paralogs

Homologies found between genes or proteins suggest an evolutionary relatedness. Genes or proteins that are **homologous** probably evolved from a common ancestral gene. Homologous genes or proteins can be classified as either orthologous or paralogous. **Orthologous** genes have functions essentially the same but occur in two or more different species. For example, the gene for glutamine synthase (*gltB*) in *E. coli* is orthologous to *gltB* in *Vibrio cholerae* and to *gltB* in the gram-positive bacterium *Bacillus subtilis*. **Paralogous** genes arise by duplication within the same species (or progenitor) but evolve to carry out different functions (**Fig. 8.41**). For example, genes encoding type III protein secretion systems, which export virulence proteins, have evolved from paralogous genes encoding flagellar biogenesis. The two sets of genes share a common ancestor but have since evolved completely different functions (for example, secretion and motility). Paralogous genes are maintained in a microbial genome because their distinct functions contribute to the organism's adaptive

Figure 8.42 **Genomic predictions of solute transport and metabolic pathways of *Helicobacter pylori* strain 26695.** The large rectangle represents a cell. The transporters arrayed around the periphery were identified by sequence comparisons characteristic to transporters in gram-negative bacteria. The ABC transporters (multicomponent) are predicted to transport oligopeptides, dipeptides, proline, glutamine, molybdenum, and iron III. There are also predicted P-type ATPases that extrude toxic metals from the cell and a glutathione-regulated potassium-efflux protein (encoded by *kefB*). An integrated view of the main components of *H. pylori* central metabolism is presented within the rectangle. This scheme is based on using glucose as the sole carbohydrate source. Urease, a multisubunit enzyme crucial for survival of *H. pylori* at acid pH, is indicated as a complex (purple circle). A question mark is attached to pathways that could not be completely elucidated. A red arrow represents pathways or steps for which no enzymes were predicted from the sequence. Pathways for macromolecular biosynthesis (RNA, DNA, and fatty acids) were found but are not shown. Other abbreviations for *H. pylori* genes: *ackA*, acetate kinase; *acnB*, aconitase B; *aspC*, aspartate aminotransferase; *dld*, D-lactate dehydrogenase; *gdhA*, glutamate dehydrogenase; *glnA*, glutamine synthetase; *gltA*, citrate synthase; *hydABC*, hydrogenase complex; *icd*, isocitrate dehydrogenase; *pfl*, pyruvate formate lyase; *por*, pyruvate ferredoxin oxidoreductase; *ppc*, phosphoenolpyruvate carboxylase; *pps*, phosphoenolpyruvate synthase; *pta*, phosphate acetyltransferase; *gldD*, glycerol-3-phosphate dehydrogenase; NDH-1, NADH–ubiquinone oxidoreductase complex.

potential. Duplicate genes of identical function usually result in loss of one copy or the other by degenerative evolution (see Chapter 9).

Many computer programs and resources used to analyze DNA and protein sequences are freely available on the Web. Here are some useful programs and websites:

- **BLAST** (**B**asic **L**ocal **A**lignment **S**earch **T**ool) compares a sequence of interest with all other DNA or protein sequences deposited in sequence databases.
- **Multiple Sequence Alignment** aligns sequences of genes identified as homologous by BLAST analysis.
- **KEGG** (**K**yoto **E**ncyclopedia of **G**enes and **G**enomes) outlines biochemical pathways in many sequenced organisms. Areas within this site graphically display reference biochemical pathways (for example, glycolysis) and then indicate which proteins in that pathway are predicted to occur in any organism with a sequenced genome.
- **PUMA2** identifies pathways containing any given substrate or enzyme.
- **Sequence Motif** searches DNA or proteins for sequence signatures such as ATP-binding sites.
- **ExPASy** (**Ex**pert **P**rotein **A**nalysis **Sy**stem) contains many molecular tools, including Swiss-Prot, the definitive index of known proteins.
- **Colibri** and **Colibase** focus on *E. coli* genomics.
- **Joint Genome Institute** has also compiled known genome sequences of microbes and eukaryotes.

A word of caution. It is enticing to make definitive proclamations about gene or protein function based on the computer analysis of a DNA sequence. As good as a prediction may seem, it is only a prediction, a well-educated guess. Biochemical confirmation of function must be made, if possible. Nevertheless, the predictions we can make are powerful. In one recent example, a metabolic model was constructed by genome annotation for *Helicobacter pylori*, the causative agent of gastritis (ulcers). The *H. pylori* model was used to predict what amino acids the organism would require (because the predicted metabolic pathway appears to be missing) and what genes might be essential (**Fig. 8.42**). In another application, some investigators are trying to predict the smallest number of genes required for a living cell (see **Special Topic 8.4**).

THOUGHT QUESTION 8.10 An ORF 1,200 bp in length could encode a protein of what size and molecular weight?

The information age has spawned what could be called Web biology, an *in silico* science that has provided new insight into evolution, physiology, and pathogenesis. Bioinformatics has not only confirmed what we know in greater detail, but also revealed new information, such as the existence of ORFs with no known function. The sequencing of entire genomes has enabled a greater understanding of sequence similarity or homology between genes or proteins and has provided a foundation for understanding evolutionary relationships. For example, the sequencing of the alpha proteobacterium *Rickettsia prowazekii* revealed many similarities to genes within eukaryotic mitochondrial DNA. This led to the conclusion that eukaryotic mitochondria were derived from a rickettsial predecessor that became an endosymbiont (an intracellular symbiotic organism), rather than food, for a eukaryotic cell.

TO SUMMARIZE:

- **Annotation** requires computers that look for patterns in DNA sequence. Annotation predicts regulators, ORFs, rDNA, and tRNA. Similarities in protein sequence (deduced from the DNA sequence) are used to predict protein structure and function.
- **An open reading frame (ORF)** is a sequence of DNA predicted by various sequence cues to encode an actual protein.
- **Eukaryotic genes** contain introns and exons, making computer predictions of an ORF more difficult than with prokaryotic genes.
- **DNA alignments** of similar genes or proteins can reveal evolutionary relationships.
- **Paralogs and orthologs** arise from gene duplications. Paralogous genes coexist in the same genome but usually have different functions. Orthologous genes occur in the genomes of different species but produce proteins with similar functions.

Concluding Thoughts

The efficient cell must use the macromolecular processes described in this chapter to synthesize its biochemical pathways without wasting energy. Microbes do this through the use of elaborate control mechanisms that sense the organism's physiological state and environment and then trigger changes in replication, transcription, translation, and/or protein processing. How bacteria regulate gene expression in response to environmental stimuli, including threats to survival, will be discussed in Chapter 10.

In Chapter 9, we explore how natural selection randomly redesigns genomes to adapt to ecological niches. Microbes use a variety of DNA exchange mechanisms, gene duplications, and alterations to evolve into forms better adapted to their environments and, in the process, may produce entirely new species.

CHAPTER REVIEW

Review Questions

1. What are some characteristics of an ORF?
2. What is a DNA sequence alignment, and what can it tell you?
3. Describe the differences between a pair of orthologous genes and a pair of paralogous genes.
4. How can bioinformatics predict a metabolic pathway for an organism that cannot be grown in the laboratory?
5. What defines a promoter?
6. What are sigma factors, and what role do they play in gene expression?
7. Describe the three stages of transcription.
8. Explain degeneracy of the genetic code. What is the wobble in codon-anticodon recognition?
9. Describe the stages of protein synthesis. Why is the ribosome called a ribozyme?
10. Discuss some antibiotics that affect transcription or translation.
11. What is meant by coupled transcription and translation? Does this occur in eukaryotic cells?
12. How do bacterial cells release ribosomes that are stuck onto damaged mRNA molecules lacking termination codons?
13. What can happen to misfolded proteins?
14. Why are only certain proteins secreted from the bacterial cell? What are some secretion mechanisms?
15. Compare protein degradation in eukaryotes and prokaryotes.
16. What is annotation? How does it apply to bioinformatics?

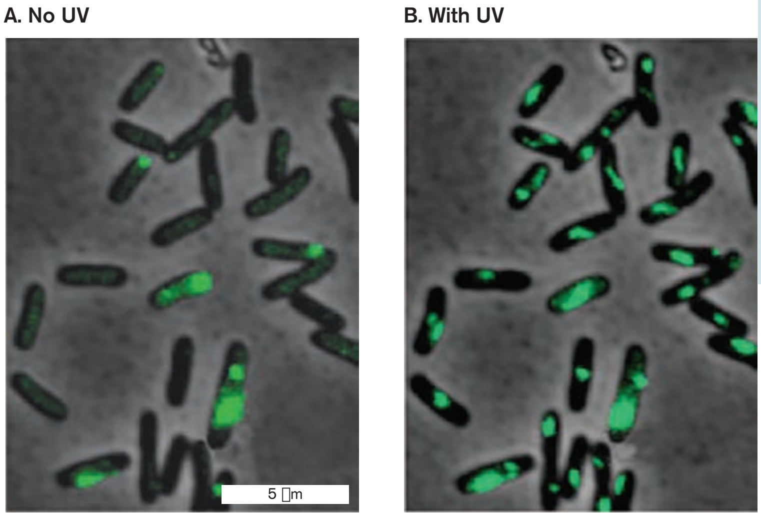
Chapter 9

Gene Transfer, Mutations, and Genome Evolution

9.1 The Mosaic Nature of Genomes
9.2 Gene Transfer: Transformation, Conjugation, and Transduction
9.3 Recombination
9.4 Mutations
9.5 DNA Repair
9.6 Mobile Genetic Elements
9.7 Genome Evolution

DNA was once thought to be a monolithic "master molecule" that governs all traits of an organism while remaining unchanged itself. We now know that DNA sequences change over generations through various mutations, DNA rearrangements, and gene transfers between species. Bacterial and archaeal genomes experience a rapid flux, sometimes shuttling large clusters of genes between members of different taxonomic kingdoms. All this inter- and intraspecies DNA traffic has led ecologists to expand the definition of the "microbial genome" to include DNA in the cell plus all the DNA out in the environment to which the microbe has potential access.

A number of important questions come to mind when we contemplate the consequences of DNA plasticity. For example, because the processes of adding, subtracting, and mutating genes are all processes that come at some cost, can the cell protect itself from undergoing too many drastic changes? Are some mutations good and others bad? Why would nature allow this much genetic uncertainty? This chapter explores these long-standing evolutionary questions and shows how microbial genomes continually change.



Visualization of *E. coli* responding to ultraviolet light. A gene fusion between the recombinant gene *recA* and green fluorescent protein (GFP) was introduced into *E. coli*. When DNA is damaged by UV light, the cell increases the production of the RecA-GFP fusion protein as part of the SOS response. Panel A shows unexposed cells; Panel B shows the increase in RecA-GFP binding to DNA 20 minutes after UV exposure.
Source: Renzette, et al. 2005. *Molecular Microbiology* 57:1074.

We think of evolution as taking place over thousands if not millions of years. However, John Sullivan and Clive Ronson, in New Zealand, witnessed evolution taking place within a mere decade. These scientists were studying the microbe *Mesorhizobium loti*, a bacterial species that establishes symbiotic relationships with plants by forming nitrogen-fixing nodules on the plant's roots. The genes encoding symbiosis are located as a group on the mesorhizobial chromosome. In addition to these symbiotic rhizobia, there are many nonsymbiotic species that are incapable of forging this relationship. In a remarkable experiment, Sullivan and Ronson inoculated a single strain of *M. loti* into an area of land devoid of natural nodulating rhizobia. Seven years later, they discovered that the area contained many genetically diverse symbiotic mesorhizobia now able to nodulate the flowering plant *Lotus corniculatus*. These microbes did not exist before the experiment. The scientists found that the 500-kbp genome segment encoding symbiosis had somehow made its way from *M. loti* into these other bacteria—essentially creating new species. How did this happen so quickly?

In this chapter, we address this question beginning with a discussion of the mechanisms that mediate transient as well as heritable DNA movements between species. Next we turn to a description of the competing processes of mutagenesis and mutation repair in the context of self-preservation and evolutionary change. The chapter closes with an examination of how all these processes collaborate over millennia to remodel genomes and build biological diversity.

9.1 The Mosaic Nature of Genomes

Genomic analysis has revealed that over the millennia, microbes have undergone extensive gene loss and gain. Archaea, for example, arose from a common eukaryotic/archaeal phylogenetic branch and as a result possess many traits in common with eukaryotes, such as the structure and function of their DNA and RNA polymerases. However, many archaeal genes whose products are involved with intermediary metabolism look purely bacterial. In fact, 37% of the proteins found in the archaeon *Methanococcus jannaschii* are found in all three domains—Archaea, Eukarya, and Bacteria. Another 26% are otherwise found only in bacteria, while a mere 5% are confined to archaea and eukaryotes. This clearly suggests that archaea enjoy a mixed heritage.

Another surprise arising from bioinformatic studies is the mosaic nature of the *E. coli* genome and, indeed, of all microbial genomes. Though we have intensively studied *E. coli* for over 100 years, we now find that the organism's DNA is rife with pathogenicity islands, fitness islands, inversions, deletions (when compared to similar species), paralogous genes, and orthologous genes. How did all this genomic blending happen? The answer appears to involve heavy gene traffic between species (horizontal gene transfer), recombination events occurring within a species, and a variety of mutagenic and DNA repair strategies. All of these processes accelerated natural selection, where trial and error helped mold genomes.

Why was this gene movement unexpected? Sometimes a powerful idea in biology actually delays discovery of the next step. For example, James Watson's vision of DNA as the "master molecule" and the concept of the single-rooted evolutionary tree led to so many important concepts in molecular biology that observations of more fluid gene exchange were ignored or resisted at first. However, the history of microbiology provided many clues as to its existence.

9.2 Gene Transfer: Transformation, Conjugation, and Transduction

In 1928, a perceptive English medical officer, Fred Griffith (1879–1941), found that he could kill mice by injecting them with *dead* cells of a virulent pneumococcus (*Streptococcus pneumoniae*), a cause of pneumonia, together with *live* cells of a nonvirulent mutant. Even more extraordinary was the fact that the bacteria recovered from the dead mice were of the live, *virulent* type. Were the dead bacteria brought back to life? Unfortunately, Griffith was killed by a German bomb during an air raid on London in 1941 and never learned the answer.

In a landmark series of experiments published in 1944, Oswald Avery (1877–1955), Colin MacLeod (1909–1972), and Maclyn MacCarty (1911–2005) proved that Griffith's experiment was not a case of reviving dead cells, but involved the transfer of DNA released from the virulent, dead strain *into* the harmless living strain of *S. pneumoniae*, an event that transformed the live strain into a killer. The process of importing free DNA into bacterial cells is now known as **transformation**.

Transformation provided the first clue that gene exchange can occur in microorganisms. But why bacteria carry out this and other forms of gene transfer was not fully appreciated until much later. Recent genomic studies indicate that the fundamental purpose of bacterial gene transfer is to acquire genes that might be useful as the environment changes. Before we can discuss how bacterial genomes evolve, we need to understand the various gene exchange mechanisms available to them. Following the explanations of gene exchange, we will discuss the mechanisms that incorporate newly acquired DNA into genomes (for example, recombination).

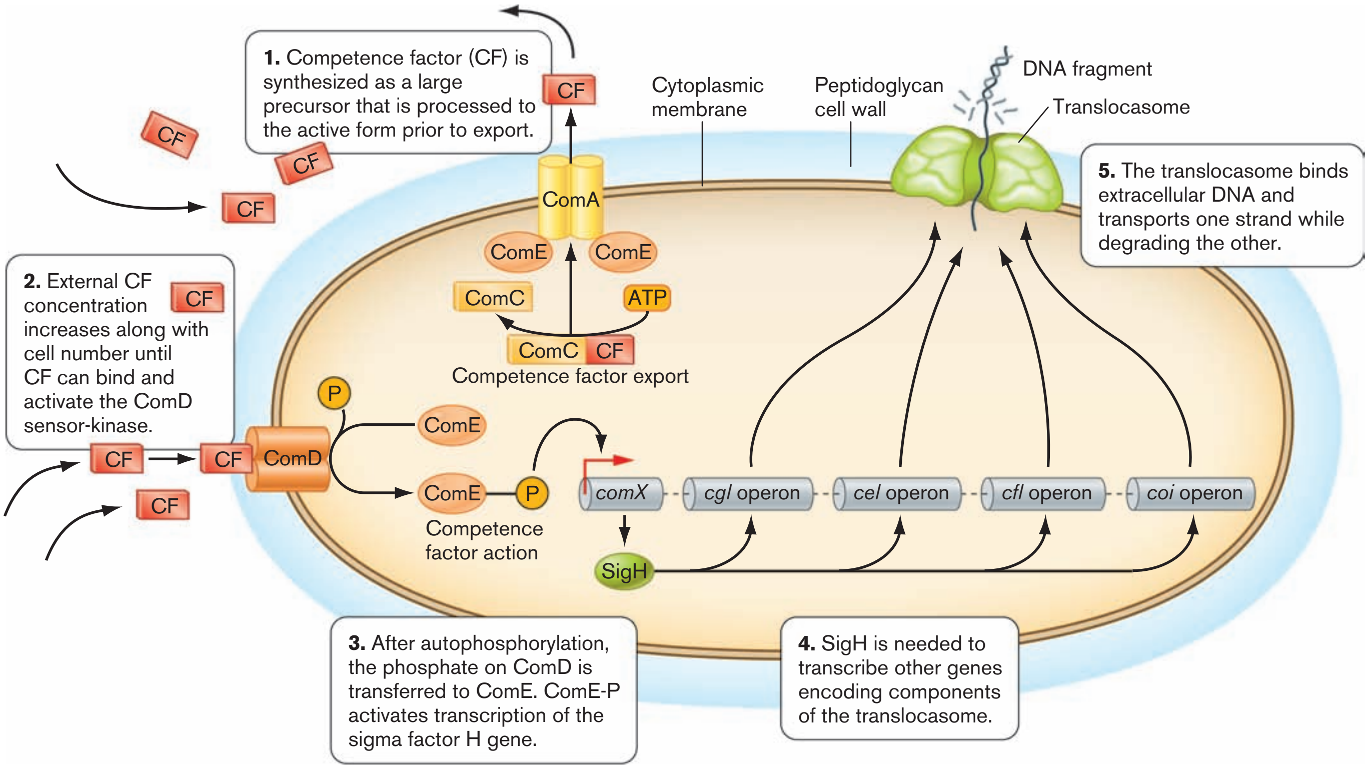
Gene Exchange by Transformation

Many bacteria have the ability to import DNA fragments and plasmids released from nearby dead cells via the process of transformation. Natural transformation is a property inherent to many species, conferred by specific protein complexes. Examples include gram-positive bacteria like *Streptococcus* and *Bacillus*, as well as gram-negative species such as *Haemophilus* and *Neisseria* species. Transformation is a natural part of their growth cycles.

Other bacteria, however, such as *E. coli* and *Salmonella*, do not possess the equipment needed to import DNA naturally. They require artificial manipulations to drive DNA into the cell. These laboratory techniques include perturbing the membrane by chemical ($CaCl_2$) and electrical (**electroporation**) methods. $CaCl_2$ alters the membrane, which makes these cells electrocompetent and allows DNA to pass. Electroporation, on the other hand, uses a brief electrical pulse to "shoot" DNA across the membrane.

Why do species such as *Neisseria* species undergo natural transformation? First, species that indiscriminately import DNA may use the transformed DNA as food. Second, the more finicky species that transform only compatible DNA sequences may use DNA released from dead compatriots to repair their own damaged genomes. Finally, transformation may play an evolutionary role, enabling species to adjust to new environments by acquiring new genes from other species in a process called **horizontal gene transfer**. Horizontal gene transfer is distinguished from vertical transfer, the generational passing of genes from parent to offspring, as in cell division. If horizontal acquisition of a gene system improves the competitiveness of the cell, the new genes will be retained and the descendants will have evolved into a new kind of organism. Pathogens such as *Neisseria gonorrhoeae*, the cause of gonorrhea, may have used transformation to acquire new genes whose protein products now help the organism evade the host immune system.

Gram-positive organisms transform DNA using a translocasome complex. Natural transformation in gram-positive organisms typically involves the growth-phase-dependent assembly of a **translocasome** complex across the cell membrane (**Fig. 9.1**). The translocasome is composed of a binding protein that captures extracellular DNA floating in the environment, plus proteins that form a transmembrane pore. The complex also includes a nuclease that degrades one strand of a double-stranded DNA molecule while pulling the other strand intact



1. Competence factor (CF) is synthesized as a large precursor that is processed to the active form prior to export.

2. External CF concentration increases along with cell number until CF can bind and activate the ComD sensor-kinase.

3. After autophosphorylation, the phosphate on ComD is transferred to ComE. ComE-P activates transcription of the sigma factor H gene.

4. SigH is needed to transcribe other genes encoding components of the translocasome.

5. The translocasome binds extracellular DNA and transports one strand while degrading the other.

Figure 9.1 Transformation in *Streptococcus*. The process of transformation in this organism begins with the synthesis of a signal molecule (competence factor) and concludes with the import of a single-stranded DNA strand through a translocasome complex.

through the pore and into the cell. Once inside, the strand can be incorporated into the chromosome by recombination, a process we will discuss in Section 9.3.

Once the translocasome is assembled, the cell is **competent**, meaning that it can import free DNA fragments and incorporate them into its genome. What triggers growth-stage-dependent competence? For some gram-positive bacteria, competence for transformation is generated by a chemical conversation that takes place between members of the culture. Every individual in a growing population produces and secretes a small, 15–20 amino acid peptide generically called **competence factor** that accumulates in the medium until it induces a genetic program that makes the population competent (**Fig. 9.1**, step 1). The sequence of the competence factor peptide is unique to each species, as are the specifics of the induction process. For *Streptococcus pneumoniae*, as the population increases—that is, as the cell density increases—so does the level of competence factor in the medium (step 2).

Above a certain concentration threshold, competence factor is able to bind to a sensory protein built into the cell membrane (ComD for *S. pneumoniae*). This binding begins what is called a phosphorylation cascade. In the phosphorylation cascade, the sensory protein uses ATP to autophosphorylate and then passes the phosphate to a cytoplasmic regulatory protein, ComE, that stimulates expression of a novel sigma factor, SigH (step 3). The resulting sigma factor is specifically used to transcribe genes encoding the translocasome (step 4). The protein products of these genes are assembled at the membrane, and the cell becomes competent (step 5).

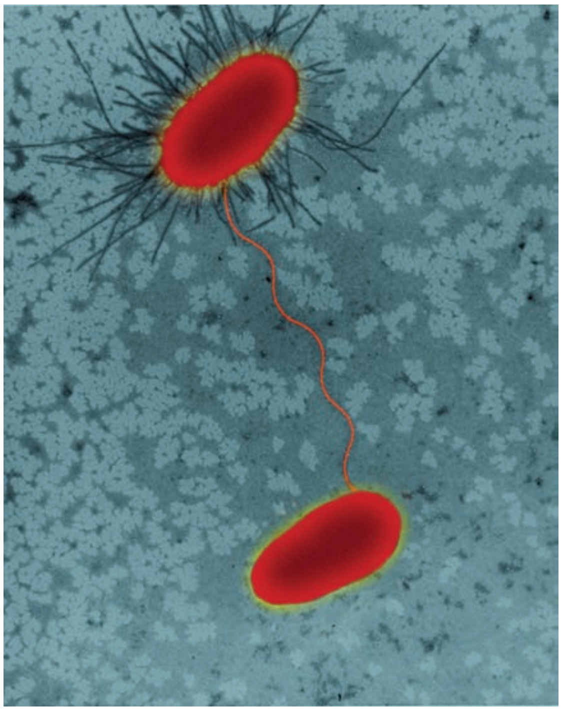
Gram-negative species transform without competence factors. Gram-negative species capable of natural transformation do not appear to make competence factors. Either they are always competent, like *Neisseria*, or they become competent when starved (for example, in *Haemophilus* species). Competence development does not depend on cell-cell communication. Gram-negative bacteria also must overcome a barrier to DNA import not faced by gram-positive bacteria, namely, the outer membrane. Thus, gram-negative organisms cannot use the cytoplasmic membrane translocasome that is employed by gram-positive microbes. *Neisseria* species, for example, appear to import DNA through a system paralogous to type IV pilus assembly (discussed in Chapter 8). Type IV pili reversibly assemble and disassemble at the cell surface, expanding and contracting as a result. This happens constantly during the growth of a culture and can help cells move across solid surfaces. During transformation in species of *Neisseria*, disassembly of a pilus is thought to drag transforming DNA into the cell and across the two membranes.

In another departure from the gram-positive example, transformation in species of *Haemophilus* and *Neisseria* is species and sequence specific, thereby limiting gene exchange between different genera. Specificity is due to particular sequences in DNA that are recognized by part of the uptake apparatus. However, not all gram-negative competence systems display such specificity; *Acinetobacter calcoaceticus,* a lung pathogen, is able to take up DNA from any source at very high frequency. This is possible because the DNA-binding part of its transformation system does not need to recognize a specific nucleotide sequence.

Gene Transfer by Conjugation

Conjugation, or "bacterial sex," requires cell-cell contact typically initiated by a special pilus protruding from a donor cell (**Fig. 9.2**). Conjugation occurs in many species of bacteria and archaea, even in hyperthermophiles such as *Sulfolobus* species. In nature, mixed-species biofilms are thought to be a way in which cross-species DNA transfer may even occur, albeit at a low frequency. Some species, especially gram-positives, use nonpilus attachment proteins. In the case of *E. coli*, the tip of the specialized sex pilus attaches to a receptor on the recipient cell and then contracts, drawing the two cells closer. The two cell envelopes fuse and generate a conjugation complex, similar to the transformation complex, through which single-stranded DNA passes from donor to recipient. The DNA passes across the membranes through a conjugation complex.

Bacterial conjugation requires the presence of special *transferable* plasmids that usually contain all the genes



©Dennis Kunkel Microscopy, Inc.

Figure 9.2 Sex pilus connecting two *E. coli* cells. The top cell with pili is the donor. The smaller, bottom cell is the recipient.

needed for pilus formation and DNA export. A well-studied, transferable plasmid in *E. coli* is called **fertility factor (F factor)** (**Fig. 9.3**). Not only does this plasmid transfer itself to a recipient cell, but if it integrates into the chromosome of its host, it can also transfer host genes. F factor contains two replication origins, *oriV* and *oriT*, located at different positions on the plasmid. The origin *oriV* is used to replicate and maintain the plasmid in non-conjugating cells, whereas *oriT* is used only to replicate DNA during DNA transfer.

Conjugation begins with cell-to-cell contact between a donor cell, called the **F$^+$ cell**, which carries the plasmid, and a recipient **F$^-$ cell** (step 1). Formation of the fused membrane conjugation conduit (step 2) triggers synthesis of an F factor helicase/endonuclease (encoded on the plasmid) that nicks the phosphodiester backbone at *oriT* (step 3). DNA polymerase III (Pol III) is then recruited to *oriT*, where replication begins (step 4). In contrast to bidirectional replication used to duplicate the chromosome, replication for conjugal transfer

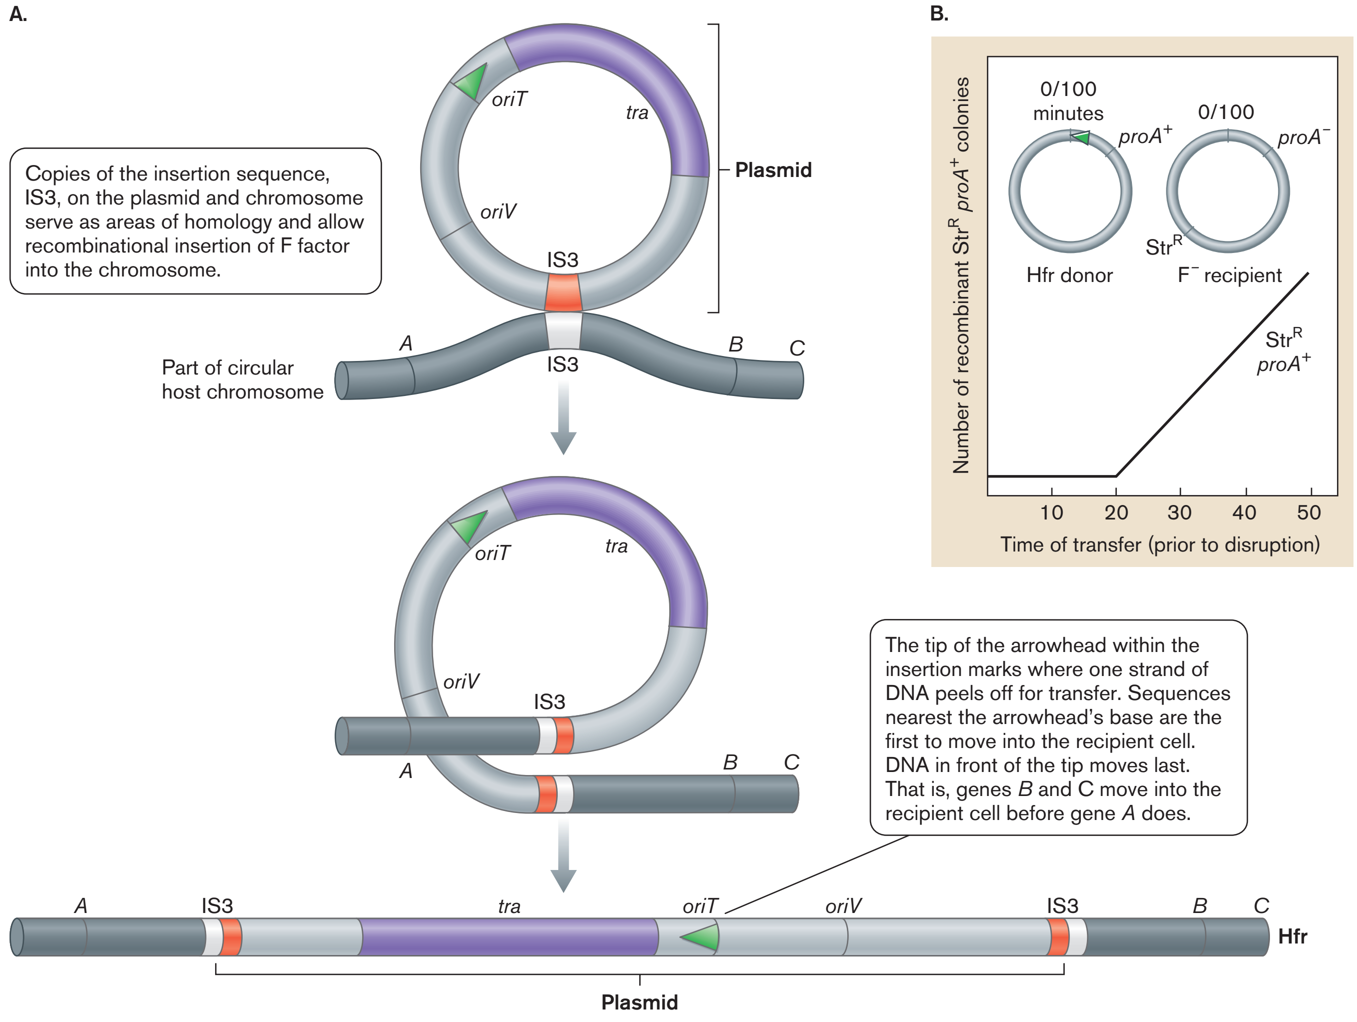
Figure 9.3 The conjugation process. Some plasmids, such as F factor in *E. coli*, can mediate cell-to-cell transfer of DNA.

occurs unidirectionally by rolling-circle replication (step 5) (see Section 7.4).

The 5′ end of the nicked strand of F factor moves through a pore in the conjugation complex by a process driven by cellular DNA polymerase III, which synthesizes a replacement strand in the donor cell using the intact strand as a template (see blowup in step 5). The intact strand remains in the donor as the transferred strand enters the recipient. The strand entering the recipient is also converted to a double-stranded molecule by DNA synthesis (see Section 7.3). The last portion of F factor moved into the recipient is *oriT*. Once transferred, the F factor circularizes to re-form a plasmid, thereby converting the F^- recipient cell to a new F^+ donor cell (step 6). The conjugation complex spontaneously comes apart, and the membranes seal.

Is it possible for two donors to exchange DNA with each other? The answer is generally no. Donors have mechanisms in place to prevent this. For example, they make a cell surface protein encoded by the F factor that inhibits formation of a conjugation complex with another donor possessing the same protein. This mechanism prevents the pointless transfer of a plasmid to a cell that already has that plasmid.

The F-factor plasmid can integrate into the chromosome. Once inside the recipient cell, F factor can remain an independent plasmid or be integrated into the chromosome of the recipient cell (**Fig. 9.4**). Integration of the plasmid into the genome involves recombination between two circular DNA duplexes, a process explained in Section 9.3. Because the plasmid can exist in extrachromosomal and integrated forms, it is sometimes called an **episome** (from the Greek *epi*, "over," and *some*, "chromosome").



Copies of the insertion sequence, IS3, on the plasmid and chromosome serve as areas of homology and allow recombinational insertion of F factor into the chromosome.

The tip of the arrowhead within the insertion marks where one strand of DNA peels off for transfer. Sequences nearest the arrowhead's base are the first to move into the recipient cell. DNA in front of the tip moves last. That is, genes *B* and *C* move into the recipient cell before gene *A* does.

Figure 9.4 Hfr formation and gene mapping. A. The making of an Hfr by F-factor integration. Regions of sequence homology between an F factor and the host chromosome are recognized by host cell recombination proteins that then integrate F factor into the host chromosome. The transfer genes (*tra*), and replication origins are shown (vegetative = *oriV*; transfer = *oriT*). **B.** Conjugational mapping of genes. The figure shows Hfr donor and recipient chromosomes. Recipient requires proline added to media in order to form colonies. The graph illustrates that it takes 20 minutes of conjugation to start seeing $ProA^+$ recombinants.

When the chromosome has integrated an F factor, the cell is designated an **Hfr**, or high-frequency recombination, strain. The term *high frequency* refers to the fact that there are more cells capable of transferring *chromosomal* DNA in an Hfr population than in an F^+ culture where very few Hfr cells are present. It does not refer to the speed with which individual DNA molecules are transferred. Because the F factor is inserted into the chromosome, an Hfr cell is capable of transferring all or part of the chromosome into a recipient cell. Essentially, the entire chromosome becomes the F factor. However, the integrated F factor is actually the last bit of DNA transferred during Hfr conjugation. Because it takes nearly 100 minutes to transfer the entire *E. coli* chromosome (as opposed to only 5 minutes for the free F plasmid), the integrated F factor is rarely transferred before the conjugation bridge breaks, and the recipient almost never becomes an F^+ or Hfr cell.

Mapping gene position by conjugation. Earlier scientists exploited Hfr integration to begin mapping the locations of genes on the *E. coli* chromosome. Because it takes nearly 100 minutes for an Hfr to transfer the entire *E. coli* chromosome, it was possible to "map" genes based on how long it took to transfer different genes to a recipient. Note that an F factor can integrate at different locations on the chromosome and in different orientations. The resulting Hfr strains will transfer different chromosomal genes early during conjugation. Timing of Hfr gene transfer was used to construct the original gene maps of *E. coli*, which were expressed in minutes. The gene map was divided into 100 equal segments of about 44 kbp each.

The mapping process required mating an *E. coli* Hfr strain with an F^- recipient that contained a mutation in the gene to be mapped. It is important in any genetic cross that the mutation create an observable phenotype. Say, for example, we wanted to map the gene *proA*, which is needed to synthesize the amino acid proline. Cells defective in *proA* will not grow on minimal medium unless proline is added. However, if the mutated *proA* gene is repaired by conjugation and subsequent recombination between the donor and recipient DNA molecules, the recombinant cell will grow and form a colony on agar medium *lacking* proline. It is also important that the F^- recipient be resistant to an antibiotic such as streptomycin.

An Hfr culture that is streptomycin sensitive is mixed with the streptomycin-resistant *proA* mutant culture (**Fig. 9.4B**). Then, at timed intervals, an aliquot (that is, a measured sample) of the mating mixture is removed and the conjugation bridges broken by blending in a blender. This is called interrupted mating. The longer the mating goes before breaking the bridges, the more of the chromosome is transferred from the Hfr into the recipient. At each interval, the disrupted mixture is plated onto a selective agar lacking proline but containing streptomycin. The *only* cell that can grow on this medium is a recombinant in which the *proA*$^+$ gene transferred from the Hfr strain and recombined into the chromosome of the streptomycin-resistant F^- cell. Until the gene transfers, no colonies will form. Because the position of the integrated F factor on the chromosome is fixed, the farther the wild-type gene is from the insertion site, the longer it will take for the gene to move into the mutant. In the example, the *proA*$^+$ gene is located 20 map minutes from the location of the F-insertion.

An integrated F factor can dis-integrate from the chromosome. Another type of gene shuffling can occur when an integrated F factor subsequently excises from the chromosome. Once an F factor has been integrated into a host chromosome, it can also be excised via host recombination mechanisms. Usually, it is excised completely and restored to its original form. Occasionally, however, it is excised along with some DNA from the host chromosome, creating a product that will be an F-factor plasmid that also contains some of the chromosomal DNA. The derivative F plasmid that contains host DNA is called an **F-prime (F′) plasmid** or **F′ factor** (**Fig. 9.5**).

In contrast to chromosomal genes whose transfer is directed by Hfr, genes hitchhiking on an F′ plasmid do not have to recombine into the recipient chromosome to be maintained. The extra genes can be expressed as part of the F′ plasmid. This establishes what is called a **merodiploid** situation in which a conjugal recipient of the F′ factor contains two copies of those few genes—one set on the chromosome, the other on the F′ factor. This is useful to the cell because the second copy of the gene could serve as the raw material needed to evolve a new gene. It is also useful to the geneticist because it allows one to ask whether a mutant allele of a gene is dominant over a normal, or wild-type, allele. Merodiploids can also help geneticists understand gene organization.

There are many different types of plasmids in the microbial world. Most are not transferable by themselves. However, one group of plasmids that cannot transfer themselves can be *mobilized* if a transferable plasmid is also present in the same cell. Mobilizable plasmids usually contain an *oriT*-like DNA replication origin recognized by the conjugation apparatus of the transferable plasmid. As a result, when the transferable plasmid begins conjugating, so does the mobilizable plasmid. This is one way in which antibiotic resistance genes on plasmids called R factors can be spread throughout a microbial population.

THOUGHT QUESTION 9.1 Transfer of an F factor from an F^+ cell to an F^- cell converts the recipient to F^+. Why does transfer of an Hfr not do the same?

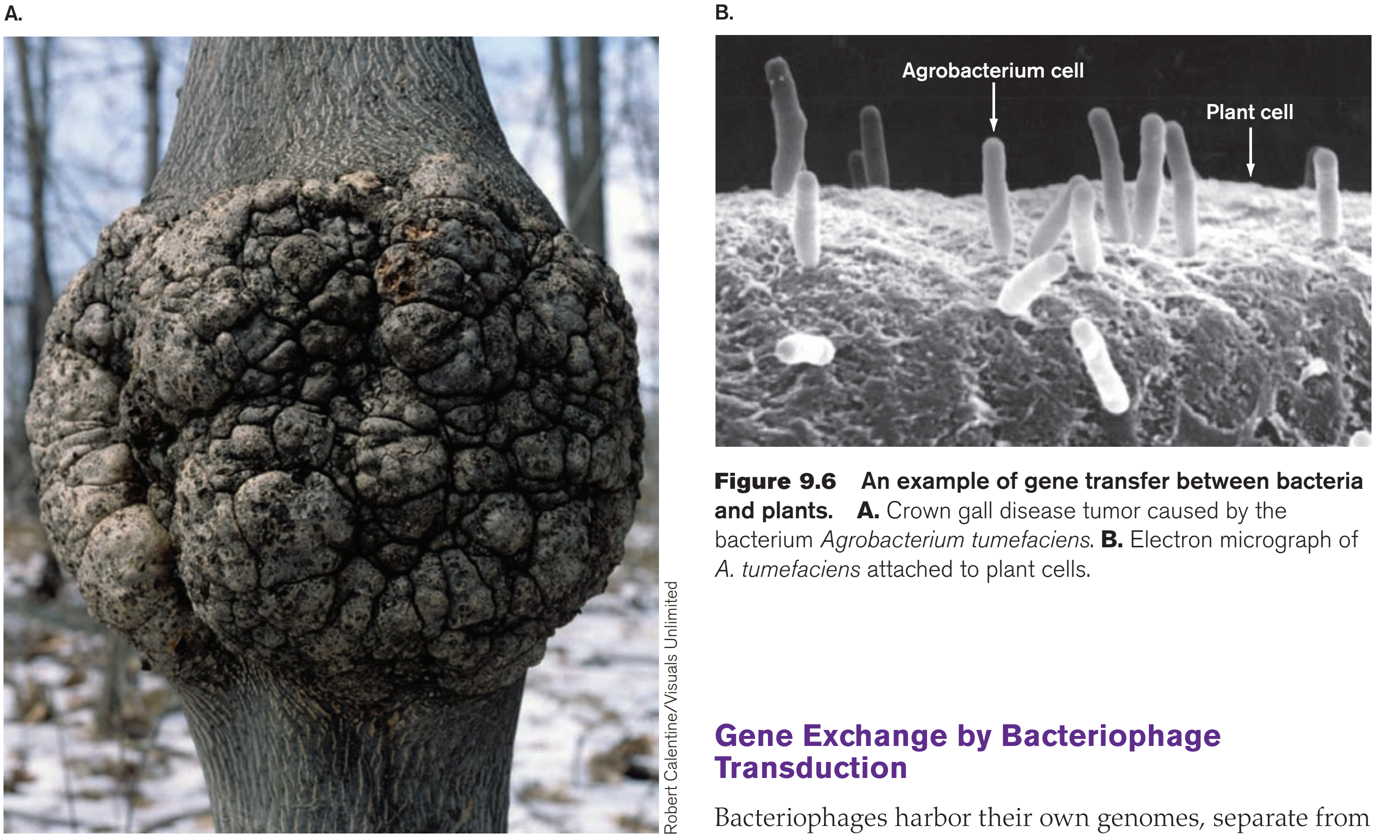
Figure 9.5 Formation of an F′ factor. A rare, illegitimate recombination event in an Hfr cell occurs between sequences within the integrated F factor and sequences in the host chromosome proper. The result is excision (deletion) of the gene from the host chromosome and production of a plasmid containing F factor and host genes. This F′-factor plasmid is capable of transferring to a new cell via conjugation.

Bacterial pheromones can promote conjugation. Conjugation can, in certain species, be promoted by chemical communication between cells. One example is plasmid pAD1 in *Enterococcus faecalis*. This plasmid produces a protein called aggregation substance, which catalyzes cell-cell contact and formation of the conjugation complex. Ordinarily, this gene and others on the plasmid are inactive. Potential recipients, however, try to entice donors to mate with them by producing small behavior-altering molecules called pheromones. The chemical signal molecules released by bacteria are small peptides that enter the donor cell through oligopeptide permeases present in the membrane. Once inside the donor cell, the pheromone stimulates transcription of the *pAD1* transfer genes. Pheromone-responsive conjugation thus far is unique to enterococci. Most known conjugation systems do not use pheromones to stimulate transfer.

Microbial transfer of genes into eukaryotes. In eukaryotes, sexual exchange of genes usually occurs only within a single species. Microbes, on the other hand, are more promiscuous. Mating among different microbial genera is common and perhaps even desirable from an evolutionary viewpoint. For example, *Salmonella* can conduct interspecies mating with *E. coli*. Sharing genes between species allows each one to sample genes from the other and keep genes that increase fitness.

What may be surprising is that some bacteria can actually transfer genes across biological domains. One striking example is *Agrobacterium tumefaciens*, which causes crown gall disease in plants. This gram-negative plant pathogen, common to the rhizosphere (the area around root surfaces), contains a tumor-inducing plasmid (Ti) that can be transferred via conjugation to plant cells. These bacteria detect and swim toward phenolic wound compounds released by damaged plant cells.



Robert Calentine/Visuals Unlimited

Martha Hawes, University of Arizona

Figure 9.6 An example of gene transfer between bacteria and plants. **A.** Crown gall disease tumor caused by the bacterium *Agrobacterium tumefaciens*. **B.** Electron micrograph of *A. tumefaciens* attached to plant cells.

The phenolic compounds signal where the microbe can gain access to plant cells. Subsequent transfer, integration, and expression of the Ti plasmid in the plant cell genome triggers the release of plant hormones that stimulate tumorous growth of the plant (**Fig. 9.6**). Plant cells within the tumor release amino acid derivatives called "opines" that the microbe can then use as a source of carbon and nitrogen.

The unique mode of action of *A. tumefaciens* has made this bacterium an indispensable tool for plant breeding. Any desired genes, such as insecticidal toxin genes (like those produced by *Bacillus thuringiensis*) or herbicide resistance genes, can be engineered into the bacterial plasmid DNA and thereby inserted into the plant genome (discussed in Chapter 16). The use of *Agrobacterium* not only shortens the conventional plant-breeding process, but also allows entirely new (nonplant) genes to be engineered into crops.

NOTE: Conjugation in bacteria and archaea is mechanistically different from conjugation among eukaryotic microbes. Some eukaryotic microbes exchange nuclei through a structure very different from that of bacteria, though also called a conjugation bridge (discussed in Chapter 20).

Gene Exchange by Bacteriophage Transduction

Bacteriophages harbor their own genomes, separate from that of their host cells. However, bacteriophages also can *accidentally* move bacterial genes between cells as an offshoot of the phage life cycle (see Sections 6.4 and 7.4). The process in which bacteriophages carry payloads of host DNA from one cell to another is known as **transduction**. There are two basic types of transduction: generalized and specialized. **Generalized transduction** can take any gene from a donor cell and transfer it to a recipient cell. In contrast, **specialized transduction** (also known as restricted transduction) can only transfer a few closely linked genes between cells.

Bacteriophages capable of generalized transduction have trouble distinguishing their own DNA from that of the host when attempting to package DNA into their capsids, so pieces of bacterial host DNA accidentally become packaged in the phage capsid. In the case of *Salmonella* P22 phage, the packaging system recognizes a certain DNA sequence on P22 DNA called a *pac* site. During rolling-circle replication, P22 DNA forms long concatemers containing many P22 genomes arranged in tandem. The *pac* site defines the ends of the phage genome, marking where the packaging system cuts the P22 DNA and starts packaging DNA into the next empty phage head. However, certain DNA sequences on the *Salmonella* chromosome also "look" like *pac* sites. As a result, the packaging system sometimes mistakenly packages host DNA instead of phage DNA.

The result of this mistake is that 1% of the phage particles in any population of P22 do not contain phage

2. DNA is packaged into capsid heads. Some capsids package host DNA.
3. New phage assembly is completed.
4. Cell lyses, phage is released.
5. Transducing phage particle injects host DNA into new cell, where it may recombine into the chromosome.
Recombination crossover events exchange host for donor DNA.

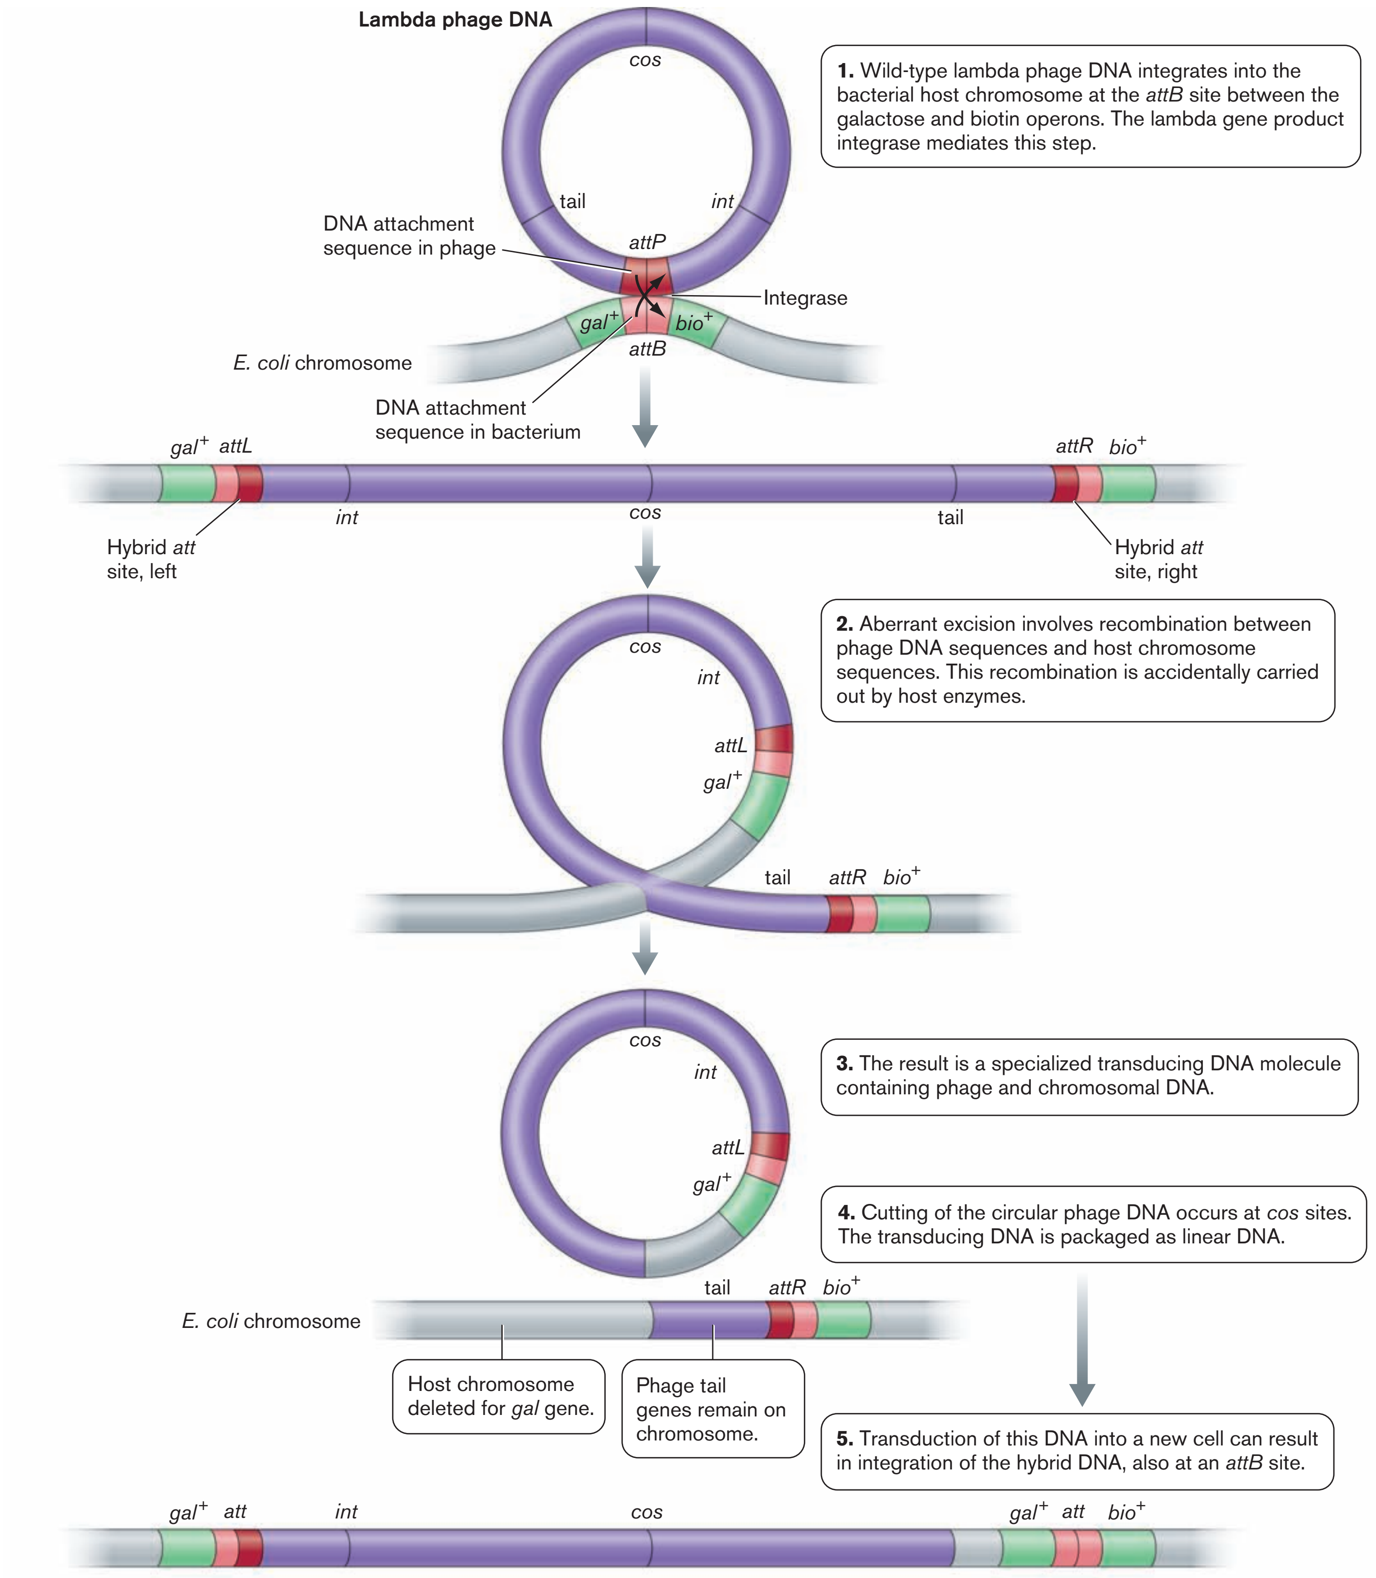
Figure 9.7 **Generalized transduction.** Generalized transduction involves the movement of any segment of donor chromosome to a recipient cell by phage vectors. The number of genes transferred in any one phage capsid is limited, however, to what can fit in the phage head.

DNA but carry host DNA plucked from around the chromosome (**Fig. 9.7**). The phages that carry host DNA are called **transducing particles**. Any one transducing particle will only contain one segment of host DNA, but different particles in the phage population will contain different segments of host DNA. When a transducing particle injects its DNA into a cell, no new phages are made, but the highjacked host DNA can recombine, or exchange, with sequences in the host chromosome of the newly infected cell, changing the genetic makeup of the recipient.

THOUGHT QUESTION 9.2 Would it be easier to demonstrate generalized transduction using a temperate phage (which generates a lysogen) or a lytic (virulent) phage?

Specialized or restricted transduction is a phage-mediated gene transfer mechanism that resembles the formation of the F′ factors previously described. In contrast to generalized transduction, specialized transduction can only move a limited number of host genes. *E. coli* phage lambda is the classic example of specialized transduction. To understand this gene exchange process, however, you must first understand the basic biology of this phage (discussed in Chapter 6). When lambda phage DNA first enters the cell, it is linear. It circularizes at cohesive ends called *cos* sites. Then a small DNA sequence in lambda called *attP* can specifically recombine with a small host DNA sequence (called *attB*) located between the *gal* (galactose catabolism) and *bio* (biotin synthesis) genes on the *E. coli* chromosome (**Fig. 9.8**, step 1). This process, carried out by the phage integrase protein, produces a chromosome with an integrated phage genome, referred to as a prophage, flanked by chimeric *att* sites called *attL* and *attR*. They are called chimeric because each one is made half from the bacterial and half from the phage *att* sites. Prophage DNA remains latent until something happens to the cell to activate it.

The process of specialized transduction begins with this prophage DNA. The majority of the time, when the prophage is reactivated, recombination mechanisms involving phage proteins can excise the lambda DNA precisely, so that the chromosome and viral DNAs are restored to their native states. The viral DNA will then replicate and make more phage particles containing normal phage DNA. However, on rare occasions, improper excision can take place between host DNA sequences that lay adjacent to the phage insertion site (*attB* in **Fig. 9.8**, step 2) and similar DNA sequences within the prophage. Improper, or aberrant, excision between virus and host sequences yields a virus that will lack a few viral genes (tail genes in step 3) but will include host genes lying adjacent to the phage attachment site (the galactose utilization gene *gal* in **Fig.**



1. Wild-type lambda phage DNA integrates into the bacterial host chromosome at the *attB* site between the galactose and biotin operons. The lambda gene product integrase mediates this step.

2. Aberrant excision involves recombination between phage DNA sequences and host chromosome sequences. This recombination is accidentally carried out by host enzymes.

3. The result is a specialized transducing DNA molecule containing phage and chromosomal DNA.

4. Cutting of the circular phage DNA occurs at *cos* sites. The transducing DNA is packaged as linear DNA.

5. Transduction of this DNA into a new cell can result in integration of the hybrid DNA, also at an *attB* site.

9.8, step 3). Aberrant excision is accidentally carried out by host recombination enzymes. With some phages, the specialized transducing particles can replicate unaided. However, in **Figure 9.8** the result is a defective, specialized transducing phage DNA (lambda d*gal*, or λd*gal*). Specialized transducing phage particles that are defective cannot replicate by themselves but require the presence of a helper phage to supply missing gene products.

Once formed, specialized transducing phages can deliver the hybrid DNA molecule to a new recipient cell. This is the transduction process. Once in that cell, the phage DNA can integrate into the host *attB* site, carrying the donor host gene(s) with it (steps 4 and 5). This will establish another merodiploid situation where the new recipient contains two copies of a host gene, one originally present on its chromosome and one brought in by the transducing DNA.

Genes other than *gal* or *bio* can also be moved by specialized transduction if lambda is used to infect mutant host strains lacking the normal *att* site. Because the primary integration site is gone, lambda DNA can integrate at low frequency to other, secondary attachment sites somewhere else in the chromosome. Improper excision at one of those locations will package adjacent host DNA.

DNA Restriction and Modification Systems Prevent Promiscuous DNA Transfer

There are dangers to the cell associated with the indiscriminate transfer of DNA between bacteria. The most obvious risk involves bacteriophages whose goal is to replicate at the expense of target cells. A bacterium that can digest invading phage DNA while protecting its own chromosome would have a far better chance of surviving in nature than cells unable to make this distinction. However, beyond the threat of overt destruction by phages, the unrestricted incorporation of foreign DNA can be an energetic drain on the cell. Genes encoding competing or useless products or products that lack regulatory restraints would squander resources and lower the overall fitness of the cell. As a result, bacteria have developed a kind of "safe-sex" approach to gene exchange. It is an imperfect approach, however, that still leaves room for beneficial genetic exchanges.

This protection system, called restriction and modification, involves the enzymatic cleavage (restriction) of alien DNA and the protective methylation (modification) of self DNA (**Fig. 9.9**). Most bacteria produce DNA **restriction endonucleases** (also known as restriction enzymes), enzymes that recognize specific short DNA sequences (known as recognition sites) and cleave DNA at or near those sequences (**Fig. 9.10**). A structural model of the restriction enzyme *Eco*RI cleaving its target DNA sequence is shown in **Figure 9.11**.

Because the producing organism's own chromosomes contain these same restriction sequences, how do bacteria avoid committing suicide? They protect themselves by producing matching modification enzymes that use S-adenosyl methionine to attach methyl groups to those same sequences. A three-dimensional model of a methylation enzyme interacting with a DNA recognition site is shown in **Fig. 9.12**. This modification makes the sequence invisible to the cognate (matched) restriction enzyme. Only one strand of the sequence needs to be methylated to protect the duplex from cleavage; thus, even newly replicated, and consequently hemimethylated (only one strand methylated), DNA sequences are invisible to the restriction enzyme.

There are three main types of restriction endonucleases based on how many subunits there are in the enzyme, what cofactors are required, and where the DNA cleavage sites are located relative to the recognition site (**Table 9.1**). Types I and III restriction enzymes have their restriction and modification activities in one multifunctional protein and cleave DNA some distance away from the recognition site. Type II restriction enzymes, those used most often for cloning, only possess endonuclease activity. A separate modification protein carries out methylation of the restriction site. Type II restriction enzymes generally recognize palandromic

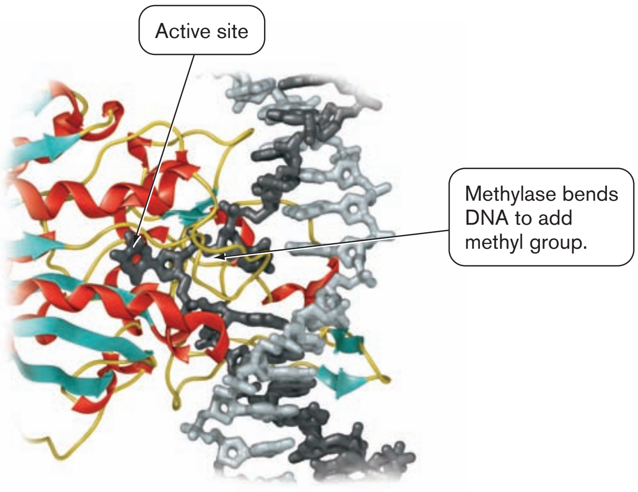

Figure 9.12 DNA methylase used for DNA modification. The DNA methylase adds a methyl group to a restriction site, changing the site's conformation so that it is no longer recognized by the restriction enzyme. The methylase bends the DNA helix to bring the target base into the active site (left side). (PDB code: 1DCT)

Table 9.1 Main types of restriction-modification systems.

Characteristics	Type I	Type II	Type III
Restriction and modification activities	Present in one multifunctional enzyme	Separate methylase and restriction enzymes	Present in one multifunctional enzyme
Subunits	Three different subunits	One or two identical subunits per activity	Two different subunits
Recognition site	5–7 bp asymmetrical	4–6 bp, palindromic	5–7 bp asymmetrical
Cleavage and modification sites	Random, 100 bp or more from recognition site	At or near recognition site	24–26 bp from recognition site
Examples	*Eco*K in *E. coli*; *Sty*LTIII in *Salmonella enterica*	*Eco*RI in *E. coli*; *Hin*dIII in *Haemophilus influenzae*	*Eco*571 in *E. coli*; *Bce*SI in *Bacillus cereus*

DNA sequences and cleave at those sites. **Figure 9.11** illustrates how the class II restriction enzyme *Eco*RI holds the DNA as it creates a staggered cut at the cleavage (restriction) site.

THOUGHT QUESTION 9.3 How do you think phage DNA containing restriction sites evade the restriction-modification screening system of its host?

THOUGHT QUESTION 9.4 Type I restriction-modification system genes are often designated *hsdR*, *hsdM*, and *hsdS*, which code, respectively, for the restriction (HsdR), modification (HsdM), and sequence recognition (HsdS) proteins. Can a plasmid grown in a wild-type strain be used to transform a strain defective in *hsdR*? An *hsdS* mutant? Can a plasmid grown in an *hsdM* mutant strain be transformed into an *hsdR* defective strain?

TO SUMMARIZE:

- **Transformation** is the uptake by living cells of free-floating DNA from dead, lysed cells.
- **Competence** for transformation in some organisms involves a genetically programmed physiological change.
- **Conjugation** is a DNA transfer process mediated by a transferable plasmid that requires cell-cell contact and formation of a protein complex between mating cells.
- **Pheromone peptides** secreted by gram-positive cocci such as *Enterococcus faecalis* activate transfer genes in nearby donor cells.
- **Some bacteria can transfer DNA across phylogenetic domains.** For example, *Agrobacterium tumefaciens* conjugates with plant cells.
- **Transduction** is the process whereby bacteriophages transfer fragments of bacterial DNA from one bacterium to another. Generalized transduction is when a phage preparation can move any gene in a bacterial genome to another bacterium. Specialized transduction is when a phage can only move a limited number of bacterial genes.
- **Restriction endonucleases** protect bacteria from invasion by foreign DNA. Restriction-modification enzymes methylate restriction target sites in the host DNA to prevent self-digestion.

9.3 Recombination

Once a new piece of DNA has entered a cell through one of the gene exchange systems, what happens to it? The answer to that question depends on the nature of the acquired DNA. If the DNA is a plasmid, capable of autonomous replication, it can coexist in the cell separate from the host chromosome. If the DNA is not capable of autonomous replication, it is usually degraded by nucleases. Alternatively, it may be incorporated into the chromosome through recombination.

Two different DNA molecules in a cell can recombine by one of several mechanisms. **Generalized recombination** requires that the two recombining molecules have a considerable stretch of homologous DNA sequence. In contrast to generalized recombination, **site-specific recombination** occurs via a mechanism that requires very little sequence homology between the recombining DNA molecules, but does require a short (10–20 bp) sequence recognized by the recombination enzyme.

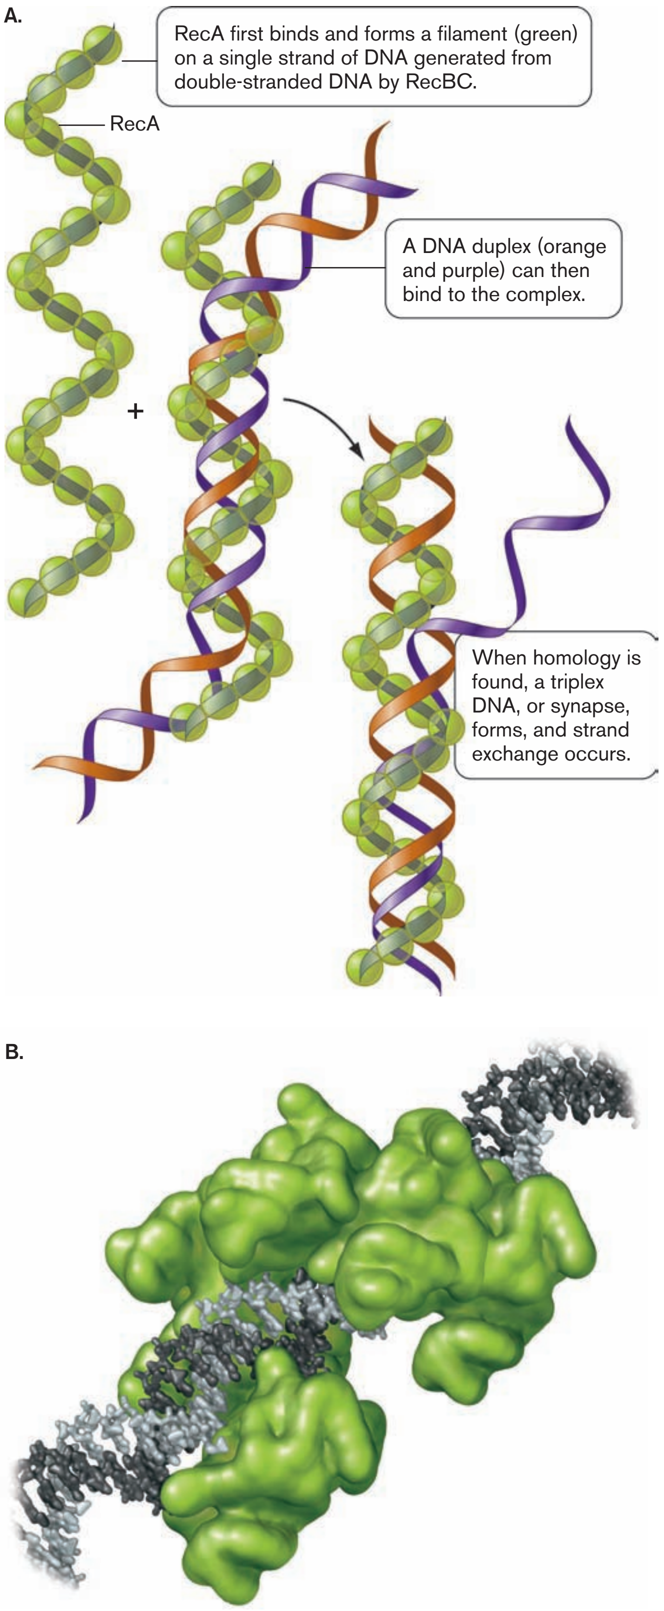
Generalized Recombination Requires RecA

Enzymes participating in generalized recombination are able to find and align homologous stretches of DNA in two different DNA molecules and catalyze an exchange of strands. The result can be a **cointegrate** molecule where a single recombination event (that is, a single crossover) joins the two participating DNA molecules. For example, when two circular DNA molecules are joined by a single recombination event, the two molecules are added together and form one large circular molecule (for example, **Fig. 9.4**; also see preceding discussion of F factor or lambda phage). A second crossover separated by some distance from the first, however, will lead to an equal exchange of DNA in which neither molecule increases in length.

Why is recombination advantageous? There are three probable functions for generalized recombination in the microbial cell:

- Recombination probably first evolved as an internal method of DNA repair, useful to fix mutations or restart stalled replication forks. This role does not involve foreign DNA.
- Cells with damaged chromosomes use DNA donated by others of the same species to repair their damaged genes.
- Recombination is also part of a “self-improvement” program that samples genes from other organisms for an ability to enhance the competitive fitness of the cell.

The central, but by no means only, player in generalized recombination is a protein called RecA. RecA molecules are also called synaptases because they are able to scan DNA molecules for homology and align the homologous regions, forming a triplex DNA molecule, or synapse (**Fig. 9.13**). Homologs of RecA are found in many other species.



A.
RecA first binds and forms a filament (green) on a single strand of DNA generated from double-stranded DNA by RecBC.
RecA
A DNA duplex (orange and purple) can then bind to the complex.
+
When homology is found, a triplex DNA, or synapse, forms, and strand exchange occurs.
B.

Figure 9.13 **RecA protein catalyzing recombination.** **A.** The standard mechanism of recombination. **B.** A molecular model of RecA protein filament catalyzing recombination. The DNA is light gray and dark gray. (PDB codes: 1N03, 1K8J)

The clearest model of RecA-mediated recombination comes from *E. coli* (**Figs. 9.13** and **9.14**). Before RecA can find homology between two DNA molecules, the donor double-stranded DNA molecule must be converted to a single strand. *E. coli* has two enzyme systems that can prepare the single-stranded template: the RecBCD and RecJ systems. The RecBCD complex, for example, enters at the end of a DNA fragment and begins to unwind it (**Fig. 9.14**, steps 1 and 2). The complex changes activity when it encounters 8-bp sequences called **Chi** that are scattered throughout most DNA molecules. RecBCD nicks DNA at a Chi site and continues unwinding the strand. RecA then loads onto the single strand as a filament (step 2).

RecA filaments coat a stretch of single-strand DNA, then RecA scans double-stranded DNA, looking for stretches of homology. When it finds homology (minimum required is about 50 bp), RecA catalyzes strand invasion and **D-loop formation** (**Fig. 9.14**, step 3). In strand invasion, the donor single-strand DNA invades the homologous region in the double-strand DNA recipient molecule and displaces its like strand. A drawing of the resulting triplex molecule resembles the letter "D" (a "D-loop," shown in **Fig. 9.14**, step 3). At this point, a single-strand crossover has been made. The single-strand crossover creates a molecule with four duplex ends.

Other recombination proteins, RuvA and B, assemble at the crossover point and pull donor and recipient DNA strands in opposite directions, extending the invasion, in a process called strand assimilation (**Fig. 9.14**, step 4, and **Fig. 9.15**) or branch migration. This process extends the base pairing between homologous donor and recipient strands.

Ultimately, the end of the displaced strand at the D loop is cleaved, possibly by RecBCD (**Fig. 9.14**, step 5), and ligated to the donor strand (step 6). When spread out on an electron microscope grid, such a structure resembles a cross (step 7 and also seen in **Fig. 9.15**) that is known as a **Holliday junction**, after the scientist (Robin Holliday) who first proposed it. The final step is resolution of the crossover Holliday junction. RuvC protein cleaves across the junction in one of two directions. To visualize this, we mentally rotate the right half of the Holliday structure as shown in **Figure 9.14**, step 7. RuvC can then cleave the junction in the horizontal or vertical direction across the two strands and then religate them as shown in step 8 to give the alternative products shown. The product on the right has exchanged only a small segment of DNA, while the other product represents a true crossover.

The results of the crossover are shown in step 9. If donor and recipient DNA both started as circular molecules in step 1, the product would form a cointegrate circle (shown to the left). If, however, we are viewing the end result of transduction, where the recipient is a

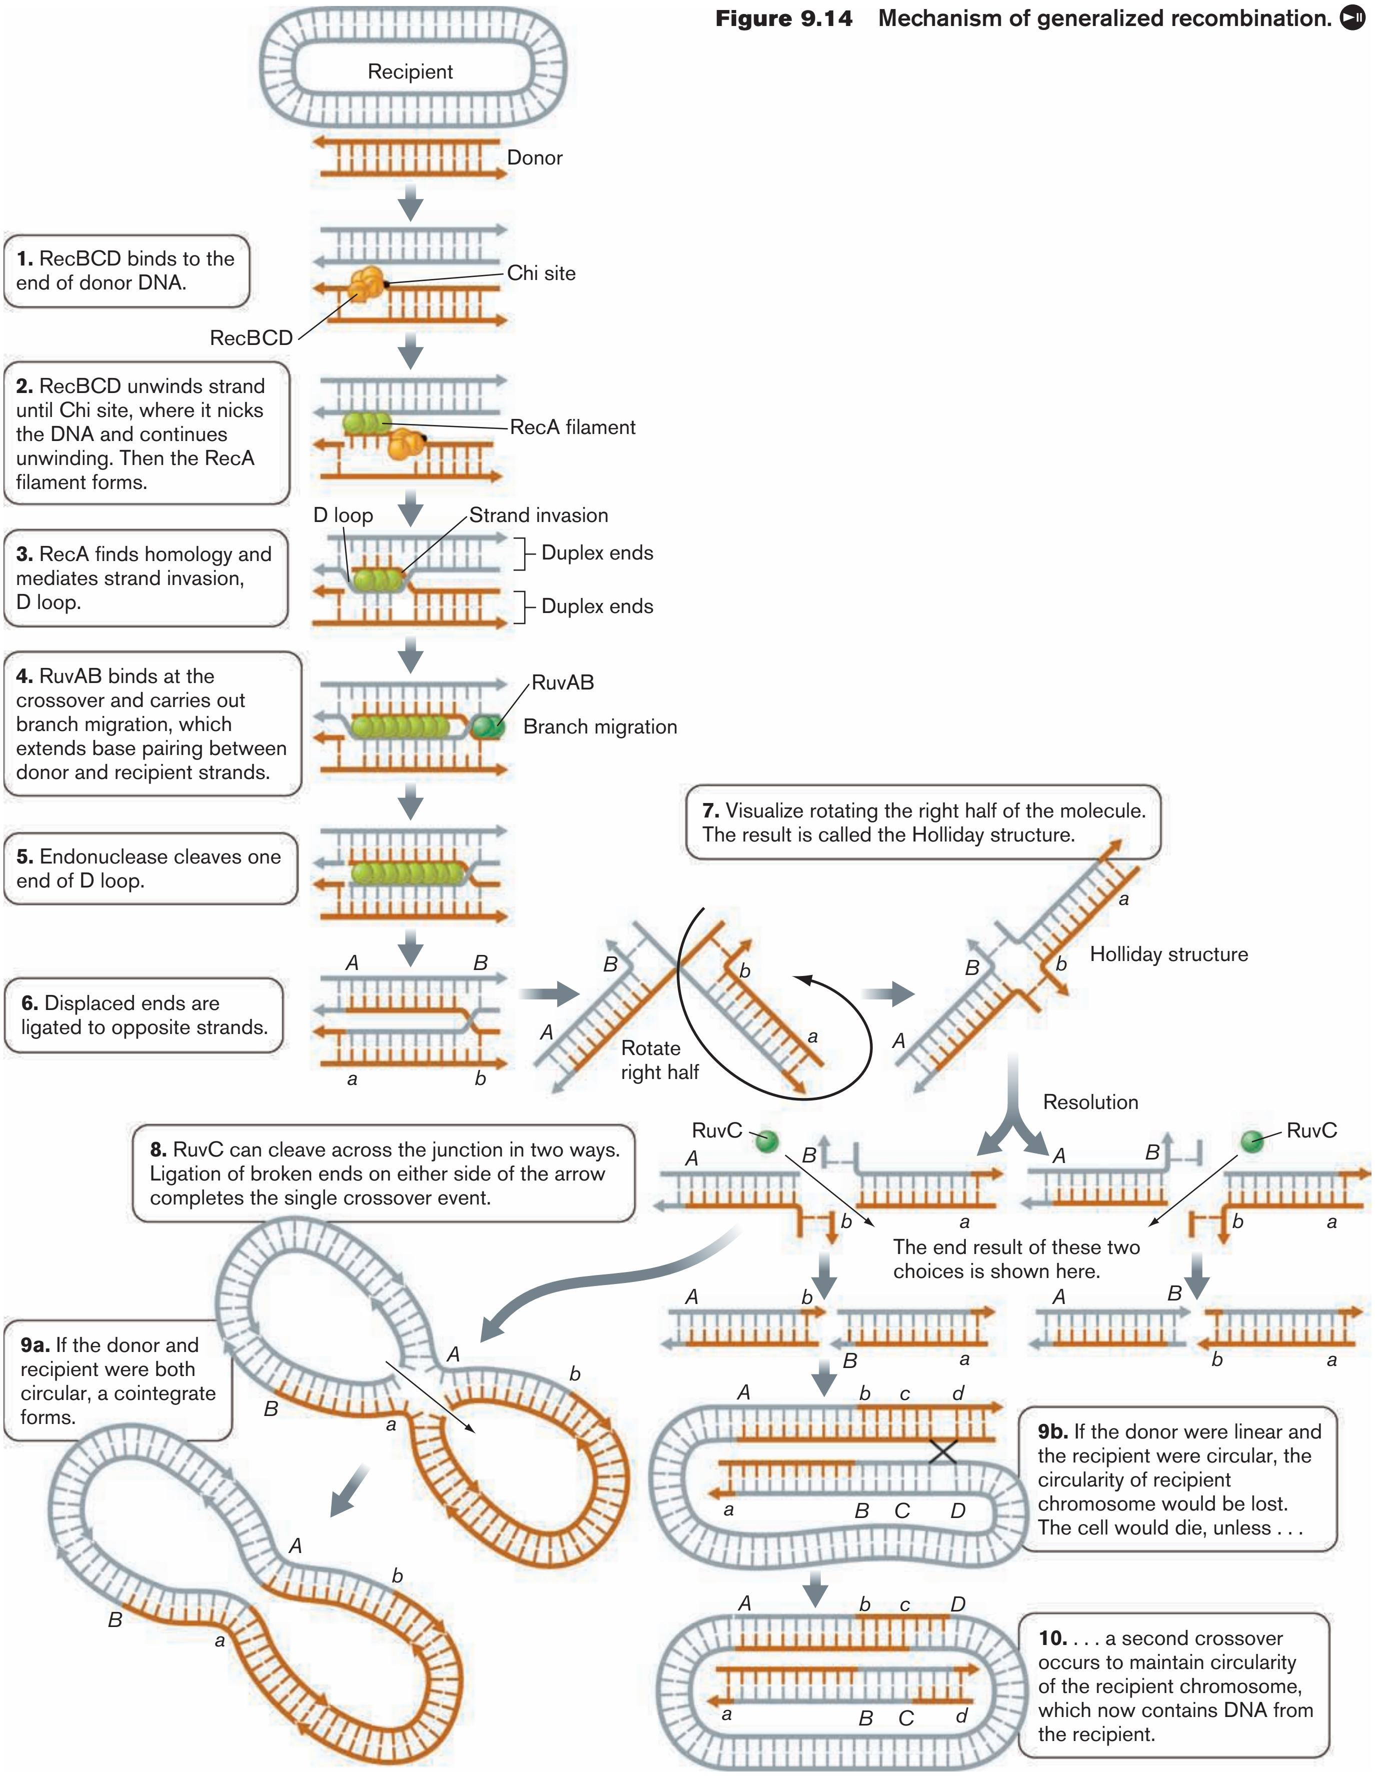


Figure 9.14 **Mechanism of generalized recombination.**

1. RecBCD binds to the end of donor DNA.

2. RecBCD unwinds strand until Chi site, where it nicks the DNA and continues unwinding. Then the RecA filament forms.

3. RecA finds homology and mediates strand invasion, D loop.

4. RuvAB binds at the crossover and carries out branch migration, which extends base pairing between donor and recipient strands.

5. Endonuclease cleaves one end of D loop.

6. Displaced ends are ligated to opposite strands.

7. Visualize rotating the right half of the molecule. The result is called the Holliday structure.

8. RuvC can cleave across the junction in two ways. Ligation of broken ends on either side of the arrow completes the single crossover event.

The end result of these two choices is shown here.

9a. If the donor and recipient were both circular, a cointegrate forms.

9b. If the donor were linear and the recipient were circular, the circularity of recipient chromosome would be lost. The cell would die, unless . . .

10. . . . a second crossover occurs to maintain circularity of the recipient chromosome, which now contains DNA from the recipient.

Vertical DNA molecules represent the two different parental helices (donor, recipient). The top vertical donor helix strands are marked as light orange/dark orange, and the bottom recipient helix is marked light gray/gray. Arrows mark movement of the helices. This movement elongates the region of base pairing between donor and recipient strands (horizontal). Bottom illustrations reveal alternative ways that RuvC can resolve this junction. (PDB codes: 1IN4, 1BDX, 3CRX)

circular chromosome and the donor is a double-stranded linear fragment, the recombinant molecule would appear exactly as the right-hand structure shown in **Figure 9.14**, step 9. As you can see, the bacterial chromosome would lose its integrity, no longer forming a circle. To restore circular integrity to the chromosome, a second crossover event would have to occur downstream of the first (bottom of **Fig. 9.14**, step 10). Note that any genes residing between the first and second crossovers are simultaneously exchanged.

One consequence of this type of double recombination is that multiple genes clustered next to each other on a chromosome can be recombined as a group into a recipient's genome. In the case of transduction, a piece of DNA from the donor bacterium replaces a segment of DNA in the recipient host. One gene in the segment is said to be **cotransduced** with another. The closer the two genes are physically on the chromosome, the higher the probability they will be cotransduced. This is because the closer two genes are to each other, the less likely a crossover will occur in between them.

THOUGHT QUESTION 9.5 In a transductional cross between an $A^+B^+C^+$ genotype donor and an $A^-B^-C^-$ genotype recipient, 100 A^+ recombinants were selected. Of those 100, 15% were also B^+, while 75% were C^+. Is gene B or C closer to gene A?

The benefit of recombination to bacteria can be demonstrated using a culture of *E. coli* that contains a defective *lacZ* gene. The *lacZ*$^+$ gene product (β-galactosidase) is normally used to catabolize the carbohydrate lactose. If lactose is the only carbohydrate available, the *lacZ* mutant cell culture fails to grow. However, if a transducing phage lysate grown on a *lacZ*$^+$ strain is added to the *lacZ* mutant cells, phage particles containing the functional *lacZ*$^+$ can inject the gene into the mutant (transduction), where recombination systems can exchange it for the defective gene. (Note that the defect may only be a single base change, so there is plenty of homology left for RecA to recognize.) The new recombinant cell has now been converted to *lacZ*$^+$ and can grow on lactose.

When trying to understand recombination (and gene exchange overall), it is important to remember that the processes are generally random. The lucky bacterium that gets the right piece of DNA and recombines the right segment of that DNA will benefit. This is why a genetic experiment usually requires screening hundreds of millions of cells to find a few recombinants that grow into visible colonies.

Deinococcus Uses RecA to Repair Fragmented Chromosomes

As first noted in Chapter 5, *Deinococcus radiodurans* is a tough microbe. It can endure 3,000 Gy of gamma irradiation and survive. That is 3,000 times the lethal dose for a human. Although *Deinococcus* chromosomal DNA is fragmented by irradiation, the organism can reassemble the pieces of DNA in the correct order to re-form the chromosome, a process that is even more amazing considering that the organism possesses two *different* chromosomes.

The *Deinococcus* protein that mediates repair is a homolog of RecA, but the sequence of strand exchange is the exact inverse of the established RecA pathway (see previous discussion). Most RecA homologs first form filaments on single-stranded DNA, then take up homologous double-stranded DNA. The *Deinococcus* RecA forms a filament on double-stranded DNA and then incorporates a homologous single-stranded molecule. *Deinococcus* RecA does not need ssDNA to bind. Instead, *Deinococcus* RecA is thought to bind the double-stranded fragments of irradiated DNA and splice homologous ends together to reconstruct the chromosome. This assumes that at least two chromosome copies are present per cell so that overlapping fragments are generated during irradiation. Unlike most bacteria, *Deinococcus* keeps several copies of each chromosome, making it more likely that it will find an intact copy of any given stretch of its sequence. It is a remarkable evolutionary adaptation that has allowed this microbe to inhabit and survive extremely stressful environments, such as the extreme dryness of the desert and the upper atmosphere exposed to cosmic radiation.

Site-Specific Recombination Is RecA Independent

In contrast to generalized recombination mechanisms that require RecA protein and can recombine any region of the chromosome, site-specific recombination does not utilize RecA and only moves a limited number of genes. This form of recombination involves very short regions of homology between donor and target DNA molecules. Dedicated enzyme systems specifically recognize those sequences and catalyze a crossover between them to produce a cointegrate molecule. The integration of phage lambda, described in Section 9.2, is one example of site-specific recombination. A short, 15-bp sequence called the *att* site is present on both the lambda phage DNA and on the *E. coli* chromosome. A phage-encoded protein called **integrase** engages the two *att* sites and, through a strand breakage and rejoining mechanism, combines the two molecules into one (see **Fig. 9.8**).

Other examples of site-specific recombination are flagellar **phase variation** in the pathogen *Salmonella enterica* and phase variation in the expression of type I pili in *E. coli*. In phase variation, the sequence of a segment of DNA is inverted (flipped), resulting in on-or-off regulation of adjacent gene expression. Phase variation is frequently employed by pathogens to evade the host immune system by changing expression of cell surface proteins. For *S. enterica,* as the immune system starts to make antibodies against one form of flagellar protein, the organism switches to make a different form not recognized by the antibody. The mechanism involves a "flippable" DNA cassette that sits adjacent to a flagellar gene on the chromosome. In one orientation, the flagellar gene is expressed; in the opposite orientation, it is not. For more on flagellar phase variation, see Section 10.6.

TO SUMMARIZE:

- **Recombination** is the process by which DNA sequences can be exchanged between DNA molecules.
- **General recombination** involves large regions of sequence homology between recombining DNA molecules.
- **RecA synaptase** mediates generalized recombination.
- **The extremely radiation-resistant *Deinococcus radiodurans*** is thought to use RecA protein to patch together homologous ends of fragmented DNA in a way that reconstructs the chromosome after extreme radiation damage.
- **Site-specific recombination** requires little homology between donor and recipient DNA molecules. Site-specific recombination enables phage DNA to integrate into bacterial chromosomes and is a process that can turn on or turn off certain genes, as in flagellar phase variation in *Salmonella*.

9.4 Mutations

Any permanent, heritable alteration in a DNA sequence, whether harmful, beneficial, or neutral, is called a **mutation**. There are two basic requirements to produce a heritable mutation: there must be a change in the base sequence and the cell must fail to repair the change before the next round of replication. Repair mechanisms will be discussed in Section 9.5. Although it is tempting to think all mutations destroy a protein's activity, this is not the case. A given mutation may or may not affect the informational content or phenotype of the organism.

Mutations come in several different physical and structural forms:

- A **point mutation** is a change in a single nucleotide (**Fig. 9.16 A** and **B**). Among point mutations, changing a purine to a different purine or a pyrimidine to a different pyrimidine is called a **transition**, while swapping a purine for a pyrimidine (and vice versa) is a **transversion**.
- **Insertions** and **deletions** involve, respectively, the addition or subtraction of one or more nucleotides (**Figs. 9.16C** and **D**). This makes the sequence either longer or shorter than it was originally.
- An **inversion** occurs when a fragment of DNA is flipped in orientation relative to DNA on either side (**Fig. 9.16E**).

Mutations can also be categorized into several informational classes. Mutations that do not change the amino acid sequence of a translated open reading frame (ORF) are called **silent mutations**. For example, a point mutation changing TTT to TTC in the sense DNA strand (corresponding to a UUU-to-UUC codon change in mRNA) still codes for a phenylalanine. (Remember, RNA polymerase reads from the DNA template strand to make RNA, whereas the complementary, or sense, DNA strand has the same sequence as the mRNA.) Thus, even though the DNA sequence has changed, the protein sequence remains the same. This is also called a synonymous substitution. However, if the UUU codon were changed to a UUA (a U-to-A transversion), the protein would have a leucine where a phenylalanine had been (see **Fig. 9.16A**). This type of mutation is a **missense mutation** because the amino acid sequence of the protein has changed.

The amino acid substitution resulting from a missense mutation may or may not alter protein function. The outcome depends on the structural importance of the original amino acid and how close in structure the replacement amino acid is to the original. Missense mutations result in either conservative amino acid replacements, where the new amino acid is structurally similar to the original (for example, leucine is substituted for isoleucine), or nonconservative replacements, in which a very different amino acid is substituted (for example, tyrosine for alanine). A missense change may decrease or eliminate the activity of the protein (a **loss-of-function mutation**), or it may make the protein more active. It could even gain a new activity such as an expanded substrate specificity or a completely different substrate specificity (these are called **gain-of-function mutations**).

A **nonsense mutation** is a point mutation that changes an amino acid codon into a translation termination codon—for example, UCA (serine) to UAA. The result will be a truncated protein most likely lacking any function. A mutation that eliminates function is known as

Figure 9.16 Changes in a DNA sequence that result in different classes of mutations. A. Missense mutation. The T to A transversion is a point mutation that converts the phenylalanine codon TTT to the leucine codon TTA. **B.** Nonsense point mutation. The C to G transversion converts the TCA codon, encoding serine, to the TGA stop codon. **C.** Insertion frameshift. The addition of AT into the middle of the TCC serine codon creates a shift in the reading frame that changes all the downstream amino acids. **D.** Deletion frameshift. Removing two nucleotides from the arginine codon also causes a frameshift. **E.** Inversion. Rotating a DNA sequence 180° relative to adjacent sequences.

a **knockout mutation** (see **Fig. 9.16B**). Knockout mutations can include multiple-base insertions and deletions as well as nonsense mutations.

Insertions and deletions can alter the reading frame of the DNA sequence (see **Figs. 9.16C** and **D**). Remarkable as it is, the ribosome simply reads RNA sequences one codon at a time, stringing amino acids together in the process. It translates each codon "word" but cannot understand the overall protein "sentence." It does not recognize when bases have been added or removed through mutation; instead, it keeps on reading the sequence in triplets. If the number of bases inserted or deleted is not a multiple of three, the ribosome will read the wrong triplets. The result is a **frameshift mutation**, which produces a garbled protein "sentence." This often results in the ribosome encountering a premature stop codon, originally in a different reading frame. If the insertion or deletion involves multiples of three bases, the reading frame is not changed but one or more amino acids are added or removed.

An inversion mutation involves the flipping of a DNA sequence (**Fig. 9.16E**). Imagine the highlighted sequence rotating 180° while the adjacent sequences in black remain stationary. The rotation would allow retention of 5′-to-3′ polarity in the new molecule, but if the inversion occurred within a gene, it would likely change the codons in the area and alter the resulting protein. What is shown in the figure is a small inversion; however, inversions often involve large tracts of DNA encompassing several genes. If an entire gene with its promoter inverts, the gene will likely remain functional, and its encoded protein may very well still be made. Inversions occur within a genome as a result of recombination events between similar DNA sequences or as a consequence of mobile genetic elements jumping between different areas of a genome.

Mutations can affect both the genotype and the phenotype of an organism. The genotype of an organism reflects its genetic makeup. Regardless of whether a mutation causes a change in a biochemical trait, every mutation causes a change in the genotype, that is, the makeup of the genome. In contrast to genotype, phenotype only comprises observable characteristics, such as biochemical, morphological, or growth traits. For instance, consider the arginine biosynthesis gene *argA*. The product of this gene allows an organism to make enough arginine to support growth in media devoid of arginine. Any mutation in *argA* is a genotypic change, but if the result is a synonomous amino acid substitution, there is no phenotypic change—the organism can still make its own arginine. However, if the mutation destroys the activity of the *argA* product, the microbe can no longer make arginine, and the amino acid must be supplied in the medium. This is a phenotypic change.

It is also important to realize that small mutations, such as a single base substitution, can have large effects on phenotype. Conversely, large mutations—for instance, the insertion of a 5-kb transposon between two genes—may have little or no effect. To illustrate, consider that a single point mutation in the *hpr* gene of the phosphotransferase sugar transport system (discussed in Section 4.2) will render a bacterium incapable of growing on many sugars. However, inserting 5 kb of DNA just past the *hpr* stop codon will have no effect on cell growth. For mutations, it's often not the size that counts, it's the location.

Mutations Arise by Diverse Mechanisms

Although DNA is quite stable, especially compared to mRNA which is rapidly degraded, it is susceptible to damage inflicted by a variety of physical and chemical

Table 9.2 Mutagenic agents and their effects.

Mutagenic agent	Effects
Chemical agent	
Base analog *Examples*: caffeine, 5-bromouracil	Substitutes "look-alike" molecule for the normal nitrogenous base during DNA replication: point mutation
Alkylating agent *Example*: nitrosoguanidine	Adds an alkyl group, such as methyl group ($-CH_3$), to nitrogenous base, resulting in incorrect pairing: point mutation
Deaminating agent *Examples*: nitrous acid, nitrates, nitrites	Removes an amino group ($-NH_2$) from a nitrogenous base: point mutation
Acridine derivative *Examples*: acridine dyes, quinacrine	Inserts (intercalates) into DNA ladder between backbones to form a new rung, distorting the helix: can cause frameshift mutations
Electromagnetic radiation	
Ultraviolet rays	Link adjacent pyrimidines to each other, as in thymine dimer formation, and thereby impairs replication; lethal if not repaired
X-rays and gamma rays	Ionize and break molecules in cells to form free radicals, which in turn break DNA; lethal if not repaired

Figure 9.17 Rare tautomeric forms of bases have altered base-pairing properties. Cytosine, which normally base pairs with guanine, will, in its imino form, pair with adenine. The imino form of adenine will also base-pair with cytosine, rather than its normal complementary base thymine. Likewise, the enol form of thymine base-pairs with guanine, while the enol form of guanine binds thymine. These tautomeric transitions can lead to permanent mutations.

agents. For example, irradiation by X-rays can cause a massive number of DNA strand breaks. When this happens, the integrity of the chromosome is lost and the cell dies. Other agents can directly modify the bases in DNA while leaving its overall structure intact. In this case, the modified bases have altered hydrogen bond base-pairing properties that result in the incorporation of an inappropriate base during replication. When that happens, a mutation occurs.

Mutations can be caused by **mutagens**, chemical agents that can damage DNA (**Table 9.2**). Even in the absence of a mutagen, mutations arise spontaneously. Because DNA proofreading and repair pathways are so efficient, spontaneous mutations are rare, having a frequency of occurrence ranging from 10^{-6} to 10^{-8} per generation.

Spontaneous mutations in a genome arise for many reasons—for example, due to tautomeric shifts in the chemical structure of the bases as shown in **Figure 9.17**. Tautomeric shifts involve a change in the bonding properties of amino ($-NH_2$) and keto ($=O$) groups. Normally, the amino and keto forms predominate (over 85%), but when an amino group, for example, shifts to an imino ($=NH$) group, base pairing changes. A cystosine, which normally base-pairs with guanine, will, in its rare imino form, base-pair with adenine. Tautomeric shifts that occur during DNA replication will increase the number of mutational events. Even though the replication apparatus is very accurate with various proofreading and repair functions, such as the 3′-to-5′ exonuclease activity of DNA polymerase III (see DnaQ in Section 7.3), mistakes do occur at a very low rate.

Besides misincorporation mistakes, naturally occurring intracellular chemical reactions with water can damage DNA. These endogenous reactions are an important source of spontaneous mutations. For example, cytosine deaminates spontaneously to yield uracil (**Fig. 9.18**). This results in a GC to AT transition. In addition, purines are particularly susceptible to spontaneous loss from DNA by breakage of the glycosidic bond connecting the base to the sugar backbone (**Fig. 9.19**). The result of this loss is the formation of an **apurinic site** (one missing a purine

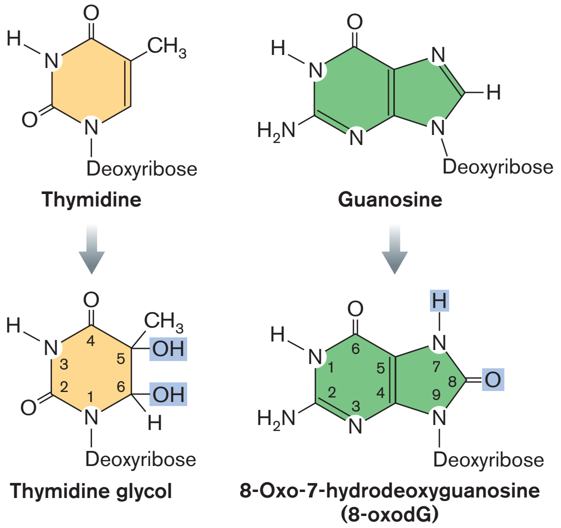

Figure 9.20 **Examples of damage caused by reactive oxygen species.** Growth in the presence of oxygen leads to the production of reactive oxygen species that can modify nucleotide residues. The modifications can interfere with polymerase function and stop replication or interfere with the transcription of affected genes. The blue highlighted groups are modifications to thymidine and guanosine residues.

base) in the DNA. This would obviously hinder transcription and replication.

DNA damage can occur as a result of metabolic activities of the cell that produce intermediates such as hydrogen peroxide (H_2O_2), superoxide radicals ($^{\bullet}O_2^-$), and hydroxyl radicals ($^{\bullet}OH$), collectively called reactive oxygen species. Even though bacteria have biochemical mechanisms to detoxify reactive oxygen species, sometimes the systems are overwhelmed. Oxidative damage causes the production of thymidine glycol or 8-oxo-7-dehydrodeoxyguanosine in DNA (**Fig. 9.20**).

Naturally occurring intracellular methylation agents (for example, S-adenosylmethionine) can spontaneously methylate DNA to produce a variety of altered bases. The spontaneous methylation of the N-7 position of guanine, for example, weakens the glycosidic bond and results in spontaneous loss of the base (apurinic site formed) or opening of the imidazole ring forming a methyl formamide pyrimidine. In addition to mispairing, some of these spontaneous events can lead to major chromosomal rearrangements, such as duplications, inversions, and deletions. Mutagens tend to increase the mutation rate by increasing the number of mistakes in a DNA molecule as well as by inducing repair pathways that themselves introduce mutations.

Ultraviolet (UV) light produces a striking structural alteration in DNA molecules because pyrimidines are highly susceptible to UV radiation. The energy absorbed by a pyrimidine hit with UV light boosts the energy of its electrons to the point where the molecule is unstable. If two pyrimidines are neighbors on a single DNA strand, their energized electrons can react to form a four-membered cyclobutane ring. The result is a pyrimidine dimer that will block replication and transcription (**Fig. 9.21**).

Clearly, there are many ways DNA can be damaged. However, the cell has many opportunities to repair that damage before it becomes fixed as a mutation. But the repair mechanisms are not perfect. These missed opportunities contribute heavily to the formation of heritable mutations and, thus, evolution. Although most mutations decrease the fitness of a species, some can improve fitness by, among other things, enabling an organism to use, or compete for, available food sources with greater efficiency.

Mutation Rates and Frequencies Are Determined Experimentally

The **mutation rate** for a given gene is defined as the number of mutations formed per cell doubling. It can be estimated according to the formula $a = m$ per number of cell generations, where a is the mutation rate and m is the number of mutations that occur as the number of cells increases from the initial number N_0 to N (see Chapter 4). The number of cell generations is equal to $(\log_{10} N_t - \log_{10} N_0) \div 0.301$ (see Section 4.5).

A less complicated calculation is **mutation frequency**. Mutation frequency tells you how many mutant cells are present in a population. It is calculated simply as the ratio of mutants per total cells in the population.

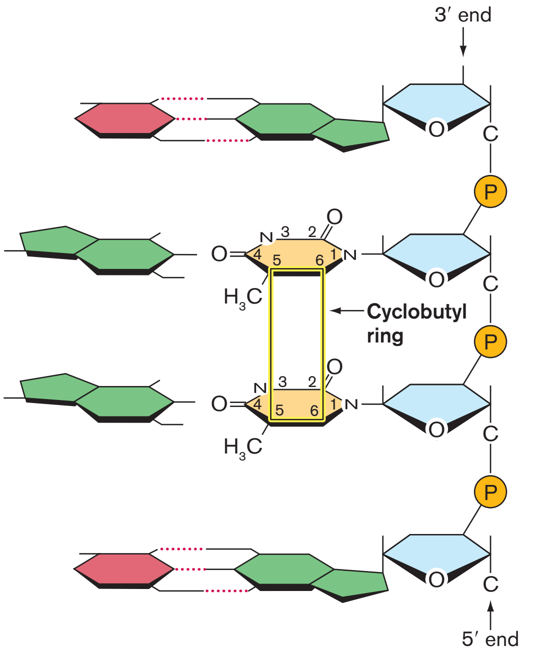

Figure 9.21 **Production of a of pyrimidine dimer.** The energy from ultraviolet light irradiation can be absorbed by pyrimidine molecules. The excited electrons of carbons 5 and 6 on adjacent pyrimidines can then be shared to create a four-member cyclobutane ring between adjacent pyrimidines. The pyrimidine dimer acts as a block to replication and transcription.

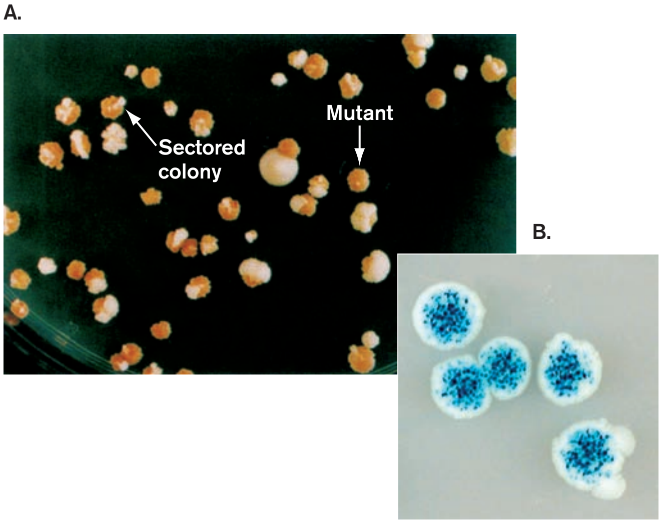
The colonies in **Figure 9.22** graphically illustrate the result of a high mutation rate. Single yeast cells placed on an agar surface multiplied to form the colonies shown (**Fig. 9.22A**). As the yeast cell replicates to form a colony, a spontaneous mutant may develop at some point. The mutant yeast is unable to metabolize a compound which then accumulates and turns the cell red. As the mutant cell increases in number alongside normal cells, a sectored colony forms.

In the case of the bacteria, the medium contains an indicator that turns blue if the organism can ferment lactose (**Fig. 9.22B**). This is a useful tool to follow the development of mutations in the gene needed to ferment lactose. Because the original cell in this case was Lac$^-$ (due to a mutation in that gene), most of the colony is white. However, the strain is a mutator strain defective in a DNA repair gene. This caused a high rate of reversion to Lac$^+$. Each cell that reverted to become a lactose fermenter produced offspring that can turn the indicator blue. These mutants appear as blue papillae on the surface of the white colony. Each papilla represents a separate mutational event.

THOUGHT QUESTION 9.6 Calculate the mutation rate for a gene in which the number of mutations increases from 0 to 50 as cell number increases from 10^1 to 10^8.



1996. *PNAS* 93:7131

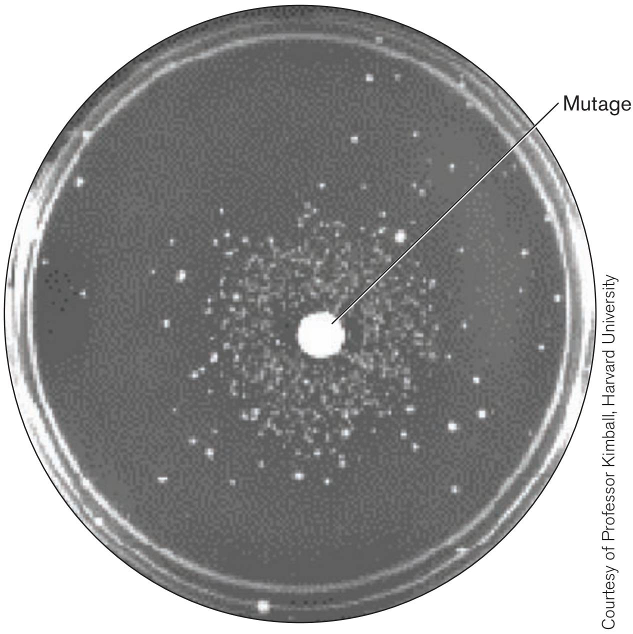
Durund, et al. 2007. *BMC Cell Biology* 8:13

Figure 9.22 **Sectored colonies of bacteria and yeast.** **A.** Sectored colonies of yeast. On this medium, normal yeast cells form white colonies. The occasional mutant cell that develops as the colony grows will replicate as part of the colony but forms a reddish-orange sector. **B.** *E. coli* mutator strain. Cells are lactose-negative mutants that do not ferment lactose and do not turn the indicator blue. However, because the strain has a mutation in one of the mutator genes, there is a high rate of reversion to the lactose fermentor strain, which shows up as blue papillae on the white colony.

Mutagens Can Be Identified Using Bacterial "Guinea Pigs"

In humans, many nonmutagenic chemicals can be transformed into potent mutagens by the liver. The liver is the chief organ for detoxifying the body, a task accomplished by chemically modifying foreign chemicals by the action of liver enzymes. In a world where new chemical entities are constantly being introduced, it is important to determine which ones are potential mutagens. Conventional methods require testing these compounds on large populations of animals. Bruce Ames and his colleagues invented a simple alternative that uses bacteria as a rapid initial screen, for which Ames received the National Medal of Science. The method, called the Ames test, relies on a mutant of *Salmonella enterica* that is defective in the *hisG* gene, whose product is involved in histidine biosynthesis (**Fig. 9.23**). The *hisG* mutant cannot grow on a minimal defined medium lacking histidine. However, if a reversion mutation occurs in the *hisG* gene, restoring the gene to its original functional state, the new mutant cell will form a colony, even in the absence of histidine. This method is called a reversion test.

Ames used this *his* reversion test to screen compounds for potential mutagenicity. If a chemical is able to mutate one gene (*hisG*), it has the potential to affect any gene. As shown in **Figure 9.23,** a mutagen-containing



Courtesy of Professor Kimball, Harvard University

Figure 9.23 **Basic Ames test for mutagenesis.** A mutation in the *hisG* gene of *Salmonella enterica* creates a histidine auxotroph, which is a strain that requires histidine to grow. When plated onto medium lacking histidine, only a few spontaneous mutations (reversions) occur that reverse the mutation so the cell can make histidine again. These cells form colonies on medium lacking histidine. A paper disk containing a mutagen placed in the center of the plate will progressively, over time, increase the number of prototrophic revertants seen orbiting the disk.

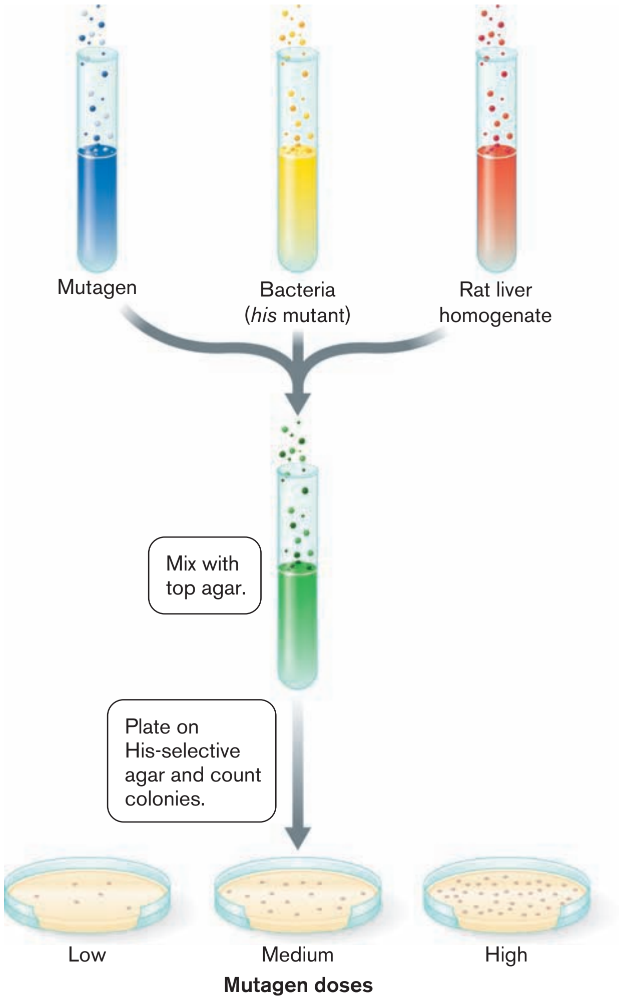


Figure 9.24 **The modified Ames assay to test for the mutagenic properties of chemical processed through the liver.** The potential mutagen, *his*-mutant bacteria, and liver homogenate are combined and mixed with agar. The combination is poured into a Petri plate. If enzymes from the liver extract modify the test compound and convert it to a mutagen, increasing numbers of His$^+$ revertants will be observed with increasing doses of mutagen.

disk is placed in the middle of an agar plate spread with the original *his* mutant. As the mutagen diffuses into the medium and causes reversion mutations, colonies start to appear, forming a ring around the disk. More revertants are produced the longer the plate is incubated.

How can this technique be used to screen for hidden mutagens that require processing by mammalian enzymes? The basic technique was modified by treating a potential mutagen with a rat liver extract before applying the mixture to bacteria for the *his* reversion test (**Fig. 9.24**). In the absence of liver enzymes, these compounds are not mutagenic. If the enzymes of the liver, the main detoxifying organ of the body, convert the compound to a mutagen (it does this accidentally—not on purpose), His$^+$ revertant colonies will be seen. This method has helped accelerate the process of drug discovery by providing an inexpensive preliminary screen for weeding out mutagenic chemicals before the more expensive animal testing is undertaken.

The most recent assays for mutagenicity involve transgenic mice. Mice are engineered to have the *lacZ* gene, for instance, inserted into their chromosomes. The *lacZ* gene encodes an enzyme that is easily assayed, so it is useful as a reporter for mutagenic activity. This reporter gene will be distributed throughout the mouse in all organs. A potential mutagen is administered to the mouse, and after some time the mouse is sacrificed, organs are removed, and the DNA is extracted and examined for mutations arising in the *lacZ* gene. This approach allows scientists to track where the mutagen is distributed in the mouse and to determine whether certain organs convert harmless precursor chemicals to dangerous mutagenic compounds.

TO SUMMARIZE:

- **A mutation** is any heritable change in DNA sequence, regardless of whether there is a change in gene function.

- **Genotype** reflects the genetic makeup of an organism, whereas **phenotype** reflects its physical traits.
- **Classes of mutations** include silent mutations, missense mutations, nonsense mutations, point mutations, insertions, deletions, and frameshift mutations.
- **Spontaneous mutations** reflect tautomeric shifts in DNA nucleotides during replication, accidental incorporation of noncomplementary nucleotides during replication, or "natural" levels of chemical or physical (irradiation) mutagens in the environment.
- **Chemical mutagens** can alter purine and pyrimidine structure and change base-pairing properties.
- **Bacterial cultures** can be used to assess the mutagenicity of a chemical.

9.5 DNA Repair

Microorganisms are equipped with a variety of molecular tools that repair DNA damage before the damage becomes a heritable mutation (see **Table 9.3**). The type of repair mechanism used (and when it is used) depends on two things: the type of mutation needing repair and the extent of damage involved. Some mechanisms excise whole fragments of DNA that contain damaged bases; others precisely excise the damaged bases or directly reverse the damage. After extensive damage, special "emergency" DNA polymerases are expressed that sacrifice replication accuracy to rescue the damaged genome. Whether damage is introduced by mutagens or by inaccurate DNA synthesis, microbial survival depends on the ability to repair DNA.

First we cover the **error-proof repair** pathways that prevent mutations. These include methyl mismatch repair, photoreactivation, nucleotide excision repair, base excision repair, and recombinational repair. We will then discuss **error-prone repair** pathways. These pathways risk introducing mutations and operate only when damage is so severe that the cell has no other choice but to die.

Error-Proof Repair Pathways

Mismatch repair. What happens if DNA polymerase simply makes a mistake and incorporates a normal but incorrect base? Although proofreading functions in DNA polymerases are designed to prevent the misincorporation of bases during replication, misincorporation does occur. Curiously, far fewer mutations arise than one would predict based on the inherent error rate of DNA polymerase III (approximately 1 mistake per 10^6 bases synthesized, after proofreading). However, the mutation rate in a live cell is actually only 10^{-9} to 10^{-10} per base pair replicated. How can a cell repair a mutation after it has been introduced during replication? One method is **methyl mismatch repair**, which is based on recognition of the methylation pattern in DNA bases. As discussed in Section 7.3, many bacteria tag their parental DNA by methylating it at specific sites. In *E. coli*, for example, deoxyadenosine methylase (Dam) methylates the palindromic sequence GATC to produce GA$^{\mathrm{ME}}$TC. The Dam methylase does this soon, but not immediately, after replication of a DNA sequence.

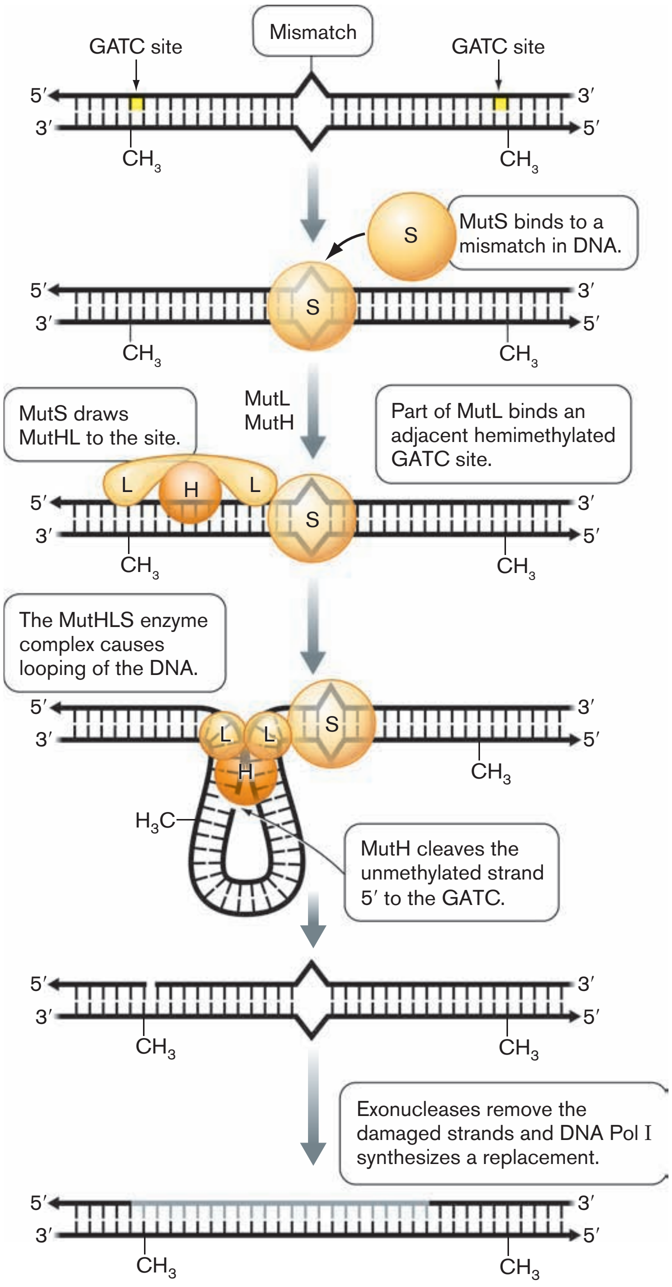
When DNA polymerase misincorporates a base during replication, a mismatch forms between the incorrect base in the newly synthesized, but unmethylated strand and the correct base residing in the parental, methylated strand. Methyl-directed mismatch repair enzymes (MutS, MutL, and MutH) bind to the mismatch. MutS first binds to the mismatch and recruits MutL and MutA. MutL recognizes the methylated strand (GATC-Me), brings it in a loop to meet MutS and MutH, and then cleaves the unmethylated strand containing the mutation, near the GATC (**Fig. 9.25**). A DNA helicase called UvrD then

Table 9.3 Basic types of DNA repair.

System	Genes	Mutations recognized	Repair mechanism	Result
Photoreactivation	*phrB*	Pyrimidine dimers	Cyclobutane ring cleaved	Accurate
Nucleotide excision	*uvrABCD*	Helical destabilization, e.g., *pyrimidine* dimers	Patch of nucleotides excised	Accurate
Base excision	*fpg, ung, tag, mutY, nfo*	Various modified bases	Glycosylases remove base from phosphodiester backbone; apurinic (AP) sites formed	Accurate
Methyl mismatch	*mutHSL, dam*	Transitions, transversions	Nick on nonmethylated strand, excision of nucleotides	Accurate
Recombination	*recA*	Single-strand gaps	Recombination	Accurate
Translesion bypass synthesis	*umuDC*	Gaps	Part of SOS sytem	Error-prone (generates mutations)

unwinds the cleaved strand, exposing it to a variety of exonucleases. The result is a gap that is filled in by DNA polymerase I (Pol I) and sealed by DNA ligase.

The methyl-directed mismatch repair proteins (and genes) are called Mut (and *mut*) because a high mutation rate results in strains that are defective in one of these proteins. A bacterial strain with a high mutation rate is called a **mutator strain**.



MutS binds to a mismatch in DNA.

MutS draws MutHL to the site.

Part of MutL binds an adjacent hemimethylated GATC site.

The MutHLS enzyme complex causes looping of the DNA.

MutH cleaves the unmethylated strand 5′ to the GATC.

Exonucleases remove the damaged strands and DNA Pol I synthesizes a replacement.

Figure 9.25 Methyl mismatch repair. The bacterial cell, in this case *E. coli*, can use specific methylations on DNA to recognize parental DNA strands for preferential DNA repair. Newly replicated strands are not immediately methylated. So when a mismatch is found, the mismatch repair system views the newly synthesized strand as suspect and replaces the section of unmethylated DNA encompassing the mismatch. The steps following cleavage are similar to what is shown in Fig. 9.26 (steps 7 and 8).

NOTE: Not all DNA methylations serve as signals for methyl mismatch repair. DNA methylation by restriction-modification systems, for example, prevent cleavage by DNA restriction enzymes but are not used to designate parental DNA after replication.

Photoreactivation and nucleotide excision. DNA repair mechanisms are not influenced by DNA methylation. Many microbes in the environment commonly encounter ultraviolet light. The pyrimidine dimers that form as a result of ultraviolet irradiation can be repaired by a light-activated mechanism called **photoreactivation**. In photoreactivation, the enzyme photolyase binds to the dimer and cleaves the cyclobutane ring linking the two adjacent, damaged nucleotides. The damage is repaired without excising any bases.

While photolyase is specific for pyrimidine dimer repair and requires light, a system called **nucleotide excision repair (NER)** operates in the dark (or light) and is used to excise other kinds of damaged DNA as well as pyrimidine dimers. In this system, a three-subunit exonuclease (UvrABC) excises a patch of 12–13 nucleotides that includes the dimer (**Fig. 9.26**). The basic mechanism involves UvrA, associated with UvrB, recognizing the damaged base (steps 1–3). UvrA is ejected (step 4), and UvrB binds UvrC (step 5), which actually cleaves the damaged strand at two sites flanking the damaged base (step 6). The small fragment is removed and the gap repaired by DNA polymerase I (steps 7 and 8). Nucleotide excision repair is also used to excise other kinds of damaged DNA besides pyrimidine dimers.

Nucleotide excision repair can be enhanced by ongoing RNA transcription. Bacteria as well as eukaryotic cells preferentially repair genes that are being transcribed. The preferential repair of transcriptionally active genes makes sense because a cell unable to transcribe such a gene due to recent DNA damage would be at a survival disadvantage. An RNA polymerase that encounters a UV dimer or other unrecognizable base on a template DNA strand will stall during transcription. The stalled RNA polymerase is then recognized by a protein that mediates a process called transcription-coupled repair. The transcription-coupled repair protein then snares a nearby UvrAB to begin nucleotide excision repair.

Base excision repair snips damaged bases from DNA. Although nucleotide excision repair can recognize and repair several types of damage, it does not work in all instances. Another error-proof process known as **base**

Figure 9.26 Nucleotide excision repair. This repair mechanism cuts out a single-stranded segment of DNA containing the mutation and uses DNA replication to repair the gap.

excision repair (BER) employs a battery of glycosylase enzymes that can recognize and clip certain damaged bases from the phosphodiester backbone. Uracil DNA glycosylase, hypoxanthine DNA glycosylase, and 3-methyladenine glycosylase recognize, respectively, uracil, hypoxanthine, and 3-methyladenine when these bases are present in DNA. Uracil can be found in DNA either as a spontaneous deamination product of cytosine (see **Fig. 9.18**) or as a result of inappropriate incorporation during replication. Spontaneous deamination of adenine residues produces hypoxanthine. Uracil and hypoxanthine have base-pairing properties very different from those of the original bases, so their formation can lead to mutations. Mutagens such as methyl methane sulfonate can alkylate adenine to produce the adduct 3-methyladenine. A 3-methyladenine residue will totally block DNA replication, making this a lethal form of damage. Consequently, repairing these mutations is vital for survival.

The glycosylases previously noted cleave the bond connecting the damaged base to deoxyribose in the phosphodiester backbone (**Fig. 9.27**, step 1). The result is an intact phoshodiester backbone missing a base (an abasic site). The site is called an **AP site** because it is missing a purine (it is apurinic) or a pyrimidine (it is apyrimidinic). The next step in base excision repair involves **AP endonucleases** that specifically cleave the phosphodiester backbone at AP sites (step 2). The 5′-to-3′ exonuclease activity of the gap-filling DNA polymerase I will degrade the cleaved strand downstream of the AP site and at the same time synthesize in its stead a replacement strand containing the proper base (step 3). DNA ligase seals the remaining nick and the repair process is complete (step 4).

THOUGHT QUESTION 9.7 It has been reported that hypermutable bacterial strains are overrepresented in clinical isolates. Out of 500 isolates of *Haemophilus influenzae*, for example, 2–3% were mutator strains having mutation rates 100–1,000 times higher than lab reference strains. Why might mutator strains be beneficial to pathogens?

All of the repair processes described thus far (mismatch repair, photoreactivation, nucleotide excision repair, and base excision repair) are error-proof pathways that rely on the presence of a good template strand opposite the damaged strand. Replication of the template strand is used to replace the damaged bases accurately. But what happens when both strands are damaged or when there is only one strand?

Recombinational repair. Figure 9.28 illustrates one repair mechanism that occurs when DNA replication takes place before a UV dimer can be excised by nucleotide excision repair. Because DNA polymerase III (the main

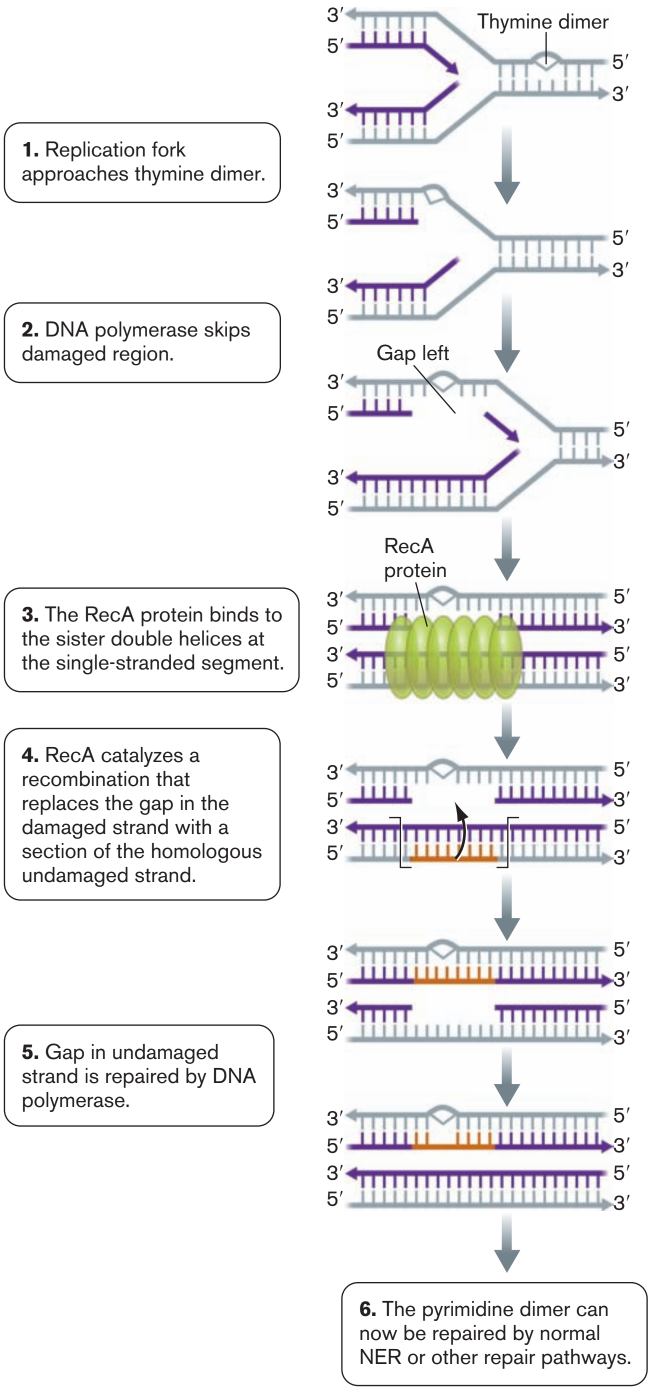
Figure 9.27 **Base excision repair.** Specialized enzymes can recognize specific damaged bases and remove them from DNA without breaking the phosphodiester backbone. The result is an abasic site (AP; apurinic or apyrimidinic) that can be recognized and cleaved by a specific AP endonuclease. This allows DNA polymerase I to synthesize a replacement strand containing the proper base.

polymerase for chromosome replication) cannot decode a dimer, it skips over the damaged area and restarts with a new RNA primer, leaving a gap opposite the dimer. At this point, the Uvr complex cannot excise the UV dimer because chromosome integrity would be lost. However, the RecA protein, involved with recombination, can bind to the gap and initiate a genetic exchange in which a piece of the undamaged, properly replicated strand is spliced into the gap. This is called **recombinational repair** and mostly occurs near replication forks. Once the gap is filled, the Uvr complex can remove the dimer and DNA polymerase I will fill the gap in the other strand.

The recombinational repair system is an error-proof repair pathway. Note that the gap formed in the donor strand is easily replaced by the gap-filling DNA polymerase I. Recombinational repair is not limited to pyrimidine dimers. It will work on any damage that causes gaps during replication.



1. Replication fork approaches thymine dimer.

2. DNA polymerase skips damaged region.

3. The RecA protein binds to the sister double helices at the single-stranded segment.

4. RecA catalyzes a recombination that replaces the gap in the damaged strand with a section of the homologous undamaged strand.

5. Gap in undamaged strand is repaired by DNA polymerase.

6. The pyrimidine dimer can now be repaired by normal NER or other repair pathways.

Figure 9.28 Recombinational repair. Recombination can be used to repair DNA damage of replicating DNA when one daughter strand is undamaged. A single-stranded segment of the undamaged daughter strand can be used to replace a gap in the damaged daughter strand.

Error-Prone DNA Repair

SOS "Save Our Ship" repair. When DNA damage is extensive, none of the repair strategies that excise pieces of DNA or that rely on one of the two strands remaining undamaged can work without destroying the chromosome. The cell must take more drastic measures known as the **SOS response**, a coordinated cellular response to DNA damage that, in order to save the cell, can introduce mutations into severely damaged DNA. So in this case, repair refers to saving the integrity of the circular chromosome even if incorrect bases are introduced. In the SOS system, RecA protein appears to sense when DNA damage is extensive based on the level of single-stranded DNA available. For example, excessive ultraviolet irradiation will produce numerous ssDNA gaps because DNA polymerase cannot replicate through pyrimidine dimers.

Formation of RecA filaments (see **Fig. 9.13**) on ssDNA activates a second function of RecA called coprotease activity that stimulates autodigestion of the LexA repressor, a protein that normally binds to DNA at the promoters of DNA repair genes and prevents their transcription (**Fig. 9.29**). Cleavage of LexA unleashes expression of these genes to make DNA repair enzymes. Among these enzymes are two "sloppy" DNA polymerases that lack proofreading activity: UmuDC, also called DNA polymerase V (Pol V), and DinB, also called DNA polymerase IV (Pol IV) (**Fig. 9.29**). The UmuDC enzyme is perfect for replicating through damaged bases (a process called translesion replication) because it sacrifices accuracy for continuity. When the enzyme encounters an undecipherable damaged base, it will insert whatever nucleotide is available. This, of course, will lead to numerous mutations, but the benefit is that the cell has a chance to live if it can tolerate the mutations. This high mutation frequency is a calculated risk. However, the cell really has no other option, since housekeeping DNA polymerases like Pol III cannot move through damaged areas of chromosomal DNA. The choice really is "mutate or die." (Note that the term *housekeeping* is applied to proteins or enzymes that keep the cell running at all times.)

When the cell is severely compromised by mutation, it temporarily stops dividing. Like a pit stop during an auto race, this pause in cell division allows time for repair enzymes to fix the damage. The product of another SOS-regulated gene called *sulA* causes this pause by binding to the FtsZ cell division protein, keeping it from initiating cell division (see Section 3.6). Once the damage has been repaired, RecA coprotease is inactivated and LexA repressor accumulates, turning off all the SOS genes, including *sulA*. The lingering SulA protein is then degraded by a protease called Lon. The protein is called Lon because when it is missing, SulA inappropriately accumulates, inhibits cell division, and produces *long* filamentous cells.

Human homologs of bacterial repair genes. About 30% of *E. coli* genes have human homologs; the functions of the human genes may be similar to those of

1. SOS system is off because the LexA repressor binds to target genes (described in text). However, a small amount of RecA is always made.

2. The system is turned on when single-stranded DNA accumulates due to extensive DNA damage.

3. RecA filaments form on the ssDNA. This activates a coprotease activity in RecA that causes autodigestion of LexA. The target genes are expressed.

Genes of the SOS system include:
sulA (inhibitor of cell division),
umuDC (Pol V, error prone),
uvrA (part of NER pathway),
lexA (repressor)

4. Products of the target genes inhibit cell division, mediate replication across lesions (Pol V), and participate in nucleotide excision repair.

Figure 9.29 Regulation of the SOS response system. The emergency DNA repair system known as the SOS response is induced when there is extensive DNA damage. The system is not a single repair mechanism but a set of different mechanisms that collaborate to rescue the cell.

E. coli or they may have newly acquired functions. These genes often turn out to play key roles in human genetic diseases. An example is *mutS*, of the methyl mismatch DNA repair system. In humans, the ancestor of *mutS* evolved to have multiple repair functions as well as participate in postmeiotic segregation. Defects in this repair mechanism have been linked to increased risk of certain colon cancers. Numerous other human genetic diseases are caused by mutations in homologs of bacterial repair genes. For example, defective excision repair genes in humans cause xeroderma pigmentosa, a disease that causes blindness and skin cancers. A deficiency in transcription-coupled repair causes Cockayne syndrome in humans, a devastating neurodegenerative disease.

TO SUMMARIZE:

- **DNA repair pathways** in microorganisms include error-proof and error-prone mechanisms.
- **Methyl mismatch repair** uses methylation of the parental DNA strand to discriminate it from newly replicated DNA. The premise is that the parental strand will contain the proper DNA sequence.
- **Photoreactivation** cleaves the cyclobutane rings of pyrimidine dimers.
- **Nucleotide excision repair** (NER) clips out a patch of single-stranded DNA containing certain types of damaged bases.
- **Base excision repair** (BER) excises structurally altered bases without cleaving the phosphodiester

backbone. The resulting AP (apurinic/apyrimidinic) site is targeted by AP nucleases.

- **Recombinational repair** takes place at a replication fork. A "good" strand of DNA is used to replace a homologous damaged strand.
- **Extensive DNA damage leads to induction of the SOS response** with increased levels of the error-proof repair systems, as well as error-prone translesion bypass DNA polymerases that introduce mutations.

9.6 Mobile Genetic Elements

In 1948, Barbara McClintock (1902–1992) noticed that certain genetic traits of corn defied the laws of Mendelian inheritance. The genes responsible for these traits, sometimes called "jumping genes," seemed to hop from one chromosome to another. Although McClintock's theories were provocative at the time, we now know that these types of genes, referred to as **transposable elements**, exist in virtually all life-forms and can move both within and between chromosomes.

Since McClintock's work, transposable elements have been most widely studied in bacteria. Nancy Kleckner, Russel Chan, Bik-Kwoon Tye, and David Botstein described the presence of transposable elements in bacteria in 1975 (**Fig. 9.30**). In this classic study, a transposable element carrying a tetracycline resistance gene (Tc) was found inserted into the P22 phage genome. P22 is a lysogenic phage that infects *Salmonella*. Recall that a lysogenic phage can integrate into the host chromosome and remain dormant for long periods of time.

The experiment used a defective P22 phage (carrying the Tc resistance gene) that could only replicate in certain strains of *Salmonella*. When this phage was used to infect nonpermissive strains of *Salmonella* (strains that would not allow the phage to grow or lysogenize), the *Salmonella* still became tetracycline resistant at a high frequency. Many of those tetracycline-resistant colonies also developed an auxotrophic requirement for an amino acid, nucleic acid base, or vitamin. The simple explanation was that the tetracycline resistance (Tc^R) element translocated ("jumped") out of the P22 DNA and into one of a number of locations on the *Salmonella* chromosome, sometimes inserting within a structural gene, thereby creating a mutation and phenotypic change. Today we know that these mobile DNA elements have contributed to remodeling of genomes throughout the evolutionary development of all species.

NOTE: The symbol :: is a convention representing insertion. The element appearing after the two colons has been inserted into the element noted in front of the two colons. For example, *proA*::Tn*10* means Tn*10* (a transposable element) is inserted into the *proA* gene involved in proline synthesis.

Transposable elements are not autonomous; unlike plasmids, they are incapable of existing outside of a larger DNA molecule. They exist only as hitchhikers integrated into some other DNA molecule (**Fig. 9.31**▶). The DNA sequence of a transposable element includes a gene encoding a **transposase**—an enzyme that catalyzes the transfer or copying of the element from one DNA molecule into another. A simple element (700–1500 bp) called an **insertion sequence (IS)** element consists of a transposase gene flanked by short inverted repeat sequences that are targets of the transposase (see **Fig. 9.31**).

NOTE: An inverted repeat is a DNA sequence identical to another downstream sequence. The repeats have reversed sequences and are separated from each other by intervening sequences:

5′-AATCGAT . . . . ATCGATT-3′

When no nucleotides intervene between the inverted sequences, it is called a palindrome.

Figure 9.30 **A. Nancy Kleckner (Harvard University) and B. David Botstein (Princeton University).** Two of the discoverers of bacterial transposition.

Transposition is the process of moving a transposable element *within* or *between* DNA molecules. During transposition, a short DNA sequence on the target DNA molecule is duplicated so that one copy of the sequence will flank each end of the element (**Fig. 9.31**). Note that the transposase randomly selects one of many possible target sequences where it will move the insertion element.

IS elements transfer by one of two mechanisms: replicative or nonreplicative transposition (**Fig. 9.32**). In nonreplicative transposition, the insertion sequence excises itself out of one host DNA while integrating into the next DNA. In replicative tranposition, the sequence copies itself into the new host DNA while the original copy remains within the original host.

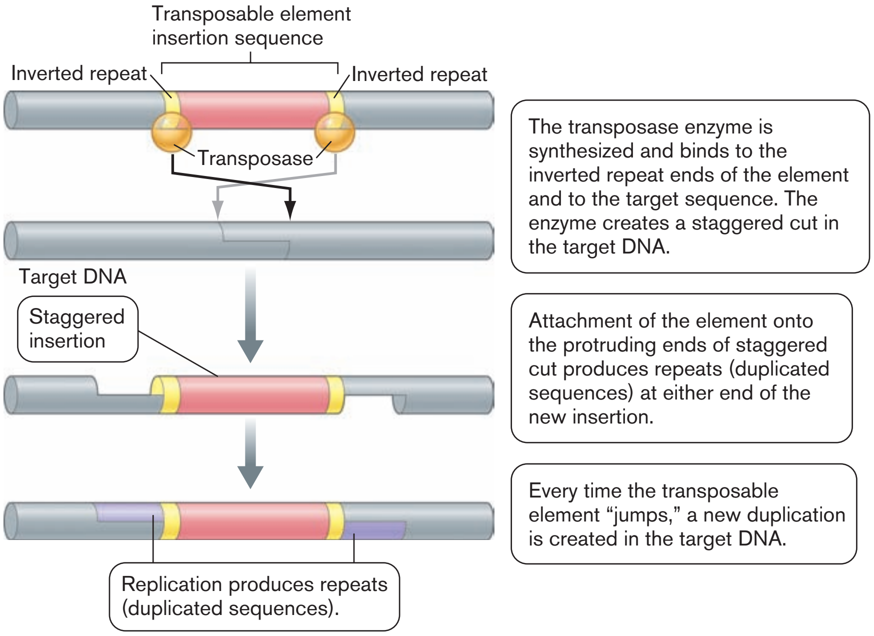
Nonreplicative Transposition

The nonreplicative model of transposition is shown in **Figure 9.33**. The transposase protein binds to the inverted repeat ends of the transposable element and to the target DNA, forming a **transposome** complex (**Fig. 9.33**, step 1). The transposase cuts the phosphodiester backbone (step 2), severing one strand at one end of the insertion sequence and the other strand at the other end. The 3′ OH ends of the IS element then attack the unnicked strands in a transesterification reaction that produces hairpin structures (step 3). In this instance, joining the ends of the double-stranded molecule produces a single strand with a hairpin.

After the host carrier DNA is ejected from the transpososome, the hairpin ends are renicked and the 3′ OH ends attack the target DNA molecule in a staggered manner (step 4). The element has successfully "jumped" from one molecule to another without replicating. Note that the target DNA segment replicates as a result of the insertion process, producing a copy of the target sequence at each end of the IS element (step 5).

Replicative Transposition

Figure 9.34 shows how a transposable element in a plasmid can bring about cointegration of the plasmid into a target DNA molecule during replicative transposition. As a result of replication of the IS element, the cointegrate molecule will contain two copies of the element flanking the integrated plasmid. Thus, transposition can provide an organism with a whole set of genes that might extend its metabolic capacity, provide drug resistance, or serve as the starting point for gene divergence through mutation. Do not be misled; transposition is not a process designed to help the host; rather, it evolved to ensure survival of the transposon. The benefit to the host is accidental.

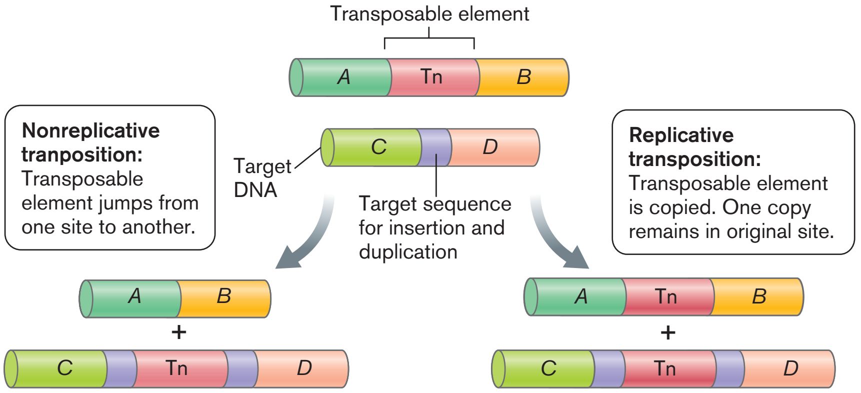


The transposase enzyme is synthesized and binds to the inverted repeat ends of the element and to the target sequence. The enzyme creates a staggered cut in the target DNA.

Attachment of the element onto the protruding ends of staggered cut produces repeats (duplicated sequences) at either end of the new insertion.

Every time the transposable element "jumps," a new duplication is created in the target DNA.

Figure 9.31 Basic transposition and origin of target site duplication. Enzymes that catalyze transposition generate duplications in the target site by ligating the ends of the insertion element to the long ends of a staggered cut at the target DNA site.



Nonreplicative tranposition: Transposable element jumps from one site to another.

Replicative transposition: Transposable element is copied. One copy remains in original site.

Figure 9.32 Products of nonreplicative and replicative transposition. Nonreplicative transposition moves an insertion element from one DNA site to another without leaving a copy of the element at the original site. Replicative transposition leaves the element at the original site and moves a replicated copy to the new site.

Figure 9.34 Transposition-mediated cointegrate formation between two DNA elements. During replicative transposition, the insertion element is copied and simultaneously ligated to the target site. This creates a transient cointegrate molecule where donor DNA and target DNA become one molecule.

Transposons are one type of transposable element. They are more complex than simple insertion elements, since they carry other genes in addition to those required for transposition. They come in different configurations. A **composite transposon** typically consists of two insertion sequences that flank an antibiotic resistance gene, or one or more catabolic genes (for example, benzene catabolism). Often the interior inverted repeats of the IS element have degenerated, so the transposase primarily acts on the two outermost inverted repeats, causing the whole transposon to move as one unit. Tn*10* is one such example (**Fig. 9.35**). Some transposons also include regulatory genes, such as a repressor that inhibits transcription of the transposase.

Complex transposons have, as the name suggests, a more complex organization. Tn*3*, for instance, not only possesses transposase and antibiotic resistance genes, but includes a gene whose product, called resolvase, specifically resolves (unlinks) the cointegrate produced by replicative transposition (**Fig. 9.34**). The transposase acts on the inverted repeat ends of the element, causing simultaneous insertion and replication. Resolvase is a site-specific recombinase that mediates recombination at the internal Tn*3 res* sites. The result of this recombination is restoration of the two original circular replicons, each one now containing a copy of the transposon.

All of the transposition events mentioned so far involve transfer between DNA molecules within the same cell. Some transposons, called **conjugative transposons**, are able to transfer from one cell to another by conjugation. One example is the transposon Tn*916* of

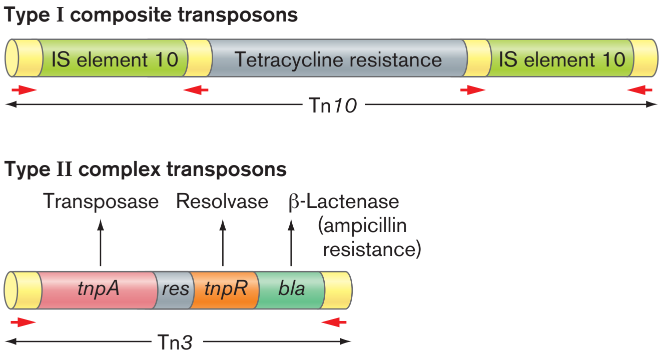

Figure 9.35 Examples of composite and complex transposons. In Tn*10*, the yellow fragments represent inverted repeats and the arrows depict orientation. TnpR is a repressor of the Tn*3* *tnpA* transposase gene and is the enzyme that recognizes the *res* site required to resolve cointegrates formed during transposition.

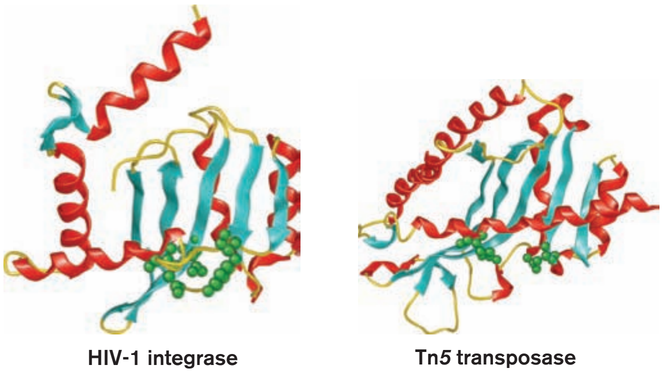

Figure 9.36 Comparison of the catalytic regions for HIV-1 integrase and Tn5 transposase. Note the similarity in structures. The alpha helices are shown in red, the beta sheets are blue, and the catalytic residues are green. Both enzymes contain a five-strand mixed beta sheet and the DDE motif (aspartate/aspartate/glutamate) of catalytic residues. (PDB codes: 1BIH, 1MUH)

Enterococci, which encodes tetracycline resistance. These conjugative transposons resemble plasmids in that they form a circular intermediate just prior to conjugation, but they do not replicate autonomously. They must be part of a larger self-replicating DNA entity (for example, plasmid, chromosome, or phage). The transfer mechanism of conjugative transposons also resembles that of temperate phage in that these elements excise from donor DNA and integrate into the recipient chromosomes. Tn*916* and some other conjugative transposons are designed to transfer when a population is facing danger. For example, in the absence of tetracycline, only a few cells in a population may have Tn*916*. However, the presence of just a small amount of tetracycline triggers conjugative transfer of the element, spreading it throughout the population.

The study of transposons may provide insight into the workings of the human immunodeficiency virus (HIV) that causes AIDS. The structure of transposase from transposon Tn*5* bears a striking similarity to the HIV integrase needed to embed the reverse-transcribed HIV viral DNA into the human genome (**Fig. 9.36**; see Section 11.5). Another type of mobile element called an integron has evolved in bacteria to capture DNA cassettes that encode antibiotic resistance genes (**Special Topic 9.1**).

THOUGHT QUESTION 9.8 Diagram how a composite transposon like Tn*10* can generate inversions or deletions in target DNA during transposition. *Hint:* This occurs when the transposon tries to jump from one site to another in the same chromosome using the ends of the inverted repeats closest to the tetracycline resistance gene (see **Fig. 9.35**). If you draw it right, you will see that in the end, the tetracycline gene is lost.

TO SUMMARIZE:

- **Transposons and insertion sequences** ("jumping genes") move from one DNA molecule to another, usually without replicating separately (that is, they are not plasmids).
- **Transposase** is an enzyme that forms a transposome complex with the transposon and target DNAs.
- **Transposons move** by nonreplicative or replicative mechanisms.
- **Transposons can carry a variety of genes**, including antibiotic resistance genes.

9.7 Genome Evolution

"Nothing makes sense in biology except in the light of evolution," said biologist Theodor Dobzhansky (1900–1975). This statement, made in 1972, rings especially true now that we have access to rapid sequencing of whole genomes. A sense of evolution, of what went before, pervades efforts to interpret the results of the many genome projects. Microbial genomes are dynamic entities that continually evolve. Genes can be removed (deletion), added (insertion), rearranged (recombination), or divided to the point where the genome has only a slight resemblance to what it once was. Evolution of a genome is a random process driven by natural selection. The process of microbial evolution is discussed in Chapter 17. Here we note the molecular mechanisms that drive genome change.

The result of genome evolution can be seen in the genomes of *Escherichia coli*. Several strains of *E. coli* have been sequenced. The first was the K12 strain (called MG1655). It contains 4,639,221 base pairs (compared with the 3 billion base pairs of the human genome). Of this genome, 87.8% encode proteins and 0.8% code for stable RNAs such as tRNA and rRNA used in translation. DNA with no known function encompasses another 0.7%. Approximately 11% of the chromosome is involved with various forms of regulation. Even though *E. coli* is the best-studied organism on the planet, 28% of the 4,288 open reading frames still remain a mystery to us, having no known or annotated function.

Examining the sequences more closely reveals how the current organism we call *E. coli* came about through the evolution of an ancestral genome. Two basic processes are thought to contribute to genome remodeling: horizontal gene transfers and duplications followed by functional divergence through mutation.

Horizontal Gene Transfer Occurs via Transformation, Conjugation, and Transduction

Microbial genomes evolve by randomly assembling an eclectic array of genes from many sources. For example, *E. coli* strain O157:H7, the culprit in several fatal outbreaks of food-borne disease in the United States and Europe, contains 1,387 genes lacking in the strain K12. These additional genes represent about 25% of the O157:H7 genome and encode virulence factors, metabolic pathways, and prophages (phage genes integrated into host chromosomes), all of which were acquired from other species. Until 1990, it was thought that bacterial genomes were rather static; one strain of *E. coli* was thought to be very similar to any other strain. But because of genomic comparisons like this, we now know that enterobacteria are subject to a great deal more interspecies recombination than previously thought.

Evidence for horizontal transfer. More evidence of gene shuffling comes from comparing the proportion of GC base pairs along the chromosome (also known as GC content). On average, the *E. coli* genome consists of 50.8% GC pairs. But 15% of the K12 genome and 26% of the O157:H7 genome show GC proportions that differ significantly from the rest of the genome and show a different codon usage, suggesting that these genes came from other bacterial lines or species and were acquired by *E. coli* more recently. These horizontal gene transfers, occurring via conjugation, transduction, or transformation, are estimated to happen at the rate of about 16 kbp, or 0.4% of the *E. coli* genome, every million years. A sudden change in the GC content within a chromosome is the equivalent of an evolutionary "footprint" marking a horizontal gene transfer.

Horizontal gene transfer appears to be a primary force in microbial evolution. Some estimates place the level of recombination between species to be about 100 times greater than the rate of mutation. In *E. coli*, it has been estimated that nearly 20% of its genome may have originated in other microbes. Gene acquisitions performed by *E. coli* have played an important role in the bacterium's ecological plasticity and contributed to its success as a pathogen.

Genome rearrangement is not restricted to *E. coli*, of course. All life forms enjoy this form of genetic "gambling." It is thought that every species of microbe has a *core* gene pool that includes the minimal set of genes needed for independent growth and replication. Every genome is also thought to possess a *flexible* gene pool that is not common to all strains within the species (**Table 9.4**). Therefore, differences in genome size between strains are usually thought to reflect variations in the flexible gene pool brought about by loss (deletion) or gain (insertion) of chromosomal DNA.

Genomic islands are large, transferred genetic elements containing a large number of genes that serve a common function. For example, a **pathogenicity island** is a genomic island that encodes virulence factors. They are found in bacteria pathogenic for plants and animals, but not in related nonpathogenic strains. *Salmonella enterica* var

Special Topic 9.1 Integrons and Gene Capture

Antibiotic-resistant pathogens are a growing problem throughout the world. One factor contributing to this situation is the movement of drug resistance transposons; another is the existence of **integrons** scattered among various microbial genomes. Integrons are large and complex mobile elements that can accept, or capture, a shopping cart full of different antibiotic resistance gene cassettes to use later when needed. Integrons come in various forms, but in general they

consist of structural genes linked to a 59-bp element (an *attC* site) and assemble as cassettes at an attachment, or capture, site (*attI*). The homologous *attI* and *attC* DNA attachment sites are used to capture the antibiotic resistance cassettes. A strong promoter next to *attI* will drive expression of an adjacent, integrated antibiotic resistance gene. Note that strong promoters initiate transcription more frequently than do weak promoters. Strong promoters have −10 and/or −35 sequences that are closer to the ideal consensus sequence for RNA polymerase binding.

There are at least three classes of integrons based on the type of integrase gene they possess. The most widely distributed integrons are of the first class. All class 1 integrons have, at their 5′ ends, an integrase gene, a capture sequence called *attI* that captures the antibiotic cassettes, and the promoter P next to *attI* (**Fig. 1A**). At the 3′ ends many contain an ethidium bromide resistance locus (*qacED*□) and a sulfonamide resistance gene (*sulI*). The antibiotic resistance genes captured by integrons are located on circular gene cassettes. Although these cassettes can exist free of a chromosome, unlike plasmids they cannot replicate, nor do the antibiotic genes come equipped with a promoter. The cassettes do contain *attC* sequences that allow them to be captured through recombination at *attI* in the chromosomal integron (**Fig. 1B**). Once captured, the cassette closest to the promoter will be expressed to the highest extent. However, the cassettes can be "shuffled" in their position by excision and reintegration. Through this shuffling process, an integron containing several antibiotic resistance genes can, though trial and error, move the resistance gene that best combats the current antimicrobial challenge to a position where it will be more highly expressed (**Fig. 1C**). *Vibrio cholerae*, for example, possesses a super integron carrying over 150 cassettes, each with a variant of an *attC* site.

Typhimurium, for example, contains three pathogenicity islands, each with a role specific to a different stage of disease. Pathogenicity islands are often flanked by boundary regions such as direct repeats or insertion elements, usually found near tRNA genes (**Fig. 9.37**). The association of pathogenicity islands with tRNA genes may reflect the fact that some tRNA genes serve as attachment sites for the integration of some phage DNAs or transposons. Also, some tRNA genes are dispensable since there are often multiple copies of a given tRNA gene within a genome. The pathogenicity island as a whole is often genetically unstable, subject to further rearrangements or deletions. In addition to virulence genes, pathogenicity islands

contain mobility genes encoding transposases, integrases, or other enzymes associated with recombination.

Another kind of genomic island helps a microbe enter into symbiotic relationships. This is called a mobile symbiosis island. For example, *Mesorhizobium loti* is a symbiotic bacterium that lives in nodules on the roots of legumes. This root nodule bacterium derives nourishment from the plant in exchange for fixing nitrogen from the atmosphere that the plant can use. Several species of rhizobia carry the genes for nodulation and nitrogen fixation on large plasmids. Others, like *Bradyrhizobium* species, have symbiosis genes as part of their genomes but clustered in a way that suggests they were once derived from horizontal transfer. These gene clusters appear to have lost whatever mobility they once had. The symbiosis genes of *M. loti,* however, are contained on a mobile symbiosis island. These were the genes horizontally transferred in the Sullivan and Ronson field experiment described in the introduction to this chapter.

Pathogenicity islands and symbiosis islands alike encode remarkable protein secretion systems (called type III and type IV secretion systems) capable of injecting effector proteins directly from the bacterium straight into a eukaryotic cell. Once inside the target cell, these effector proteins alter the function of eukaryotic cell proteins, making the plant, in the case of symbiosis, more accepting of the symbiont. Type III and IV secretion systems are discussed further in Chapter 25.

Other genomic islands are called fitness islands. Fitness islands encode functions that are important to survival in the environment. *E. coli,* for example, possesses an acid fitness island that enables the organism to survive at pH 2, a condition found in the human stomach (see Section 12.1).

Genome Evolution Includes Genome Reduction

It is important to note that evolution toward pathogenicity involves gene loss as well as gene acquisition. Large-scale loss of genes through evolution is known as genome reduction. For example, pathogenic shigellae (the cause of bacillary dysentery) exhibit chromosomal "black holes," regions lacking genes that occur in the closely related *E. coli.* Absence of these genes is required for a fully virulent phenotype. Similarly, the genome of the organism responsible for whooping cough, *Bordetella pertussis,* is 100 kb smaller than the genome of the less pathogenic *Bordetella bronchiseptica,* another example of evolution by genome reduction. Genome reduction is discussed in Chapter 17.

Sometimes, evidence of genome reduction in the making can be observed. Many genomes contain pseudogenes, genes that by homology appear to encode an enzyme but are nonfunctional because a portion is missing through deletion. These appear to be the remnants of genes that were useful to an ancestral species but made superfluous when one of its descendants adapted to a new environmental niche. When evolutionary pressure to retain a functional form of the gene no longer exists, the imperative to repair mutations within that gene also evaporates. The pseudogene, therefore, is in the process of being eliminated.

Duplications and Divergence Generate New Genes

Gene duplication is the most important mechanism for generating new genes and biochemical processes. Duplication frees a gene from its previous functional constraints and allows divergent evolution through mutation. Duplications can arise in several ways, including transposition of a transposable element and recombination after replication between multiple direct or inverted repeat sequences located in the chromosome. **Figure 9.38** shows a duplication formed by recombination between direct repeats of chromosomal sequences. Superfamilies of proteins arising from divergent evolution share structural and functional features but may catalyze different reactions. One example is the ABC superfamily of ABC transporters. Homology between members of the ABC family may be as little as 10%, suggesting that once an enzyme adopts a new function, sequence diverges rapidly.

TO SUMMARIZE:

- **Horizontal gene transfers** between species are thought to have occurred by conjugation, transformation, and transduction.
- A DNA sequence with a **GC content** different from that of flanking chromosomal DNA is one sign of horizontal gene transfer.
- **Pathogenicity islands** are the result of horizontal gene transfers that improve the pathogenicity of a recipient. Fitness islands are similar to pathogenicity islands but improve environmental survival characteristics of the recipient.
- **Superfamilies of functional proteins** result from gene duplications and mutations that cause divergent evolution of function.

THOUGHT QUESTION 9.9 The heat-shock gene *dnaK* in *E. coli* encodes a chaperone (Hsp70), homologs of which are found in all three domains of life. However, there is no other phylogenetic evidence that a *dnaK*-like gene was present in the most recent common ancestor of all organisms. For instance, some species of archaea do not encode a *dnaK* homolog, while other archaeal species do. In fact, molecular phylogenies indicate that the archaeal homologs are quite closely related to those of bacteria. It seems the most recent common ancestor of all *dnaK* (or *hsp70*) genes existed more recently than the common ancestor of all organisms. That being the case, how do you suppose *hsp70* genes arose in archaea?

Concluding Thoughts

Fortuitous movement of genes between species through conjugation (cell-cell contact), transformation (DNA uptake), transduction (phage vector), and transposition (jumping genes) has contributed in a fundamental way to evolution, causing evolutionary leaps and enabling ancestral bacteria to develop, among other things, symbiotic and pathogenic mechanisms that opened up new ecological niches. It has become apparent that DNA repair mechanisms, while designed to prevent the establishment of deleterious mutations, nevertheless allow some mutations to occur. An imperfect DNA repair mechanism offers the cell the opportunity to throw the genetic dice. The vast majority of mutations will be detrimental, but a key few may benefit the organism and enable the variant strain to outcompete its neighbors in its ecosystem. A serious question is raised by our new awareness of genetic mobility: How do we now define a species? For instance, there are numerous strains of *Helicobacter pylori* where large differences in gene sequence and organization are evident. Should each be called a different species? An arbitrary setting of ribosomal RNA gene divergence is used to assign species, but some wonder whether this is still a valid landmark. For further discussion of microbial evolution, see Chapter 17.

CHAPTER REVIEW

Review Questions

1. What are the basic ways microorganisms exchange DNA?
2. Discuss horizontal versus vertical gene transfer.
3. Describe competence and how it comes about in a population.
4. What is an F factor, and how does it (and other factors like it) contribute to gene exchange?
5. What is a merodiploid? Explain how a cell can become a merodiploid.
6. Compare the differences between the activities of competence factor made by *Streptococcus* and pheromones made by *Enterococcus*.
7. What does microbial gene exchange have to do with the plant disease called crown gall disease?
8. Compare specialized versus generalized transduction.
9. Discuss how bacteria protect themselves from invading bacteriophages.
10. What is the value of recombination to a species?
11. List the major proteins that contribute to recombination, and specify their roles in the process.
12. Define Holliday structure, strand assimilation, cointegrate, and cotransduction.
13. List and explain the different types of mutations.
14. How are genotype and phenotype different?
15. Describe six different DNA repair mechanisms. Which ones contribute to mutations?
16. Explain the basic process of transposition. Why are insertion sequences always flanked by direct repeats of host DNA? How are transposons different from plasmids?
17. What is a pathogenicity island? A fitness island? What are their characteristics?

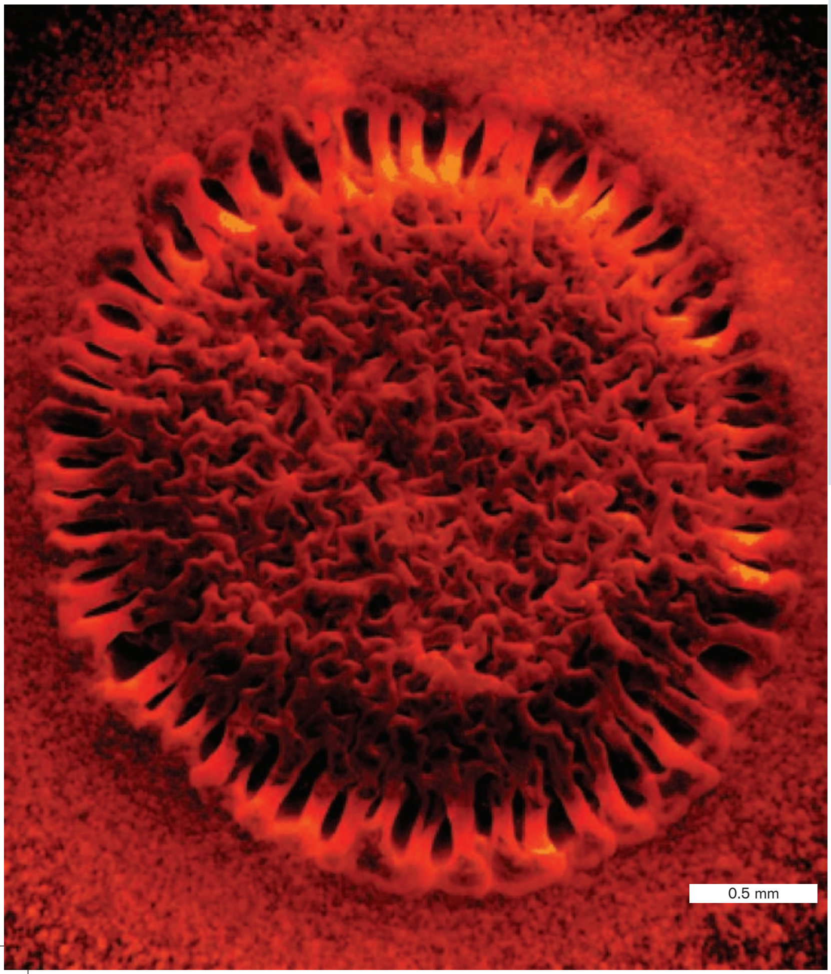
A bacterial genome encodes thousands of different proteins needed to handle many different environmental contingencies. Some proteins, such as RNA polymerase, are always required for growth; these are called "housekeeping proteins." Most proteins, however, are needed only under a limited set of conditions. Proteins that degrade the sugar lactose, for example, are only useful when lactose is present. Likewise, *Vibrio cholerae* needs to make cholera toxin only when it's growing inside the human body, not when it's living in the ocean. To compete successfully with others, the microbe will not waste energy making unneeded proteins. Cells achieve molecular efficiency using elegant control systems that selectively increase or decrease gene transcription, mRNA translation, or mRNA degradation, as well as by degrading or sequestering regulatory proteins. But how does a cell "know" when to alter expression?

This chapter describes the variety of mechanisms used by bacteria to sense changes in internal and external environments, and adjust gene expression accordingly to maintain biochemical homeostasis and achieve optimum growth.



Pseudomonas aeruginosa cells form a wrinkled aggregate (3 mm in diameter) protruding above the surface of swimming motility agar. Autoaggregation is caused by activation of the regulatory protein WspR, which controls expression of cell surface factors, including aggregative fimbriae and exopolysaccharides. *Source*: David A. D'Argenio, et al. 2002. *Journal of Bacteriology* 184(23):6481.

During the day, the bobtailed squid, *Euprymna scolopes*, remains buried in the sand of shallow reef flats around Hawaii. After sunset, the animal emerges from its hiding place and begins its search for food. As it swims in the moonlit night, its light organ projects light downward in an apparent attempt to camouflage the squid from predatory fish swimming below. Looking up, the fish would not see the squid, but would instead see what appeared to be stars. What does this have to do with microbiology? Inside the light organ are luminescent bacteria called *Vibrio fischeri.* The bacteria, not the squid, produce the light. However, these microbes do not *constantly* glow. They only light up when their cell density rises above a certain level, at which time the genes needed to make light are "turned on." This intricate level of genetic control by such a small, seemingly simple bacterium is truly amazing.

Microbes use numerous mechanisms to sense their internal and external environments and then translate that information into action. The cell's surface, for example, contains an array of sensing proteins that monitor osmolarity, pH, temperature, and the chemical content of the surroundings or that detect the presence of a host or competitor. When triggered, a sensor phosphorylates itself using ATP and transfers the phosphate to another protein called the response regulator. Response regulators are typically DNA-binding proteins that, when phosphorylated, activate or inactivate the expression of functionally related sets of target genes.

Even more elaborate are the sigma factor cascades and protein localization mechanisms that control developmental processes such as sporulation or asymmetrical cell division (as in the stalked bacterium *Caulobacter*, discussed in Section 4.7). Other systems, such as quorum sensing, in which bacteria secrete and sense chemical signal molecules, make it possible for members of microbial communities to communicate and cooperate. All these mechanisms orchestrate the synthesis of waves of proteins whose concentrations change with changing environments. Even virulence genes have tapped into these sensing systems, using them to determine whether the microbe has entered a susceptible host. This chapter explores the fundamental principles of gene regulation in microbes and discusses how individual systems are woven into a global regulatory network that interconnects many processes throughout the cell.

Why are there so many different mechanisms for controlling microbial gene expression? Part of the answer is evolutionary: If it works, it stays. Another reason is timing: Different mechanisms act over different time scales. Some changes in an environment may require a very rapid increase in the level of a specific protein; other changes may be more forgiving of a delay. Still other situations require sequential expression. Sporulation, for instance, is a differentiation pathway in which it is critical that certain proteins are not made until other prerequisite proteins have been produced. A feature common to all control mechanisms, however, is an ability to sense that something inside or around the cell has changed.

10.1 Regulating Gene Expression

A cell needs to monitor two different compartments in order to know when to alter gene expression and adjust its physiology: the cytoplasm within the cell and the environment outside. Intracellularly, the concentrations of vitamins, amino acids, and nucleotides must be sufficient and balanced to supply the biosynthetic and energetic needs of the cell. This usually requires controlling de novo (new) synthesis of these compounds. The cell must also know what carbon and energy sources are present within the cell in order to assemble the proper catabolic pathway.

The microbe also needs to know whether conditions outside the cell are hazardous, and it needs to distinguish, based on the combination of chemicals present, whether it is floating in a pond of water, in a gastrointestinal tract, or within a mammalian host cell. Once the environment is sensed, the cell can change the repertoire of genes it expresses to meet its needs or to protect itself.

Cells use different mechanisms to sense and respond to conditions within and outside the cell membrane. Sensing conditions within the cell is relatively straightforward. **Regulatory proteins**, also called **regulators**, bind specific small-molecular-weight compounds called ligands to determine their concentrations (**Fig. 10.1A**). Different regulators bind different ligands. For example, one regulator will bind a carbohydrate ligand and alert the cell that a new potential carbon source is available, while a different regulator will sense if there is enough of the amino acid tryptophan present in the cytoplasm to carry out protein synthesis. The ligand, once bound, then alters the ability of the regulatory protein to latch onto specific DNA regulatory sequences located near the promoters of target genes. These DNA regulatory sequences are called **operators** (or operator sequences) if binding downregulates expression of the target genes; and **activators** (or activator sequences) if binding increases expression. In this way, regulatory proteins can then activate or dampen transcription, depending on the gene. Note that the term "operator" is used generically by some investigators to indicate *any* DNA sequence that binds an activator or a repressor protein. To avoid confusion, we will avoid that usage.

General Concepts of Transcriptional Control by Regulatory Proteins

Genes encoding regulatory proteins are usually, but not always, transcribed separately from the target gene (**Fig. 10.1A**). As noted earlier, regulatory proteins come in two forms: repressors and activators. Repressor proteins bind to operator sequences and prevent the transcription of target genes, an event known as **repression**. However, repression happens in one of two ways, depending on the

Figure 10.1 General aspects of transcriptional regulation by repressor and activator proteins. A. Schematic drawing of a regulatory system. The regulatory gene may be located near or quite far away from the target gene on the chromosome. When it is located nearby, it is often, but not always, transcribed separately from the target gene. The product of the regulatory gene (the regulatory protein) binds to DNA sequences near the promoter of the target gene and controls whether or not transcription occurs. **B.** Repressor proteins bind to operator sequences and prevent transcription. One type of repressor (scenario 1) releases from the operator *after* binding a chemical ligand (called an inducer) that is specific for that repressor. The target gene is thereby induced. The second type of repressor (scenario 2) must bind a chemical ligand, called a corepressor, *before* it binds to operator DNA. **C.** Activator proteins generally bind to specific chemical ligands in the cytoplasm before the protein can bind to activator DNA sequences near target genes.

repressor. Some repressors bind operator DNA by themselves and prevent transcription (**Fig. 10.1B**, scenario 1). Expression of the target gene requires that a specific ligand, called an **inducer**, bind to the repressor, causing it to release from the operator. Because a small inducer molecule is required, the increased expression of the target gene is called **induction**. The lactose operon, discussed later, is one example of an inducible system.

Other repressor proteins do not bind well to operator DNA unless they first bind a small ligand called a **corepressor** (**Fig. 10.1B**, scenario 2). As the ligand disappears from the cell, it is no longer available to bind to the repressor. When this happens, the repressor releases from the operator and the target gene is expressed. This process is called **derepression** rather than induction. The tryptophan operon, also discussed later, is an example of a repression/derepression system.

Activator proteins, on the other hand, generally bind poorly to activator DNA sequences unless an inducer is present (**Fig. 10.1C**). Most activator proteins, once bound to DNA, directly contact an RNA polymerase molecule stuck at the nearby promoter, spurring it to initiate transcription. When the intracellular concentration of inducer falls, the activator protein (without inducer) either leaves the DNA or moves to a nearby site from which it can no longer contact RNA polymerase. Thus, transcription of that target gene stops.

Sensing the Extracellular Environment

Sensing what goes on outside the cell is more challenging because intracellular regulatory proteins cannot reach through the membrane and touch what is outside. A common mechanism used by gram-positive and gram-negative organisms to transmit information from outside to inside the cell relies on a series of two-protein phosphorylation relay systems. Each protein pair will activate different sets of genes. The first protein in each relay, the **sensor kinase** protein, spans the membrane (**Fig. 10.2**). One end of this sensor protein contacts the outside environment

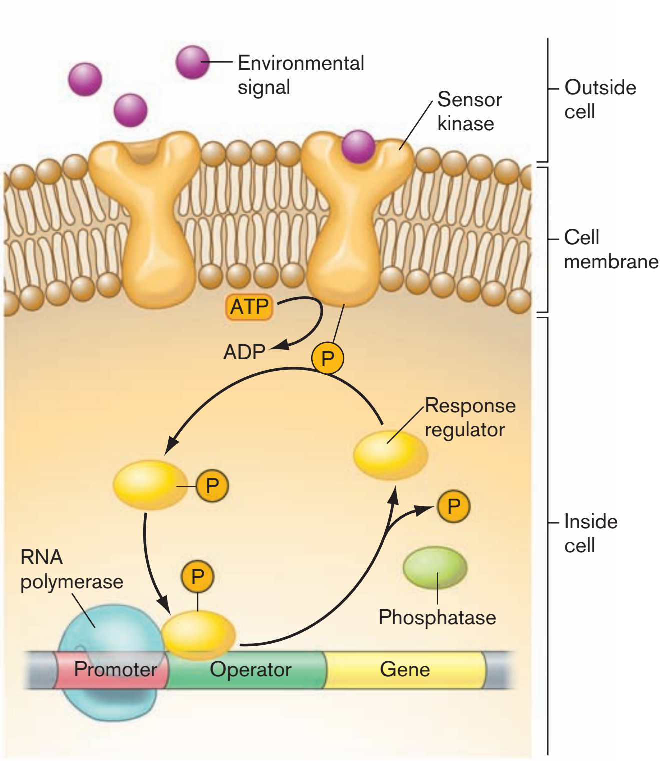

Figure 10.2 Two-component signal transduction systems sense the external environment. A transmembrane sensor kinase protein senses an environmental condition outside the cell (as in gram-positive bacteria) or in the periplasm (as in gram-negative bacteria). Binding of the environmental signal triggers autophosphorylation of the sensor kinase, as shown in the example, and in other instances prevents it. The phosphorylated sensor kinase will then transfer the phosphate to a cognate response regulator protein in the cytoplasm. The response regulator then binds to target operator or activator DNA sequences and inhibits or stimulates gene expression. A phosphatase will downregulate the system by removing the phosphate.

(or periplasm), and the other end protrudes into the cytoplasm. Activating the external sensory domain of the molecule triggers a conformational change in the cytoplasmic part, called the kinase domain. Each sensor protein recognizes a different molecule or condition (for example, PhoQ in *Salmonella* senses magnesium). The altered kinase domain activates a self-phosphorylation reaction that uses ATP to place a phosphate on a specific conserved histidine residue located in a different part of the protein. Then, like two relay runners exchanging a baton, the phosphorylated sensor kinase protein passes the phosphate to a cognate (matched) cytoplasmic protein called a **response regulator**. This transfer, called transphosphorylation, occurs at a specific glutamate residue within the response regulator. The phosphorylated response regulator commonly binds to regulatory DNA sequences in front of one or more specific genes and activates or represses expression. Regulatory relays of this type are called **two-component signal transduction systems**.

Microbes Control Gene Expression at Several Levels

Hundreds of intracellular and extracellular sensing mechanisms monitor the overall health of the cell and its environment. But how do these systems control gene expression?

It is important to note that expression of genes and operons and their products (mRNA, which produces the protein product, or small functional RNAs) can be controlled at various levels. Different levels of control offer different advantages to the cell. The major levels of control can be categorized as DNA sequence controls, transcriptional controls, translational controls, and posttranslational modifications. In general, DNA sequence-level control is the most drastic and the least reversible, whereas control at the protein (translational/posttranslational) level offers the most rapid and reversible control. Examples of these control levels are summarized here and then discussed in detail later in the chapter.

- **Alterations of DNA sequence.** Some microbes can program the mutation of DNA so as to activate or disable a particular gene. An example of such a mechanism is phase variation, in which DNA rearrangement involving the reversible flipping of a DNA segment enables a pathogen to turn on or turn off expression of cell surface proteins to evade the host immune system.
- **Control of transcription and mRNA stability.** Many types of gene regulation occur at the level of transcription. The most common mechanisms of transcriptional control in prokaryotes involve operons. Recall that an operon is a string of two or more genes in a chromosome that are expressed from a common promoter in front of the first gene in the operon. Sets of genes in operons are coordinately regulated by protein repressors, activators, and sigma factors, as well as by small RNAs (sRNA). Coordinate regulation means that the expression of all members of the gene set increase or decrease simultaneously. The regulatory proteins recognize and bind to sequences of DNA usually located within 100–200 bp upstream of the regulated genes. Binding of these regulatory molecules determines how much mRNA is made. **Repressor** proteins, when bound to DNA, *prevent* transcription, while activators stimulate it. Levels of specific mRNA molecules are also regulated by RNase activity, which degrades some mRNA molecules as fast as they are transcribed. In some, but not all, instances, sRNA molecules bind RNA transcripts and help or hinder degradation.
- **Translational control.** Translation by ribosomes can be regulated by *translation initiation sequences* in the mRNA, which recognize specific translational repressor proteins. Translational control mechanisms are often coupled to transcriptional mechanisms, offering "fine-tuning" of operon control. Attenuation, for

instance, is a mechanism that uses *translation* to sense the level of an amino acid in the cell and then increase or decrease transcription of the genes encoding the enzymes that synthesize the amino acid.

- **Posttranslational control.** Once proteins are made, their activity can be controlled by modifying their structure—for example, by protein cleavage, phosphorylation, methylation, or acetylation.

In recent years, studies of bacterial biology have revealed **integrated control circuits** in which all the previously described levels of control work together to coordinately regulate systems throughout the cell. We will discuss examples of integrated control circuits, such as the phage lambda lysis/lysogeny decision and the metabolic/genetic system of nitrogen regulation (see Section 10.7). But first we will explore model examples of control. Most of these examples are at the transcriptional level, which is the level best understood.

TO SUMMARIZE:

- **Regulatory proteins** help a cell sense changes in its internal environment and alter gene expression to match.
- **Repressor and activator proteins** bind to operator and activator DNA sequences, respectively, in front of target genes. Repressors prevent transcription, whereas activator proteins stimulate transcription.
- **Two-component signal transduction** systems also help the cell sense and respond to its environment, both inside and outside.
- **Gene expression** can be controlled at several levels: DNA sequence, transcription, translation, or by modifying the protein posttranslationally.
- **Integrated control circuits** connect many individual regulatory systems to coordinate regulation throughout the cell.

10.2 Paradigm of the Lactose Operon

In 1961, French scientists Jacques Monod (1910–1976) and François Jacob (1920–) proposed the revolutionary idea that genes could be regulated (**Figs. 10.3A** and **B**). They, among others, noticed that the enzyme used by *Escherichia coli* to consume the carbohydrate lactose was produced *only* when lactose was added to growth media. The term *induction* was coined to describe this phenomenon. The enzymes required to metabolize glucose, however, were different. They were always (that is, *constitutively*) present. The groundbreaking work of Jacob and Monod, and of André Lwoff (**Fig. 10.3C**) for his study of phage lysogeny, won them the Nobel Prize and launched the field of gene regulation, a scientific realm where discoveries continue to surprise us. Still, it took many years after Monod and Jacob's discovery to learn exactly how the lactose-degrading enzyme β-galactosidase is induced. Many of the concepts presented here hold for numerous bacterial gene systems.

Lactose Induces Expression of the *lacZYA* Operon

Figure 10.4A shows the genes in *E. coli* that encode the simple regulatory circuit for lactose catabolism. Catabolism is a general term to describe the degradation of an organic food source. The genes *lacZ*, *lacY*, and *lacA* form an **operon**, which is a group of genes cotranscribed from

a common promoter. The *lacY* gene encodes lactose permease (LacY), an integral membrane protein that imports (transports) lactose from the extracellular environment. The product of *lacZ*, β-galactosidase (LacZ), intracellularly cleaves the disaccharide lactose into its component parts, glucose and galactose (**Fig. 10.5**). Both of these sugars are subsequently degraded by the enzymes of glycolysis (Section 13.4). To break down lactose in this way requires synthesis of both β-galactosidase and lactose permease; without these two gene products, the catabolic energy of lactose is unavailable to the cell.

The role of *lacA*, encoding thiogalactoside transacetylase (LacA), is unclear, but it is not needed to ferment lactose. One function may be to detoxify a harmful by-product of lactose metabolism. As we can see, even well-studied systems such as the *lac* operon still pose unanswered questions.

NOTE: Lactose operon, *lac* operon, and *lacZYA* operon all refer to the same system.

THOUGHT QUESTION 10.1 If the gene *lacZ* has a nonsense mutation in its open reading frame, will *lacY* be translated?

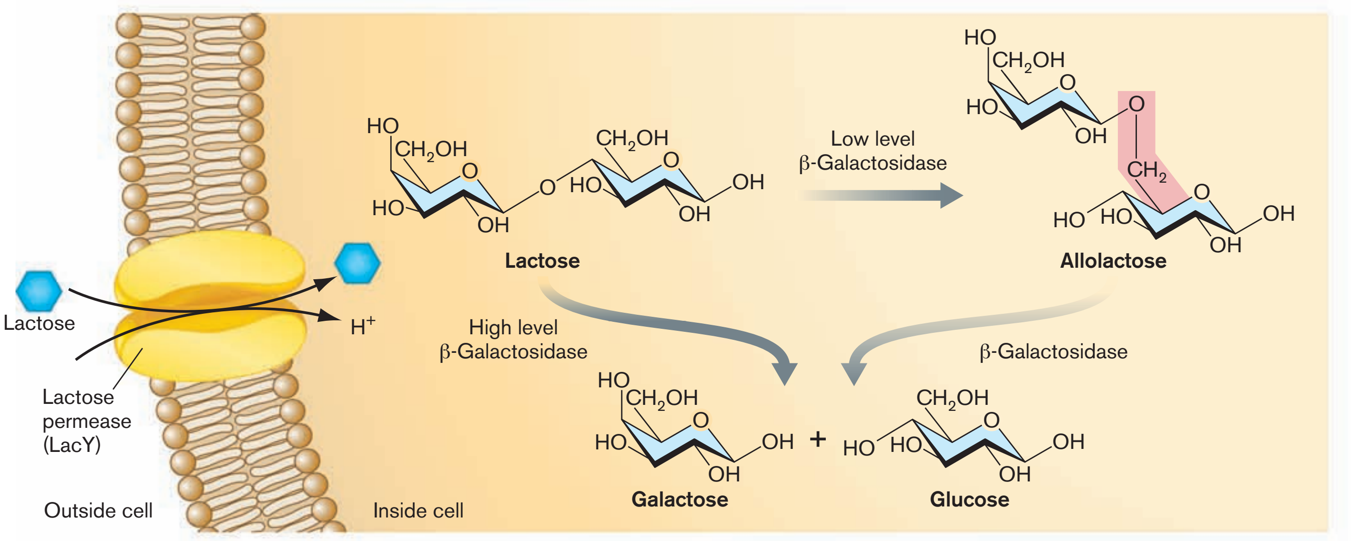

Figure 10.5 Lactose transport and catabolism. A dedicated lactose permease uses proton motive force to move lactose (and a proton) into the cell. Once there, the enzyme β-galactosidase can cleave the disaccharide into its component parts, galactose and glucose, or alter the linkage between the monosaccharides to produce allolactose, an important chemical needed to induce the genes that encode this pathway.

In the absence of lactose, the *lac* operon is transcribed at extremely low levels, generating less than ten molecules of β-galactosidase per cell. The reason is that transcription of *lacZYA* is repressed by the protein product of the regulator gene, *lacI*. The gene *lacI* is situated immediately upstream of *lacZYA* but is transcribed from a different promoter. A tetramer of LacI repressor protein forms in the cell and binds to two regions of DNA called operators. One operator sequence is called *lacO*, which partially overlaps the *lacZYA* promoter (P_{lacZYA}). The second operator site occurs within *lacI* and is called *lacO*$_{\mathrm{I}}$ (**Fig. 10.4A**). The *lac* operators control whether the three structural genes are transcribed. The LacI tetramer simultaneously binds the *lacO* and *lacO*$_{\mathrm{I}}$ operators (a dimer at each site). This causes the intervening DNA to loop out (**Figs. 10.4B** and **10.6A**) and prevents RNA polymerase from continuing transcription into the structural *lacZYA* genes. (A third binding site for LacI exists but is not important to our discussion here.)

Once lactose is added to the medium, the *lac* operon is expressed at 100-fold higher levels. How does lactose get into the cell to induce the operon if the operon encoding its transport protein is not expressed? It turns out that even when the *lacZYA* operon is uninduced, it is constitutively expressed at a low level. This means that lactose can be transported into the cell in low amounts because of constant low-level expression of the lactose transporter LacY. The tiny amount of β-galactosidase (LacZ) that is expressed in uninduced cells is also important. At this low level, the enzyme does not completely *cleave* the glycosidic bond of lactose but rearranges it to form **allolactose**, the form of lactose that activates the operon (the structure of which can be seen in **Fig. 10.5**). Allolactose binds the repressor and "unlocks" the protein, so it is released from the operator (**Fig. 10.4C**). Once this happens, sigma D (the housekeeping sigma factor of *E. coli*, not shown in the figure) can find the *lac* promoter sequences and enable RNA polymerase to initiate transcription of the *lacZYA* structural genes. The roles of cAMP and CRP will be described later.

Glucose Represses the lac Operon

What happens if, in addition to lactose, the medium also contains an alternative carbon source, such as glucose? Enzymes for glucose catabolism (glycolysis) are always produced at high levels because glucose is the favored catabolite (carbon source), providing the quickest source of energy. Many carbohydrates such as lactose must first be converted to glucose to be catabolized. So, should *E. coli* forestall induction of the *lac* operon while glucose is present, in the interest of greater efficiency? In fact, this is precisely what happens. The repression of an operon enabling catabolism of one nutrient by the presence of a more favorable catabolite (commonly glucose) is known as **catabolite repression**.

When glucose and lactose are both present in the medium, cells grow by breaking down glucose until the glucose is depleted; then growth stops. At this point, the cells sense a need for carbon and induce the *lacZYA* operon (because lactose is present). This allows them to begin consuming lactose and reinitiate growth. The biphasic curve of a culture growing on two carbon sources is often called **diauxic growth** (**Fig. 10.7A**). But, if lactose was present from the start, why was *lacZYA* turned off? The answer is that glucose actively *prevents* the induction of *lacZYA*. **Figure 10.7B** illustrates that even when *lacZYA* is already induced, adding glucose stops (or represses) induction.

Figure 10.7 Catabolite repression of the *lacZYA* operon. A. The diauxic growth curve of *E. coli* growing on a mixture of glucose and lactose. **B.** Glucose repression of LacZ (β-galactosidase) production. Lactose was added at the beginning of the experiment into parallel cultures, and β-galactosidase activity was measured. At the point indicated, glucose was added to one culture. The synthesis of β-galactosidase continues to increase in the culture without glucose but stops in the culture with glucose. **C.** Although the inducer allolactose removes the repressor LacI and allows expression of *lacZYA*, maximum expression requires the presence of cAMP and cAMP receptor protein (CRP, also known as CAP for catabolite activator protein), which bind to a separate site at the *lacZYA* promoter. Bound CRP can interact with RNA polymerase and increase the rate of transcription *initiation*.

Catabolite Repression Changes the Level of Cyclic AMP

Catabolite repression of the lactose operon by glucose occurs because growth of *E. coli* on glucose prevents the synthesis of the nucleotide cyclic AMP (cAMP). This molecule, which activates numerous operons, including *lacZYA*, is a derivative of AMP in which the 5′ phosphate is linked to the 3′ OH group of the ribose, making a cyclic bond. Cyclic AMP controls the expression of many genes by combining with a dimeric regulatory protein called cAMP receptor protein (CRP). The cAMP-CRP complex binds to specific DNA sequences located near many bacterial genes and modifies their transcription, usually acting as an activator. This is the case for the *lacZYA* operon (**Figs. 10.7C** and **10.4C**).

NOTE: The original name for CRP was catabolite activator for protein (CAP), given to reflect its role in catabolite repression. Though some investigators still use the CAP designation, the term CRP is generally preferred today. Thus, the gene encoding the protein is called *crp*.

Glucose inhibits cAMP production by a clever mechanism that ties the synthesis of cAMP, catalyzed by adenylate cyclase (**Fig. 10.8**), to the transport of glucose. Many sugars, including glucose, are transported by the multicomponent phosphotransferase system (PTS; see Section 4.2). This system transfers a phosphate group from phosphoenolpyruvate (PEP), along a series of protein intermediates, ending with different membrane transport proteins that import specific carbohydrates. The carbohydrate-specific membrane proteins pass the phosphate to the sugar during transport. The glucose-specific PTS relay includes a cytoplasmic protein called IIA^{Glc} and the integral membrane protein IIBC^{Glc}. Protein IIA^{Glc} is the key to glucose repression.

NOTE: IIA^{Glc} and IIBC^{Glc} are also referred to as Enz IIA and Enz IIBC in the literature.

Glucose is changed to glucose 6-phosphate during its transport through the PTS system. Thus, as the cell imports glucose, phosphate is continually removed from IIA^{Glc}, making unphosphorylated IIA^{Glc} the predominant form of the protein. This is important because unphosphorylated IIA^{Glc} interacts with and inhibits adenylate cyclase activity (**Fig. 10.8A**). The net effect of inhibiting adenylate cyclase is that cAMP levels fall. This happens because cAMP synthesis stops and because cAMP is continually degraded by cAMP phosphodiesterase. This is the basis of glucose repression.

If, however, glucose is not in the medium and therefore is unavailable for transport, the phosphorylated form of IIA^{Glc} accumulates because there is no sugar to receive the phosphate (**Fig. 10.8B**). Because the phosphorylated protein $\text{IIA}^{\text{Glc}}\text{-P}$ does *not* interfere with adenylate cyclase, cAMP levels rise and complex with CRP, enabling CRP-dependent, catabolite-repressible genes such as the *lac* operon to be expressed. Thus, catabolite repression by glucose is linked to glucose transport in *E. coli*.

Figure 10.8 Control of adenylate cyclase via the phosphotransferase system. A. When glucose is present, the phosphorylated forms of IIA^{Glc} are low because glucose siphons off the phosphate. IIA^{Glc} then interacts with and inhibits adenylate cyclase activity. **B.** In the absence of glucose, the phosphorylated forms of glucose-specific IIA^{Glc} and IIBC^{Glc} accumulate because they cannot pass the phosphate to substrate (there is no glucose). Adenylate cyclase functions in this situation to produce cAMP. The inset on the right shows the conversion of ATP to cyclic AMP by adenylate cyclase. The figure illustrates control over adenylate cyclase activity.

In contrast to gram-negative bacteria, cAMP is not generally found in gram-positive bacteria. Catabolite repression in these organisms is mediated by other mechanisms.

Activation of Transcription by cAMP-CRP

How does the cAMP-CRP complex ultimately activate the expression of *lacZYA*? RNA polymerase cannot easily form an open complex and is essentially "stuck" at *lacP* and other CRP-dependent promoters, even in the absence of a repressor. This problem is overcome when the cAMP-CRP complex binds to a 22-bp DNA sequence located –60 bp from the start of transcription (just upstream of the *lacZYA* operator), which causes the DNA to curve (see **Figs. 10.4D** and **10.6C**). CRP can then directly interact with RNA polymerase bound at the *lac* promoter.

Interaction with RNA polymerase at the *lac* promoter and at the promoters of several other genes typically occurs at the C-terminal domain of the RNA polymerase alpha subunit (**Fig. 10.9**, class I promoters). With some other promoters affected by cAMP, CRP can also engage the N-terminal domain of the alpha subunit (Fig. 10.9, class II promoters). These protein-protein interactions stimulate RNA polymerase bound at the promoter to initiate transcription. Notice in Figure 10.6B that when neither glucose nor lactose is present, cAMP-CRP cannot by itself activate *lacZYA* transcription because it binds within the DNA loop formed by the LacI tetramer, so there is no room for RNA polymerase to bind to DNA.

There are three classes of promoters requiring CRP activation, with each class differing in where CRP binds. CRP binds class I, II, and III promoters at –60 bp, –41 bp, and –90 bp, respectively, from the start of transcription. The differences in binding location reflect the amount of "encouragement" a particular RNA polymerase–promoter complex must receive from CRP to change from a closed promoter complex to the open promoter complex necessary for transcription. The C terminus of the RNA polymerase alpha subunit can bind DNA sequences near certain promoters and inhibit RNA polymerase movement. When cAMP-CRP touches regions in the C terminus of the alpha subunit, this inhibition is relieved. This contact is enough to stimulate class I promoters (such as *lacP*). In class II promoters, however, where CRP binding overlaps the –35 promoter region, CRP also touches the N terminus of the alpha subunit, which, along with contact at the C terminus, is needed to stimulate transcription. CRP essentially strengthens a weak –35 site. Transcription of class III promoters requires activator proteins in addition to CRP (see the discussion of the arabinose operon in Section 10.3).

Figure 10.9 CRP interactions with RNA polymerase. There are three classes of CRP-dependent promoters, which differ as to where CRP binds relative to the promoter region. Class I promoters, like the one at the *lacZYA* operon, possess a CRP-binding site positioned around –60 bp from the transcriptional start. CRP on these promoters interact with the alpha subunit C-terminal domain (αCTD) of RNA polymerase. The CRP-binding site on class II promoters (–41 bp) overlaps the RNA polymerase (RNAP)-binding site, allowing CRP to interact with the C-terminal and N-terminal domains of the alpha subunit. CRP binds the third class of promoter (not shown) at –90 bp.

WWW | Catabolite activator protein, Biomolecules at Kenyon

NOTE: In presenting a genotype, gene names written *with* a superscript + are considered wild-type. Gene names written *without* a superscript + are considered mutant genes. Also recall that writing a gene name in roman (not italic) type and with a capital first letter is really the name of the protein product of that gene. Thus, *lacZ* is the gene, but LacZ is the protein.

THOUGHT QUESTION 10.2 Null mutations completely eliminate the function of a mutated gene. Predict the effect of the following null mutations on the induction of β-galactosidase by lactose and predict whether the *lacZ* gene is expressed at high or low levels: *lacI*, *lacO*, *lacP*, *crp*, *cya* (the gene encoding adenylate cyclase). Also, what effect will those mutations have on catabolite repression?

THOUGHT QUESTION 10.3 Predict what will happen to the expression of *lacZ* under the following partial diploid conditions (see Section 9.1). The genotypes of these strains are presented as follows: chromosomal genes/plasmid gene. (a) $lacI\ lacO^+P^+Z^+Y^+A^+$/plasmid $lacI^+$; (b) $lacO\ lacI^+P^+Z^+Y^+A^+$/plasmid $lacO^+$; (c) crp $lacI^+O^+P^+\ Z^+Y^+A^+$/plasmid crp^+.

Glucose Also Causes Inducer Exclusion

Failure of lactose to induce *lacZYA* during growth on glucose (**Fig. 10.7B**) is partly due to the effect of the PTS protein IIA^{Glc} on cAMP levels, but it is not the whole story. Growth on glucose also keeps lactose out of the cell. This phenomenon is known as **inducer exclusion**. As already noted, glucose transport results in the accumulation of the unphosphorylated PTS protein IIA^{Glc} in the membrane. The unphosphorylated form of the protein binds to and inhibits the activity of certain non-PTS carbohydrate permeases, like LacY, the transporter for lactose. Shutting transport down keeps the inducer out, which, in the case of lactose, prevents *lacZYA* expression. The precise nature of the communication between these two proteins is not well understood.

THOUGHT QUESTION 10.4 Researchers often use isopropyl-β-D-thiogalactopyranoside (IPTG) rather than lactose to induce the *lacZYA* operon. IPTG structure resembles lactose, which is why it can interact with the LacI repressor, but it is not degraded by β-galactosidase. Why do you think the use of IPTG is preferred in these studies?

TO SUMMARIZE:

- **The lactose utilization *lacZYA* operon** of *E. coli* was the first gene regulatory system described.
- **LacI binds as a tetramer** to the operator region and represses the *lac* operon by preventing open complex formation by RNA polymerase.
- **β-galactosidase (LacZ)**, when at low concentration, cleaves and rearranges lactose to make the inducer allolactose.
- **Allolactose complexes to LacI**, reducing repressor affinity for the operator and allowing induction of the operon.
- **The cAMP-CRP complex** binds to the *lac* operator region and stimulates RNA polymerase through CRP interaction with the C-terminal domain of the RNA polymerase alpha subunit. cAMP-CRP regulates many types of operons.
- **Catabolite repression** is a process whereby a preferred carbon source, such as glucose, will prevent induction of the *lac* operon by lactose. Catabolite repression works by lowering cAMP levels.
- **Glucose transport through the phosphotransferase system** inhibits adenylate cyclase, the enzyme that makes cAMP, and inhibits function of the LacY permease.

10.3 Other Systems of Operon Control

The lactose operon is not the only model of regulation. Many other mechanisms that regulate genes and operons are utilized by bacteria. In this section, we discuss proteins that have dual regulatory functions—that perform as both activators (positive control) and repressors (negative control). We will also see how the coupling of transcription and translation is used to regulate gene expression by attenuation and how an idling ribosome sends a chemical signal that affects the expression of many genes and operons.

Repression of Anabolic (Biosynthetic) Pathways

Many different gene systems use repressor proteins to inhibit transcription. Repressing biosynthetic pathways is fundamentally different from repressing catabolic (degradative) systems. Repressor proteins that control catabolic pathways, such as lactose degradation, typically bind the initial substrate or a closely related product (for example, allolactose in the case of the *lac* operon). Binding the substrate decreases repressor protein affinity for operator DNA. Thus, increased concentration of the substrate or inducer actually removes the repressor from the operator and *derepresses* expression of the operon. This derepression makes sense because the cell wants to make the enzymes that use the substrate as a carbon and energy source.

In contrast, genes encoding biosynthetic enzymes are regulated by repressors (called inactive aporepressors) that must bind the end product of the pathway (for example, tryptophan for the *trp* operon) to become active repressors. The end product that binds the aporepressor is called a corepressor. Binding of the corepressor (end product) to the repressor increases the repressor's affinity for the operator sequence upstream of the target gene or operon. As the concentration of end product, such as an amino acid or nucleotide, increases in the cell beyond that needed to support growth, the cell will shut the biosynthetic pathway down and not waste energy making a superfluous pathway or compound.

The AraC Regulator Activates and Represses Transcription

The *lac* operon regulatory paradigm is a wonderful way to regulate gene systems involved in catabolism. What could

Special Topic 10.1 How Do We Study Protein-DNA Binding?

A long series of painstaking experiments led to the discovery of how the *lac* operon is regulated, but current techniques have made it much easier to study how DNA and proteins interact and how these interactions control gene expression. Three experimental techniques are widely used to show whether a protein binds DNA and to determine where it binds.

Sequence Analysis

DNA sites that bind regulatory proteins typically exhibit a sequence symmetry that allows unambiguous recognition. Dimers of a regulatory protein bind to the DNA, with each member of the duo binding half of the symmetrical DNA sequence. Symmetry usually involves an inverted repeat (**Fig. 1**). Once a potential regulatory protein and a presumed target gene have been identified, the DNA sequence extending 200–300 bp upstream of the target gene's transcriptional start site is examined using computer programs designed to reveal possible binding sites. Finding an inverted repeat within 100–200 bases of a promoter suggests the presence of a regulatory binding site. Finding very similar sequences in front of two or more different promoters controlled by the same regulatory protein is stronger evidence that, in fact, the sequences represent regulatory binding sites. Proof ultimately requires showing that the protein will bind a piece of DNA containing this sequence. Protein-DNA binding can be demonstrated in several ways, as described below.

Electrophoretic Mobility Shift Assay

DNA fragments containing the suspected binding site are generated by PCR and radiolabeled. The labeled target fragment is then mixed in vitro with purified regulatory protein and subjected to electrophoresis through a nondenaturing polyacrylamide gel. The fragment alone will travel quickly through the gel matrix, but if a DNA-protein complex forms in the lane loaded with protein *and* the DNA fragment, it will travel more slowly due to its larger size. Thus, a shift in position of a DNA band indicates DNA-protein binding. This technique is called an **electrophoretic mobility shift assay (EMSA)** or gel shift (**Fig. 2**).

Figure 1 Examples of DNA regulatory sequences. The sequences shown are located upstream of the genes noted in italics. Inverted repeats are shown in yellow. Note that in some inverted repeats, the occasional base is not repeated (only those bases that repeat are highlighted in the diagram). Arrows indicate direction of symmetry.

DNA Footprinting

Once a DNA fragment that binds the regulator has been identified, it is useful to determine the specific DNA sequences that contact the protein. One way to define where a regulatory protein contacts DNA is to allow the protein to bind the DNA and then to treat the complex with a DNase (**Fig. 3**). The area of DNA in close contact with the regulatory protein will be protected from the cleaving enzyme.

The basic procedure is to radiolabel the 5′ end of *one* strand before adding DNase. Just enough DNase is added so that each individual DNA molecule is cut only once. The result-

be better than having a substrate induce expression of the operon needed to catabolize it? How about a regulator that can repress *or* activate gene expression, depending on whether substrate is available? This would provide very tight control over the synthesis of catabolic enzymes and enable an accelerated induction. One such regulator, called AraC, regulates the genes encoding arabinose catabolism. When arabinose is absent, AraC represses

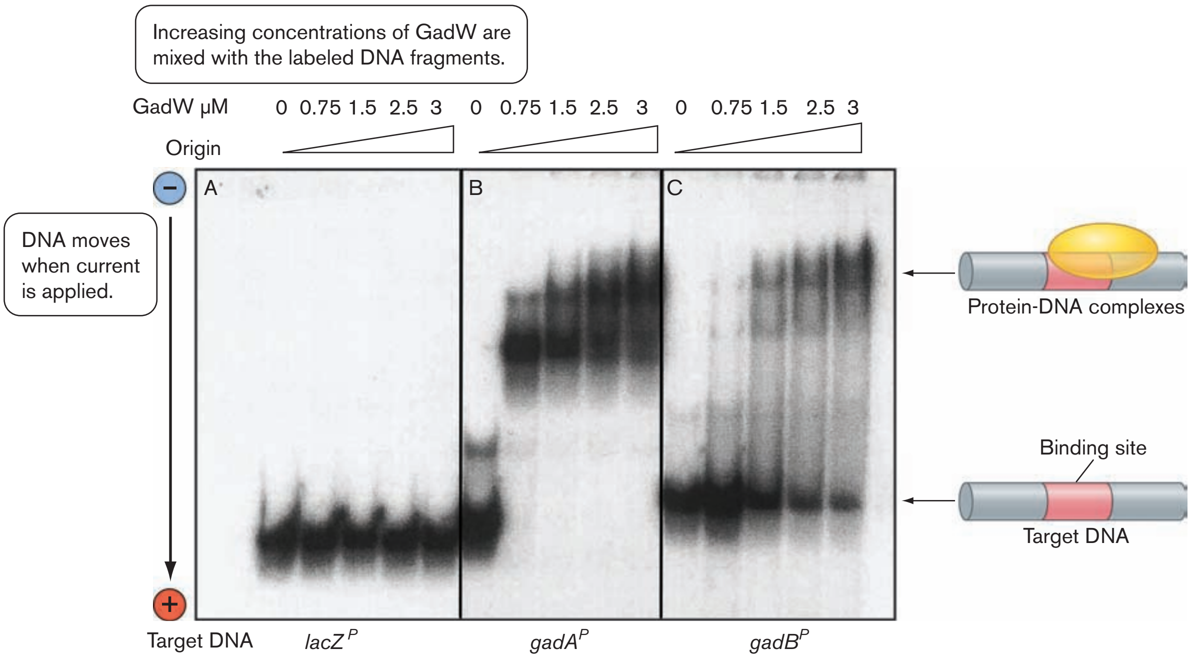

Figure 2 Electrophoretic mobility shift assay (EMSA). To test DNA-protein interactions, target DNA fragments (roughly 50–1,000 bp in length) are labeled at the 5′ end with a radioactive phosphate group (^{32}P) from ATP. The fragment may then be visualized using X-ray film. Varying concentrations of the protein are mixed with the labeled DNA fragments and loaded at the top of a polyacrylamide gel. Because DNA is negatively charged, it will move toward the positive pole (bottom of gel) once a current is applied. Free (unbound) DNA will travel most quickly down the gel, while DNA bound to protein is larger and travels more slowly. This figure illustrates the addition of increasing concentrations of a protein regulator called GadW to three DNA fragments: the promoter regions of *lacZ* (panel **A**) and the two genes encoding glutamate decarboxylase, *gadA* (panel **B**) and *gadB* (panel **C**). Glutamate decarboxylase is an enzyme that contributes to *E. coli*'s resistance to extreme acid (pH 2) environments. After electrophoresis, the gel is dried by vacuum and exposed to X-ray film. No shift in fragment mobility is seen in panel A, meaning GadW does not bind to the promoter for *lacZ*. The progressively slower band movements seen in panels B and C with increasing concentrations of GadW indicate that this regulator will bind the *gad* promoters. *Source:* A–C. ©American Society for Microbiology, *Journal of Bacteriology.* 2002. 184:7001–7012.

ing fragments of varying size are then separated by gel electrophoresis and visualized by autoradiography. A DNA sequence ladder of the same strand is run parallel to the DNase-treated lanes. (See DNA sequencing, Fig. 7.29.) A DNase-treated band and a DNA sequence band that are the same size will end with the same base. So a band in the DNase lane whose sequence matches in size a G (guanosine)-ending band in the DNA sequence lane will itself end in G. Ideally, unprotected DNA cut with DNase will yield as many fragments as it has bases. DNA protected by a binding protein, however, will leave a "footprint" where the binding protein comes in close proximity to DNA. Because DNase cannot cut DNA protected by the protein, bands generated by cuts in the region of the DNA that binds to the protein will disappear. Thus, by observing the DNA sequencing lanes, the sequence of DNA covered or protected by the protein can be determined.

(*continued on next page*)

expression of the genes that break down arabinose; when arabinose is present, AraC activates these same genes. The products of these genes ultimately convert the five carbon sugar L-arabinose to D-xylulose 5-phosphate, an intermediate in the pentose phosphate shunt, a pathway that provides reducing energy for biosynthesis (see Section 15.2). It turns out that many regulatory systems, including some virulence regulators, use AraC-type regulation.

Figure 3 DNA footprinting. **A.** DNA fragments are labeled with ^{32}P at just one 5′ end to tag one strand. The DNA-binding protein (for example, a repressor or activator protein) is added to the appropriate tube (right side). Mixtures with binding protein (protected) and without binding protein (unprotected) are treated with a DNase. The area of DNA bound by the regulatory protein will be protected from DNase digestion. Just enough DNase is added to nick each DNA molecule only once (indicated by vertical arrows). Each molecule will be a different size, depending on where the enzyme cut. The mixtures are loaded onto a polyacrylamide gel (bottom) to separate the fragments by size. The original uncut fragment is sequenced and loaded into adjacent lanes (lanes 1–4). The size of each footprint fragment (lanes 5 and 6) can be compared with the sequencing ladder to determine at which base the DNase has cut. **B.** An actual footprint showing where RNA polymerase and LacI bind to the *lacP* partial sequence (lanes 1 and 2). In the figure, lane 1 shows fragments that end in G or A and lane 2 shows fragments that end in C. The unprotected digest of the DNA fragment is in lane 3, the DNA fragment plus RNA polymerase is in lane 4, and the DNA fragment plus LacI repressor protein is in lane 5. Note that the area protected by the repressor overlaps the area protected by RNA polymerase. From this, one can conclude that repressor bound to the DNA will prevent RNA polymerase access to this promoter. *Source*: B. Albert Schmitz and David J. Galas, Department de Biologie Moleculaire, University de Geneve.

The *ara* operon. Part of the operon encoding the arabinose degradation enzymes is shown in **Figure 10.10A**. Note that the *ara* operon is transcribed divergently from a central promoter region. The structural genes (*araBAD*) are transcribed in one direction and the regulator gene, *araC*, is transcribed in the opposite direction. The product of *araC* is a 33-kDa protein (AraC) with two domains: the C-terminal end and the N-terminal end (**Fig. 10.10B**). The C-terminal end contains a DNA-binding domain that contains two helix-turn-helix motifs. Helix-turn-helix motifs are made up of two alpha helices separated by a short amino acid chain that allows a bend. Usually, the helix closer to the C terminus fits into the major groove of the target DNA. The C-terminal DNA-binding domain is attached by a flexible linker peptide to an N-terminal dimerization domain. AraC forms a dimer in vivo that can assume one of two conformations depending on whether arabinose is available. When arabinose is absent, the dimer exists in a rigid, elongated form that represses expression of the machinery for arabinose degradation (*araBAD*). When arabinose is present, it binds to the dimer, which then assumes a more compact form that activates expression of *araBAD* (**Fig. 10.10C**).

The flexible N-terminal arm of an AraC monomer is the key to determining what type of dimer forms. When

The structural genes (*araBAD*) are transcribed in the opposite direction of the regulator gene, *araC*.

AraC forms a dimer. When bound to arabinose, the N-terminal arm binds to the C terminus of the same molecule. Without arabinose, the N-terminal arm binds the C terminus of the other AraC subunit.

Elongated AraC binds at *araI* and *araO*$_2$ and the DNA forms a loop.

Compact AraC binds at *araI*$_1$ and *araI*$_2$, and interacts with RNA polymerase to permit *araBCD* transcription. Arabinose is catabolized.

AraC in this position cannot interact with RNA polymerase bound at the P$_{araC}$ promoter, so *araBCD* is not transcribed.

Figure 10.10 Regulation of *araBAD* operon by the AraC regulator. A. Divergently transcribed *araC* and *araBAD* operons showing binding sites for the AraC and CRP proteins. The region shown is about 400 bp. **B.** View of AraC showing dimerization and DNA-binding domains. **C.** Alternative conformations of AraC dimers. The different conformations change the location of where the dimer can bind DNA. (Note that O_1 and O_2 are operators, and I_1 and I_2 are other DNA-binding sites that, when occupied by AraC, induce expression.)

arabinose is not present, the N-terminal arm of an AraC monomer binds to the C domain of the same molecule, forming a rigid, extended structure. However, when arabinose docks to its binding site in the AraC protein, the N arm can bend and bind to the C domain of its partner protein, producing a more compact structure. **Figure 10.10C** shows the alternative dimerization configurations of the AraC N-terminal domain in the absence and presence of L-arabinose.

So how does AraC act as both repressor and activator? First, unlike the *lac* repressor, AraC does not function by denying RNA polymerase access to the promoter. Instead, AraC represses *araBAD* expression by producing a looped DNA structure that limits activation by cAMP-CRP, which, as discussed in Section 10.2, is a global regulator of many bacterial genes. Then, when placed in the right position on the DNA, AraC, as well as CRP, can activate *araBAD* transcription by physically contacting an RNA polymerase complex that is already bound to the promoter.

There are four DNA sites to which AraC can bind, as illustrated in **Figure 10.10C**. With arabinose absent, the elongated, repressor form of the AraC dimer (AraC$_2$) can only bind the widely separated sites I$_1$ and O$_2$, causing the intervening DNA to form a loop. This positions AraC too far from the *araBAD* promoter to ever interact with RNA polymerase. The loop also prevents CRP from interacting with RNA polymerase. However, the compact, inducer form of AraC$_2$, formed by the binding of arabinose, can bind to the DNA sites I$_1$ and I$_2$ (I represents inducer site), which are closer to the promoter. This places AraC closer to an RNA polymerase idling on the *araBAD* promoter and allows the two complexes to touch. This contact releases RNA polymerase from the promoter and allows it to move into and transcribe the *araBAD* structural genes. This position also allows bound CRP to activate expression. **Figure 10.11** illustrates the structural effect of arabinose on the N-terminal dimerization domain of AraC. The binding of arabinose to AraC engineers dimerization through interactions between coiled-coil alpha-helical regions of the protein.

Advantages of the activator-repressor strategy. This system offers an advantage over a simple repressor circuit. In the *lac* operon, LacI repressor must fully dissociate from operator DNA during induction and ends up dispersing throughout the cell, often nonspecifically binding to other DNA sequences. Reestablishing repression requires random diffusion of LacI protein back to the *lacO* DNA sequence. This takes some time because random diffusion of bulky proteins in the cytoplasm is slow. In contrast, AraC protein rarely leaves the vicinity of the *ara* operon. The response of AraC to varying levels of arabinose allows AraC to simply shuttle back and forth between repressor and activator sites, shortening the delay between induction and repression. The inducer arabinose is relatively small; thus, it can diffuse quickly throughout the cell to find AraC positioned at the promoter.

This is a common structure present in many DNA-binding proteins. The helix-turn-helix is able to fit into the major groove of a DNA molecule. (PDB code: 2ARC)

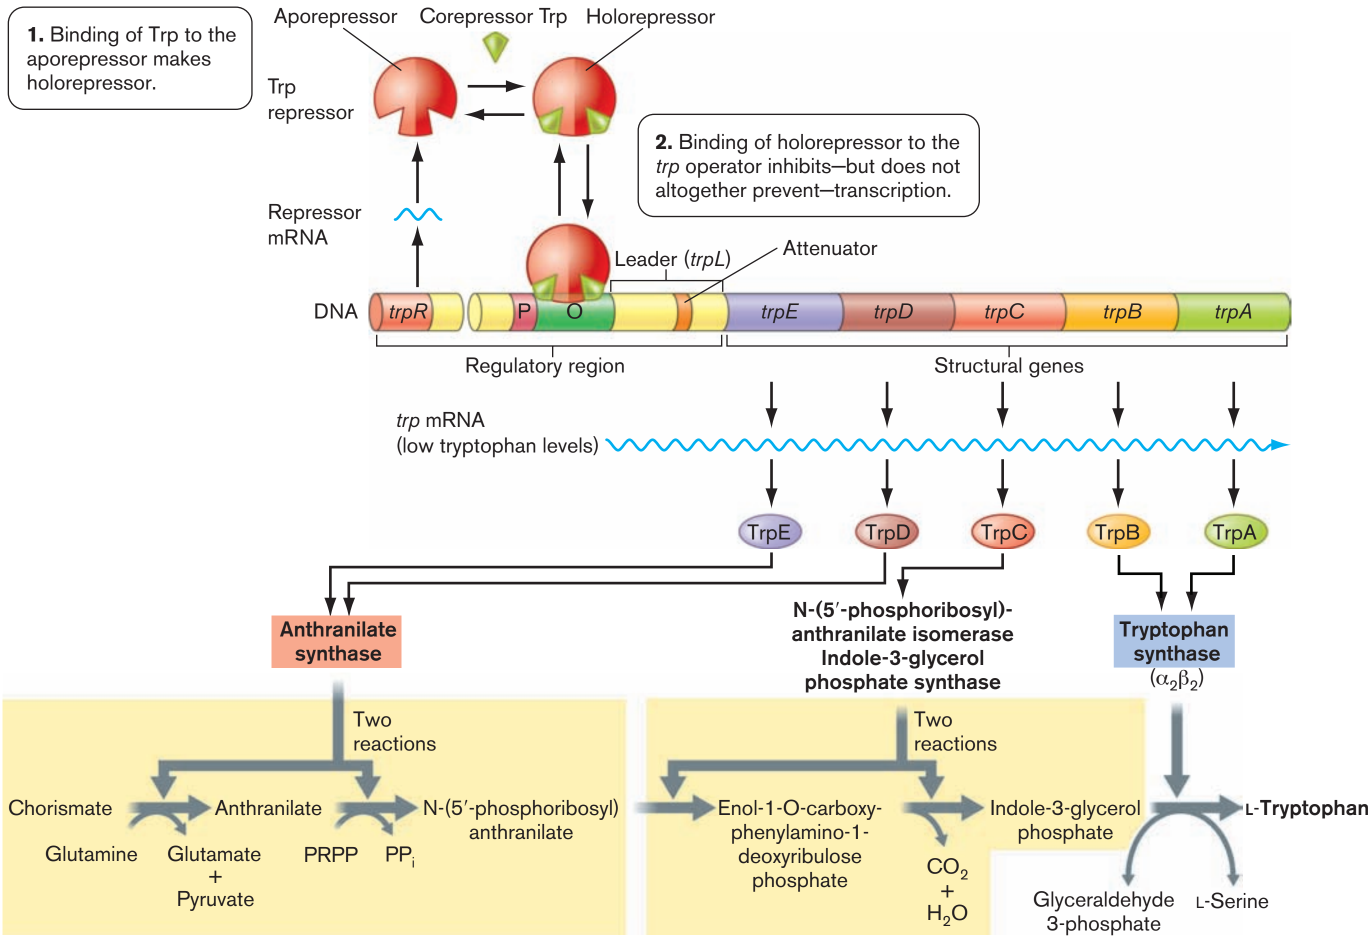
AraC-like Regulators: A Diverse Group of Intracellular Sensors

Computer analysis of numerous microbial genomes reveals a family of over 800 regulators that share a 100-amino-acid region of homology with AraC and the closely related XylS activator (xylose catabolism). This signature sequence, found at the C-terminal end of AraC, forms an independently folding domain that contains two helix-turn-helix DNA-binding motifs. The AraC/XylS family members regulate a variety of different cell functions, including carbon metabolism and virulence, as well as many responses to environmental conditions.

Although family resemblance is strong at the DNA-binding domains of these AraC-like proteins, homology usually evaporates at the other end of the protein, known as the dimerization domain. The nonfamily domain is where these proteins appear to bind or respond to some ligand (for example, arabinose). However, for many, if not most, of the AraC/XylS family members, the identity of the ligand remains a mystery.

In Attenuation, Translation Regulates Transcription

As noted previously, many amino acid biosynthetic pathways are controlled by transcriptional repression in which a repressor protein binds to a DNA operator sequence to prevent transcription. For instance, when internal tryptophan levels exceed cellular needs, the excess tryptophan (acting as a corepressor) will bind to an inactive aporepressor protein, TrpR, converting it to an active holorepressor (**Fig. 10.12**). TrpR holorepressor then binds to an operator DNA sequence positioned upstream of the tryptophan operon (*trp* operon), which encodes the enzymes required for tryptophan biosynthesis. Holorepressor bound to the *trp* operator represses expression by blocking



1. Binding of Trp to the aporepressor makes holorepressor.

2. Binding of holorepressor to the *trp* operator inhibits—but does not altogether prevent—transcription.

Figure 10.12 The tryptophan biosynthetic pathway in *E. coli* and repression of the tryptophan operon. The tryptophan biosynthetic enzymes and their encoding genes. TrpR aporepressor (inactive repressor) binds excess tryptophan when intracellular concentration exceeds need. The holorepressor (active repressor) then binds to the *trp* operator and prevents transcription. Note the long polycistronic message in blue. Repression lowers expression about 100-fold.

RNA polymerase. But repression is not the whole story in regulating the *trp* operon. Many amino acid biosynthetic operons, including the *trp* operon, have adopted a second strategy for downregulating tryptophan synthesis, which can be used alone or in conjunction with repression. This second mechanism is called **transcriptional attenuation**. Attenuation uses the ribosome as a sensor of amino acid levels. It is a transcriptional control mechanism in which the ability to *translate* part of an mRNA determines whether the RNA polymerase that began transcribing the operon is allowed to continue downstream transcription. Because attenuation halts transcription in progress, it affords an even quicker response to changing amino acid levels than simple repression.

Transcriptional attenuation was discovered by Charles Yanofsky and his colleagues at Stanford University. While examining the beginning of the *trp* operon in *E. coli*, they discovered an odd DNA region located between the *trp* operator and the first structural gene, *trpE*. This region, called the **leader sequence**, does not directly control the biosynthesis of tryptophan, but instead determines whether or not RNA polymerase, already authorized to begin transcription, is granted permission to proceed into the *trp* structural genes. The leader sequence encodes a peptide, but the peptide has no enzymatic function. The importance of the leader sequence lies in a pair of tryptophan codons (UGGUGG) imbedded within it. The act of translating those codons couples the intracellular level of tryptophan (measured as charged tryptophanyl-tRNA) to transcription. If the level of tryptophan is sufficient to maintain a level of charged tryptophanyl-tRNA adequate to support growth at a rapid growth rate, the mRNA of the leader region jettisons RNA polymerase before it reaches *trpE*, the first structural gene involved in the biosynthesis of tryptophan.

The attenuation mechanism hinges on four complementary nucleotide stretches within the leader mRNA. These regions, numbered 1 through 4, can base pair to form competing stem loop structures (**Fig. 10.13A**). Two of the stem loop structures are critical to the mechanism. These are the **anti-attenuator stem loop** formed by regions 2 and 3 and the **attenuator stem loop** (or terminator stem loop) formed by regions 3 and 4. If the 3:4 attenuator stem loop forms, then the RNA polymerase is ejected and transcription stops (**Fig. 10.13B**). Formation of the 2:3 anti-attenuator stem loop, however, prevents formation of the 3:4 stem loop because the 2:3 stem is longer than the 3:4 stem and, thus, more thermodynamically stable. The anti-attenuator stem allows RNA polymerase to transcribe into *trpE* (**Fig. 10.13C**). What controls which stem loop forms?

High tryptophan levels. When the cell is replete with charged tryptophanyl-tRNA and needs no more, the ribosome quickly translates through the key Trp codons and runs into a translation stop codon between regions 1 and 2. The ribosome in this position envelops region 2 and prevents formation of the 2:3 stem. As a result, once RNA polymerase transcribes through region 4, the 3:4 attenuator stem snaps together. This structure interacts with the RNA polymerase ahead of it and halts transcription. As you would expect, the ribosome dissociates after reaching the region 2 stop codon, but because the 3:4 stem loop is already in place, a 2:3 stem loop does not form. Ribosome release, therefore, leads to formation of a 1:2 stem structure, precluding all possibility of regions 2 and 3 annealing.

Low tryptophan levels. However, if the level of charged tryptophanyl-tRNA is low, the ribosome following behind RNA polymerase stalls over the tryptophan codons. Because these codons occur right before region 1, the ribosome does not cover and protect region 2. As soon as RNA polymerase transcribes region 3, the 2:3 anti-attenuator stem loop forms and precludes formation of the 3:4 attenuator stem loop. The result is that RNA polymerase can continue into the structural genes, and ultimately more tryptophan is made. Transcriptional attenuation is a common regulatory strategy used to control many operons that code for amino acid biosynthesis.

NOTE: Even though translation is part of the attenuation control mechanism, attenuation is not considered translational control. This is because RNA polymerase, rather than the ribosome, is the target of the control. Translational control of gene expression will be discussed later.

When Energy Sources Dwindle, Ribosome Synthesis Slows

During transitions from nutrient-rich to nutrient-poor conditions, microbes must contend with dramatic fluctuations in growth rate. This presents a problem. When a cell is growing rapidly, its molecular machinery is geared for peak performance, and the synthesis of new ribosomes is frenetic, trying to keep pace with rapid cell division. The more ribosomes a cell contains, the faster that cell can make new proteins and the faster it can grow. But what happens when the party's over—when poor carbon and energy sources cannot supply enough energy to maintain rapid cell division? Without a way of curbing ribosome construction, cells would soon fill with idle ribosomes. Under these conditions, bacteria undergo a process called the **stringent response**. The stringent response causes a decrease in the number of rRNA transcripts made for

ribosome assembly and alters the expression of numerous other genes.

In the stringent-response strategy, idling ribosomes produce a signal molecule called guanosine tetraphosphate (ppGpp) that interacts with RNA polymerase and lowers its ability to transcribe genes encoding ribosomal RNA (**Fig. 10.14**). How is ppGpp made? When there is an uncharged tRNA bound at the ribosome A site, which can happen during amino acid starvation, a ribosome-associated protein called RelA transfers phosphate from ATP to GTP to form ppGpp. This signal nucleotide interacts with the beta subunit of RNA polymerase and

Figure 10.14 **Ribosome-dependent synthesis of guanosine tetraphosphate and the stringent response.**

diminishes its recognition of promoters for operons producing rRNA and tRNA. The result is the downregulation of rRNA and tRNA synthesis. The less rRNA scaffolding there is available for building ribosomes, the fewer ribosomes will be produced.

This raises another question. Even though the synthesis of ribosomal RNA has been curtailed, won't the cell continue to waste resources on the synthesis of ribosomal proteins? It turns out that some ribosomal proteins can bind to the mRNA that encodes them and inhibit translation. So when there is less rRNA in the cell, free ribosomal proteins accumulate in the cytoplasm, unassociated with ribosomes. These excess ribosomal proteins begin to bind to their own mRNA molecules and inhibit the translation of their own coding region, as well as the coding regions of other ribosomal proteins residing on the same polycistronic mRNA. This is an example of **translational control**, where regulation affects translation of an mRNA by ribosomes rather than transcription by RNA polymerase.

In Eukaryotes, Most Genes Are Controlled Individually

There are a number of differences between gene regulation in prokaryotes and eukaryotes. In eukaryotes, most genes are present as isolated sequences encoding a single polypeptide, rather than as multigene operons. Eukaryotic microbes, like multicellular animals and plants, possess three different RNA polymerases: RNA polymerases I and III (pol I and pol III) to transcribe small functional RNAs and RNA polymerase II (pol II) for mRNA. Prokaryotes generally use a single RNA polymerase. Protein-coding sequences of eukaryotic microbes are interrupted by introns that do not encode protein. Special splicing mechanisms are required to remove the introns from mRNA prior to translating the exons that make up a single protein. Single-celled eukaryotic microbes generally have fewer introns than multicellular eukaryotes. There are even fewer examples of introns in the prokaryotic world. Some introns occur in archaea, a feature of genetics that archaea share with eukaryotes.

Transcription in eukaryotes is regulated by general transcription factors such as TATA-binding protein, which are considered comparable to bacterial sigma factors because they help locate eukaryotic promoters; and specialized transcription factors, which are comparable to the activator and repressor proteins of bacteria. Both general and specialized transcription factors of eukaryotes bind regulator DNA sequences, including **enhancers** and **silencers**, that activate or repress RNA transcription, respectively. Enhancers are regions of DNA that may be located thousands of base pairs away from the gene they control. Binding of transcriptional factors to enhancer sequences increases the rate of transcription of the gene. Enhancers can be located upstream, downstream, or even within the gene they control. Silencers are control regions of DNA that, like enhancers, may be located thousands of base pairs away from the gene they control. When transcription factors bind to silencers, expression of the gene they control is repressed.

Translational control in eukaryotes is poorly understood. One form of control involving translation is that of nonsense-mediated mRNA decay, which terminates transcription in the nucleus. As the mRNA is being transcribed, nuclear ribosomes begin to translate the message. If a ribosome runs into a stop codon (resulting from faulty RNA transcription), transcription terminates and the faulty RNA is degraded.

TO SUMMARIZE:

- **DNA-binding proteins** often recognize symmetrical DNA sequences.
- **Many anabolic pathway genes** (for example, for amino acid biosynthesis) are repressed by the end product of the pathway (for example, the amino acid), which binds to a corepressor that inhibits transcription.
- **AraC-like proteins** are a large family of regulators, present in many bacterial species, that can activate or repress operons by assuming different conformations.
- **Attenuation** is a transcriptional regulatory mechanism in which translation of a leader peptide affects transcription of a downstream structural gene.
- **Idling ribosomes** synthesize the signal molecule ppGpp, which interacts with the beta subunit of RNA polymerase and decreases the affinity of RNA poly-

merase for ribosomal RNA and a variety of other genes needed for rapid growth. The result, called the **stringent response**, is lower transcription of these genes, reduced levels of rRNA, and a decrease in the number of ribosomes.

10.4 Sigma Factor Regulation

DNA repressor and activator proteins are great for controlling the expression of individual genes and operons and are even used to coordinate expression of regulons, genes scattered around the chromosome that have related functions (such as tyrosine biosynthesis). In many cases, such as in the stringent response, bacteria need to coordinately activate large sets of genes and operons of seemingly disparate function that nevertheless collaborate to aid survival in particularly hostile environmental situations. One way to indirectly regulate expression of large sets of genes is to first regulate the synthesis or activity of the sigma factor that directs the expression of all those genes.

Many bacteria employ alternative sigma factors to direct transcription of distinct sets of genes (see Section 8.2). For example, many gram-negative bacteria, such as *E. coli* or *S. enterica*, use the sigma factor called sigma S (also called sigma-38, RpoS, σ^S or σ^{38}) to initiate the transcription of a variety of genes associated with survival in stationary phase. The level of sigma S is low in exponentially growing cells but rises dramatically as cells enter stationary phase. There are myriad ways to control whether a sigma factor gene is expressed and, if expressed, whether its product accumulates or functions.

Sigma Factor Activity Can Be Regulated

The cell can regulate an enzymatic reaction by changing the amount of the enzyme in a cell or by changing the *activity* of an enzyme already present. The same is true for sigma factors. Some microbes use **anti-sigma factor** proteins to inhibit sigma factor activity. Anti-sigma factor proteins target specific sigma factors, blocking their access to core RNA polymerase (that is, blocking their activity). This strategy prevents expression of that sigma factor's target genes.

Salmonella uses an anti-sigma factor (FlgM) to time events involved in constructing flagella. The transcription factor sigma F (also called sigma-28, RpoF, σ^F, or σ^{28}) is required to synthesize proteins used in the last stages of flagellar biosynthesis. The anti-sigma factor FlgM, however, keeps sigma F function at bay until membrane assembly of the flagellar basal bodies is complete. Once completed, the basal body selectively secretes the anti-sigma factor from the cell. This frees intracellular sigma F to direct transcription of the final set of flagellar assembly genes.

But what happens when the blocked sigma factor is suddenly needed? How do cells counter anti-sigma factors? Some systems counter anti-sigma factors with **anti-anti-sigma factors** that bind the blocking protein, like a decoy, and free the sigma factor to join core RNA polymerase. Other systems link the liberation of a bound sigma factor with a cell cycle event or with the assembly of a structure. *Bacillus* species, for instance, produce spores. During the process of making a spore, the cell couples formation of a forespore crosswall (see Section 5.8) to the activation of an anti-anti-sigma factor, which triggers the release of a whole cascade of new sigma factors needed only to complete spore formation (discussed later in this section).

Sigma Factor Translation Is Regulated by mRNA Secondary Structure and by Proteolysis

The synthesis or accumulation of sigma factors can also be regulated. The regulation of the heat-shock sigma factor sigma H (also called sigma-32, RpoH, σ^H, or σ^{32}) in *E. coli* illustrates how the synthesis of a sigma factor can be controlled at the level of translation (**Fig. 10.15**). Excessive heat, above 42°C for *E. coli*, will cause proteins to denature and membrane structure to deteriorate. All cells subjected to heat above their comfort zones (optimal growth range) will express a set of proteins called heat-shock proteins. These proteins include chaperones that refold damaged proteins and a variety of other proteins that affect DNA and membrane integrity. The transcription of many *E. coli* heat-shock genes requires the sigma factor sigma H. So one of the first consequences of growth at elevated temperature is an increase in the amount of sigma H present in the cell.

The level of sigma H is regulated by two temperature-dependent mechanisms; one of these controls the rate of sigma H synthesis, while the other determines its rate of proteolysis. The gene encoding sigma H is *rpoH*. At 30°C, *rpoH* mRNA adopts a secondary structure at the 5′ end that buries a ribosome-binding site, so *rpoH* mRNA is poorly translated. A sudden rise in temperature melts this secondary structure and exposes the ribosome-binding site, allowing translation to occur more readily. Thus, heat shock increases sigma H synthesis, which in turn increases transcription of the heat-shock genes whose products include chaperones and proteases.

Sigma Factor Levels Are Regulated by Proteolytic Degradation

Proteolysis is another mechanism used to control the level of certain sigma factors. This works by limiting sigma factor accumulation. For example, at 30°C, the *rpoH* message is poorly translated owing to secondary structure, as previously described, but some sigma H protein is made. To prevent inappropriate expression of the sigma H–dependent heat-shock genes at 32°C, the DnaK, DnaJ, GrpE chaperone system interacts with sigma H and shuttles it to various

Attempt to refold denatured proteins
Heat-shock genes

Figure 10.15 **The heat-shock response of *E. coli*.** Two mechanisms control sigma H levels. The small amount of sigma H that can be made at 30°C is met by the DnaK/GrpE/DnaJ chaperones and shuttled toward degradation. At 42°C, however, misfolded cytoplasmic proteins siphon off the chaperone trio and release sigma H to direct transcription of the heat-shock genes.

proteases for digestion (see **Fig. 10.15**). At 42°C, however, proteolysis of sigma H decreases, and sigma H is allowed to accumulate. Decreased degradation occurs because at the higher temperature, the chaperones are siphoned away from sigma H by the many other heat-denatured proteins formed. The new goal of the chaperones is to refold and rescue those damaged proteins. Chaperone redeployment frees sigma H to transcribe the heat-shock genes, which include the chaperone genes *dnaK*, *dnaJ*, and *grpE*. Thus, as the temperature rises, the amount of sigma H is increased by two temperature-dependent mechanisms: One increases translation by exposing the ribosome-binding site, while the second redeploys chaperones that direct its proteolysis.

In Sporulation, Different Sigma Factors Are Activated in the Mother Cell and Forespore

Bacillus and *Clostridium* species produce spores when nutrients become scarce. This requires an asymmetrical cell division in which one of the compartments becomes the spore (see Section 4.7). The regulation of this system is quite complex, involving programs of transcription in the mother cell that are separate from those in the forespore compartment. How is this possible? The answer is that at the time of septum formation, when the forespore is first produced, only 30% of the chromosome (the part near the replication origin) is actually inside the forespore. The remainder of the chromosome is slowly pumped in over a 15-minute period. The sporulating cell takes advantage of this delay to selectively express different genes in different compartments.

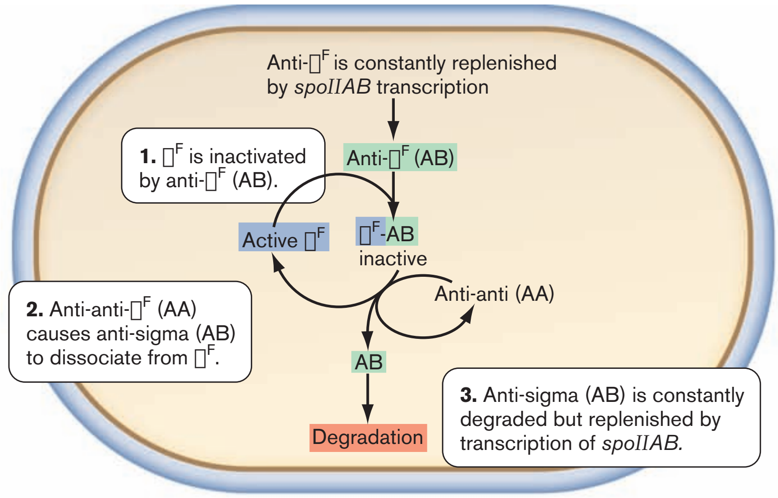
For example, distinctly different transcriptional programs are directed by sigma F in the forespore and sigma E (σ^E) in the mother cell. Soon after formation of the septum that divides the forespore from the mother cell, sigma F becomes associated with RNA polymerase to direct the transcription of select genes in the forespore while sigma E directs transcription of specific genes in the mother cell. Later, sigma G and sigma K associate with RNA polymerase to direct transcription of the next developmental sequence in the forespore and mother cell compartments, respectively.

How does the cell selectively direct transcription in the forespore? It starts with an intricate timing mechanism that involves anti-sigma and anti-anti-sigma factors (**Fig. 10.16**). Like all sporulation sigma factors, sigma F is inactive when first synthesized. It is inactive because it binds to an anti-sigma F protein dubbed SpoIIAB that is cosynthesized with sigma F in the predivisional cell (**Fig. 10.16A**, step 1). After division, both proteins become equally partitioned between the two compartments. However, in addition to an anti-sigma, there is an anti-anti-sigma F protein, called SpoIIAA (AA for anti-anti), which is also equally distributed (steps 2 and 3). Anti-anti factor frees sigma F from anti-sigma F, which is degraded by another protein complex, the ClpPC protease. This is not a problem in the mother cell because that compartment just makes more AB (anti-sigma), so sigma F is never active.

But all of the previous events occur in both compartments (forespore and mother cell). So why is sigma F activation limited to the forespore? Recall that at the time of septum formation, one chromosome is slowly pumped into the forespore. The gene encoding the AB anti-sigma factor is located far from the origin and, as such, is not in the part of the genome trapped in the forespore immediately after septal formation (**Fig. 10.16B**, step 2). Thus, no new AB (anti-sigma) is made in the forespore during this time, and what was there is inactivated by anti-anti factor and degraded by ClpPC (**Fig. 10.16B**, steps 3 and 4). This depletion of anti-sigma in the forespore efficiently frees sigma F to act only in the forespore compartment. Liberated sigma F transcribes the genes needed for subsequent sporulation steps; these genes reside in the part of the genome trapped early on in the forespore.

Elegant proof for this model was obtained in the laboratory of Richard Losick, a leading scientist in the field of microbial development. In Losick's experiment, the gene for SpoIIAB (anti-sigma) was moved from its normal location to a position near the origin, where it stopped sporulation. Because its new position was near the origin,

A. Vegetative cell—σ^F is inactive



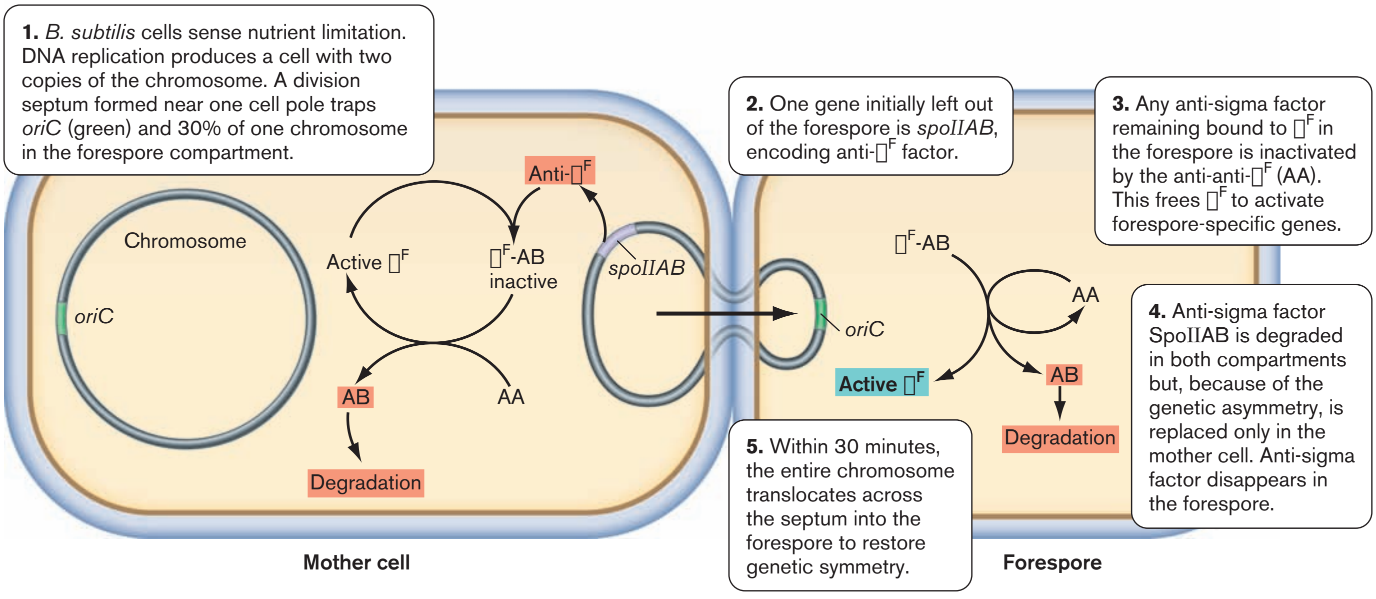
Anti-σ^F is constantly replenished by *spoIIAB* transcription

1. σ^F is inactivated by anti-σ^F (AB).

2. Anti-anti-σ^F (AA) causes anti-sigma (AB) to dissociate from σ^F.

3. Anti-sigma (AB) is constantly degraded but replenished by transcription of *spoIIAB.*

B. Forespore—σ^F is active



1. *B. subtilis* cells sense nutrient limitation. DNA replication produces a cell with two copies of the chromosome. A division septum formed near one cell pole traps *oriC* (green) and 30% of one chromosome in the forespore compartment.

2. One gene initially left out of the forespore is *spoIIAB*, encoding anti-σ^F factor.

3. Any anti-sigma factor remaining bound to σ^F in the forespore is inactivated by the anti-anti-σ^F (AA). This frees σ^F to activate forespore-specific genes.

4. Anti-sigma factor SpoIIAB is degraded in both compartments but, because of the genetic asymmetry, is replaced only in the mother cell. Anti-sigma factor disappears in the forespore.

5. Within 30 minutes, the entire chromosome translocates across the septum into the forespore to restore genetic symmetry.

Figure 10.16 Regulating sporulation by genetic asymmetry. A. Summary of mechanisms that control sigma F activity in growing cells of *Bacillus subtilis*. The interactions between sigma F, anti-sigma F (AB), anti-anti-sigma (AA), and SpoIIE phosphatase collectively keep sigma F inactive. **B.** Activation of sigma F in the forespore occurs as the forespore chromosome is pumped into the forespore. Activation of sigma F leads to synthesis of sigma G in the forespore (not shown), which directs the next stage of spore development.

the anti-sigma F gene entered the forespore early and continued to replenish the anti-sigma F that was lost by degradation.

The simple, unequal distribution of the chromosome during septal formation is heavily exploited during sporulation to trigger differential gene expression in two different cell compartments.

THOUGHT QUESTION 10.5 Predict the phenotype of a *spoIIAA* mutant that completely lacks this anti-anti sigma factor (see **Fig. 10.16**).

TO SUMMARIZE:

- **Changing the synthesis or activity of alternative sigma factors** is used to coordinately regulate sets of related genes.
- **Sigma factors can be controlled** by altered transcription, translation, proteolysis, and anti-sigma factors.
- **Secondary structures** at the 5′ end of mRNA can obscure access to ribosome-binding sites. Conditions that melt the secondary structures will increase translation of the sigma factor.
- **Chaperones** can direct certain sigma factors toward degradation by proteases. Conditions that draw those chaperones away from the sigma factor will allow the sigma factor to accumulate.
- **Sporulation** relies on the hierarchical activation of a series of different sigma factors.
- **Temporary asymmetrical distribution** of the chromosome between the forespore and the mother cell results in differential activation of compartment-specific alternative sigma factors.
- **Sigma F is a forespore-specific sigma factor** preferentially activated by temporary asymmetrical distribution of the chromosome during the early stages of sporulation.

10.5 Small Regulatory RNAs

A considerable fraction of a bacterial chromosome does not encode mRNA, rRNA, or tRNA. Many of these intergenic regions encode small untranslated RNA (sRNA) molecules that carry out a variety of biological functions. Examples of sRNA can be found in many different organisms, ranging from bacteria to mammalian cells. Many act as regulators of gene expression at a posttranscriptional level, either by interacting with proteins or by acting as **antisense RNAs** that bind to complementary sequences of target transcripts and stimulate or prevent translation. Regulatory RNAs are involved in the control of a variety of processes, such as plasmid replication, transposition in both prokaryotes and eukaryotes, phage development, viral replication, bacterial virulence, environmental stress responses, and developmental control in lower eukaryotes.

An example of regulation by an sRNA occurs within the Fur (ferric uptake regulator) **regulon** of *E. coli* (**Fig. 10.17**). (A regulon is made up of genes that, despite being scattered around the chromosome, are controlled by the same regulatory protein). Iron is an important component of living systems. However, too much iron can be detrimental to the cell by increasing oxidative stress. Fur is a repressor protein that regulates genes whose products scavenge iron from the environment or store iron in the cell (see Section 4.2). When intracellular iron levels are high, Fur represses expression of scavenging genes but induces production of iron storage proteins (**Fig. 10.17**). Fur represses gene expression by directly binding to spe-

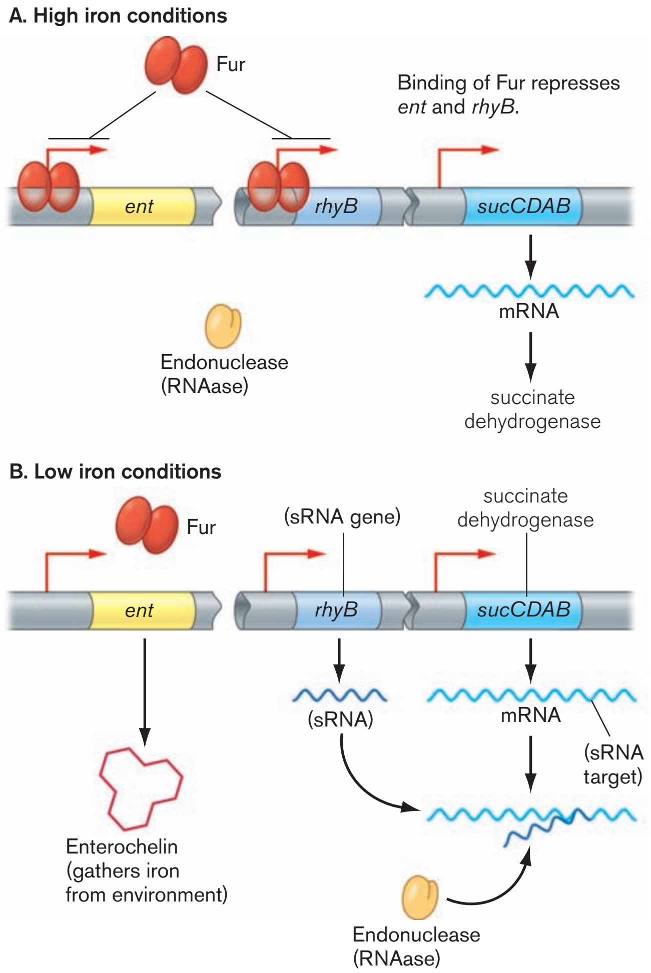


Figure 10.17 **Activity of a small regulatory RNA molecule.** **A.** When iron levels are high, Fur repressor protein binds to the *ent* and *rhyB* Fur box DNA sequence (a short specific DNA sequence in front of the genes regulated by Fur) and represses their expressions. Enterochelin is no longer made, but the *sucCDBA* message encoding succinate dehydrogenase can be translated. **B.** Under low iron conditions, the small RNA *rhyB* is expressed. RhyB sRNA binds to the *sucCDAB* message and renders it susceptible to an RNase.

Figure 10.18 **A.** Susan Gottesman (center) and **B.** Gisela Storz, both from the National Institutes of Health, played instrumental roles in establishing the importance of sRNA molecules in bacteria.

cific DNA sequences in front of target genes. But how does Fur activate other genes? One mechanism involves controlling production of a small RNA called RhyB (90 nt) (see **Fig. 10.17**). When iron levels are low, RhyB sRNA downregulates production of several iron storage and iron-using proteins (such as, succinate dehydrogenase). In this way, the cell prevents the shuttling of limited iron resources in wasteful directions. The cell needs to use the available iron, not store it. When iron is plentiful, however, Fur will directly repress *rhyB* and indirectly promote expression of the storage genes. Succinate dehydrogenase, an iron-containing enzyme, can also be made, which enables the use of succinate as a carbon and energy source.

What is the advantage to the cell of using sRNA to control expression? Using sRNA does not require protein synthesis and could be one of the most economical and efficient ways to globally repress genes. Global regulation refers to the coordinated control of many genes and regulons. Because sRNA molecules typically act on preexisting messages, they should also work more quickly than mechanisms that regulate transcription, which require degradation of preexisting mRNA before synthesis of the protein stops.

sRNA Genes Are Hard to Identify

How common are regulatory sRNA molecules? How can you look at a genome and predict what sequences encode sRNA genes? Identifying sRNA genes requires a different approach than identifying ORFs, which is relatively easy to do. ORFs have a translational start codon heading up a string of amino acid codons; sRNAs do not. The translational start codon of an ORF is preceded by a potential ribosome-binding site, which is itself preceded by a potential –10/–35 (or similar) promoter site sequences. Genes encoding sRNA will not have the ribosome-binding site but should have a recognizable promoter (see Sections 8.1 and 8.2). The promoter is not, however, enough to mark a potential sRNA gene. This is because all genomes contain sequences that resemble promoters yet fail to bind RNA polymerase.

The laboratories of Susan Gottesman and Gisela Storz at NIH (**Fig. 10.18**) discovered that genes encoding known sRNA molecules always occur in intergenic regions between genes encoding ORFs and exhibit high degrees of homology between related species (greater than 80%). The researchers used this knowledge to compare the intergenic regions of *E. coli* with those of *Salmonella* and *Klebsiella*. After eliminating tRNAs, rRNAs, and other repetitive elements, they ended up with 295 possible sRNA candidates. A microarray experiment (see Section 10.9) using oligonucleotide probes to intergenic regions was then used to determine if any of the predicted sRNA molecules were actually made. Using this strategy, 23 new sRNA species were identified (**Fig. 10.19**). It appears that sRNA genes are common and integral players in gene control.

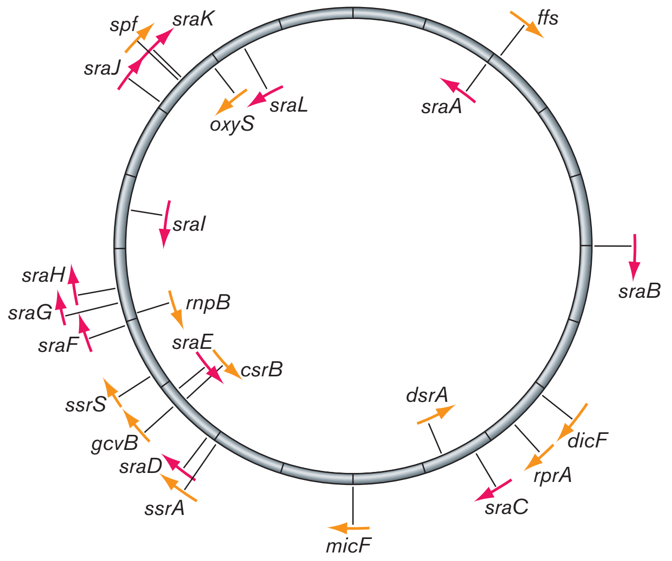

Figure 10.19 **Predicted sRNA genes in *E. coli*.** Location of various sRNA genes identified in the *E. coli* genome. Orange arrows depict sRNAs of proven function; red arrows indicate predicted sRNAs of unknown function.

Compared with prokaryotes, eukaryotic microbes possess an even broader array of small functional RNA molecules, including those of the spliceosome and of various cytoplasmic protein-RNA complexes. The genomes of eukaryotes such as yeast reveal thousands of potential sRNA sequences. The significance of sRNA discovery was highlighted by the decision of the journal *Science* to designate sRNA as the "Molecule of the Year" in 2002.

TO SUMMARIZE:

- **Small regulatory RNAs** found within bacterial intergenic regions regulate the transcription or stability of specific mRNA molecules.
- **The antisense nature** of sRNA allows these molecules to bind target mRNA. Binding can either stabilize the target mRNA or make it susceptible to degradation.
- **Identifying sRNAs** is more complex than identifying ORFs.
- **Eukaryotic microbes** use small interfering RNA to silence genes.

10.6 DNA Rearrangements: Phase Variation by Shifty Pathogens

All of the operon mechanisms previously described involve binding reactions between DNA, RNA, and proteins. More drastic means of control involve altering the DNA sequence itself.

Like a chameleon changing its color, some microbes use gene regulation to periodically change their appearance in a process called **phase variation**. Phase variation involves changing the amino acid composition of a particular protein on the bacterial surface. Bacteria that infect mammals, for example, must contend with immune systems whose mission is to destroy any and all invaders (discussed in Chapter 24). A central feature of immunity is the production of antibodies that recognize and bind foreign structures like microbial proteins and lipopolysaccharide (LPS). An infection will trigger the production of antibodies that are specific to the invader's component parts, such as pili, flagella, and LPS. Antibodies that bind to these microbial surface structures are especially useful for clearing an infection. Some pathogens, however, confound the immune system by changing the composition of these structures while the infection is in progress. This "shape-shifting" by the microbe, called **immune avoidance**, renders useless those antibodies specific for the old structure, and the embattled immune system must start all over making new antibodies. As a result, the course of infection is prolonged.

Gene Inversion Acts as an On-Off Switch

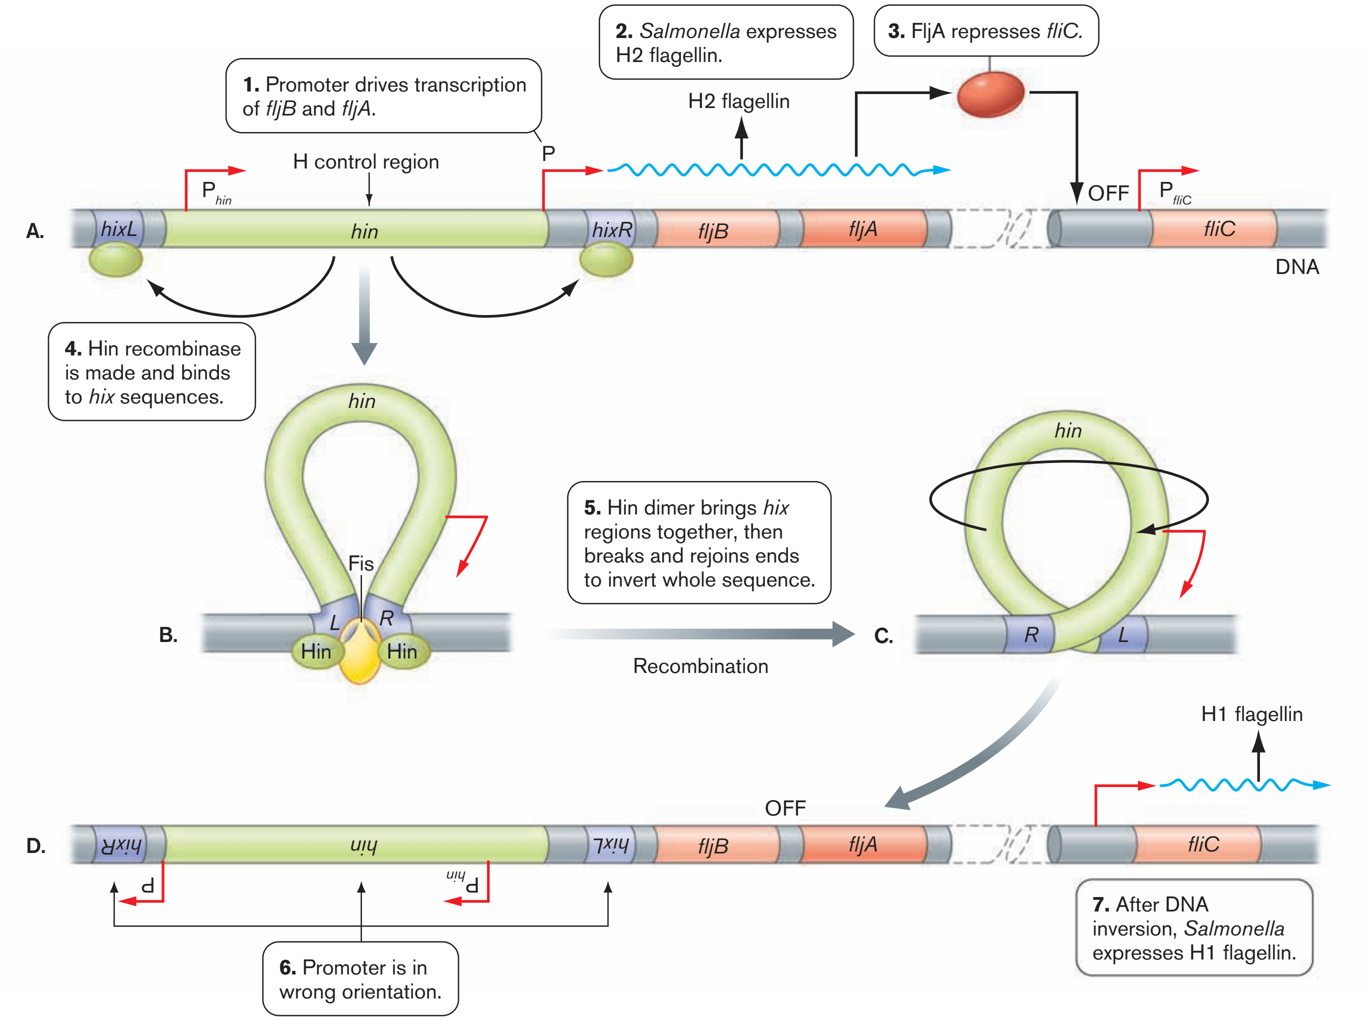
Flagellar phase variation in the gram-negative bacterium *Salmonella enterica* is a classic example of the regulatory genre known as **gene inversion**. Gene inversion is a recombinational event that flips the orientation of a gene or DNA segment in the chromosome, thereby turning that gene, or an adjacent gene, on or off. A major cause of diarrhea, *S. enterica* periodically changes the type of protein, called flagellin, used to make its flagella. Each organism has two genes, widely separated on the chromosome, that encode different forms of flagellin. The mechanism of the switch is a site-specific DNA recombination that turns off one gene while turning on the other. The target of the switch is a 993-bp DNA fragment (or cassette) called the H region that contains an outwardly directed promoter and a gene called *hin*, whose product, Hin recombinase (also called Hin invertase), mediates the recombination (**Fig. 10.20**). In antigenic parlance, the term *H antigen* refers to flagella, so the acronym Hin stands for *H in*version. The DNA cassette is flanked by short (26-bp) inverted repeats called *hixL* (left) and *hixR* (right).

NOTE: An **inverted repeat** is a sequence found in identical (but inverted) forms at two sites on the same double helix (for example, 5′-ATCGATCGnnnnnnnnnnnnnCGATCGAT-3′). A **direct repeat** is a sequence found in identical form at two sites on the same double helix (for example, 5′-ATCGATCGnnnnnnnnnnnnnATCGATCG-3′. A **tandem repeat** is a direct repeat without any intervening DNA sequence (for example, ATCGATCGATCGATCGATCGATCG).

WWW Hin recombinase molecular tutorial, Biomolecules at Kenyon

The Hin recombinase collaborates with other less specific DNA remodeling proteins, such as Fis, to engineer an association between the 26-bp left (*hixL*) and right (*hixR*) ends of the invertible DNA element. The two ends, each bound to a Hin monomer, are brought together by Hin-Hin protein interactions. DNA within the cassette then forms a loop. Hin cuts within the center of each *hix* site, producing staggered ends. An exchange of Hin subunits is thought to lead to strand inversion, so that the orientation of the DNA cassette is reversed relative to the flanking DNA on either side.

In one orientation, the outwardly directed promoter of the H region directs expression of H2 flagellin, encoded by *fljB*, and a repressor, FljA, that prevents transcription of the other flagellin gene, *fliC* (see **Fig. 10.20A**). After the switch, however, the promoter points in the wrong direction, so there is no produc-



1. Promoter drives transcription of *fljB* and *fljA*.

2. *Salmonella* expresses H2 flagellin.

3. FljA represses *fliC.*

4. Hin recombinase is made and binds to *hix* sequences.

5. Hin dimer brings *hix* regions together, then breaks and rejoins ends to invert whole sequence.

6. Promoter is in wrong orientation.

7. After DNA inversion, *Salmonella* expresses H1 flagellin.

Figure 10.20 Phase variation of flagellar proteins in *Salmonella enterica*. An invertible region containing a promoter controls the expression of two unlinked flagellar protein genes. In one orientation (**A**), the promoter drives synthesis of H2 flagellin (*fljB*) and a repressor (FljA) of the H1 flagellin gene (*fliC*). Action by the Hin recombinase causes the segment to invert (**B** and **C**), thereby removing the promoter. Because the repressor FljA is not formed, the gene for H1 can be expressed (**D**).

tion of H2 flagellin or FljA, the repressor of *fliC* (see **Fig. 10.20D**). Lacking this repressor, the *fliC* flagellin gene is expressed. Thus, H1 flagellin (present in phase 1 cells) is synthesized instead of H2 flagellin, which is present in phase 2 cells. The amino acid sequences, and thus the antigenicities, of the two flagellar proteins are different, so this mechanism allows *Salmonella* to change its appearance to a host immune system. In each generation, the rate of the reversible switch varies from about one cell in 10^3 to one in 10^5. Note, however, that this switch would not accomplish much if the infecting population of bacteria started out mixed—that is, producing both types of flagella. The initial infection must be of one phenotype.

THOUGHT QUESTION 10.6 What is the phenotype of a *fljA* mutant? A *fliC* mutant?

Slipped-Strand Mispairing Is Another Mechanism of Phase Variation

A different type of phase variation occurs within the *opa* genes of *Neisseria gonorrhoeae*, the causative agent of gonorrhea. The *opa* multigene family encodes 11 related outer membrane proteins that help the microbe adhere to the host cell epithelium. Opa refers to the *opaque* appearance of the bacterial colonies that result from the presence of these proteins on the cell surface. Variable numbers of the 5-bp repeat CTCTT are interspersed within the signal peptide regions of each of the genes for the outer membrane proteins. As discussed in Section 8.4, signal peptide sequences mark some membrane proteins for membrane insertion. Mispairing occurs during DNA replication when one of the strands, either the growing strand or the template strand, slips and pairs with the wrong repeat on the other strand (**Fig. 10.21**). If the newly synthesized strand slips back rela-

Slipping events (1 and 2) are portrayed on the lagging strand. **B.** The series of events that occur if the newly synthesized strand slips back relative to the template strand. When this new dsDNA, containing the looped-out slipped strand, is subsequently replicated, one of the daughter dsDNA molecules will have an extra repeat because of the slippage. **C.** What happens if, prior to replication, the original template strand slips back relative to the newly synthesized complementary strand. If repair enzymes get to the loop prior to replication, the loop is excised and a pentanucleotide repeat is removed. Subsequent daughter strands will be shortened.

tive to the template strand, one extra copy of the repeated unit is inserted in the growing strand (panel A). If instead the template strand slips back relative to the growing strand, one copy is deleted in the growing strand (panel C).

The effect of slipped-strand mispairing is to change the number of bases in a run of repeats. Because the length of the repeated sequence is not an even multiple of three, its insertion or deletion within the coding region of a gene generates a frameshift. The frameshift causes the gene to encode a run of amino acids completely different from that encoded by the original sequence (see Section 9.4). For *opa*, the number of CTCTT repeats in the amino-terminal portion of the gene determines whether the full-length protein is made (in which case the *opa* gene is considered on) or not (in which case the gene is off). One repeat more or less means a shift in the reading frame of the *opa* message so that a translation stop codon materializes, terminating production of that protein. The frequency of such slippage is very high; each time the bacteria divide, approximately one out of every 100 or 1,000 daughter cells will carry a mutation that changes the number of CTCTT repeats.

Each *opa* gene switches on or off independently. As a result, none, one, or several Opa polypeptides can be expressed simultaneously. Because no regulatory proteins are made, this is a wonderful low-maintenance way to evade the immune system.

Eukaryotic microbes, especially pathogenic sporozoans, possess elaborate mechanisms of phase variation. The trypanosome that causes "sleeping sickness" undergoes extensive genetic shuffling and mutation of its coat proteins over successive generations, essentially overwhelming the host immune system by presenting every possible form of antigen.

SUMMARY:

- **Phase variation** occurs when a bacterial protein structure reversibly changes from one form to another as a result of a genetic mechanism.
- **An invertible promoter switch** regulates two genes of *Salmonella enterica* encoding two alternative structural types of flagellin.
- **Slippage while replicating** through repetitive DNA sequences, a process called **slip-strand mispairing**, can reversibly activate or inactivate a series of outer membrane proteins in *Neisseria gonorrhoeae*.

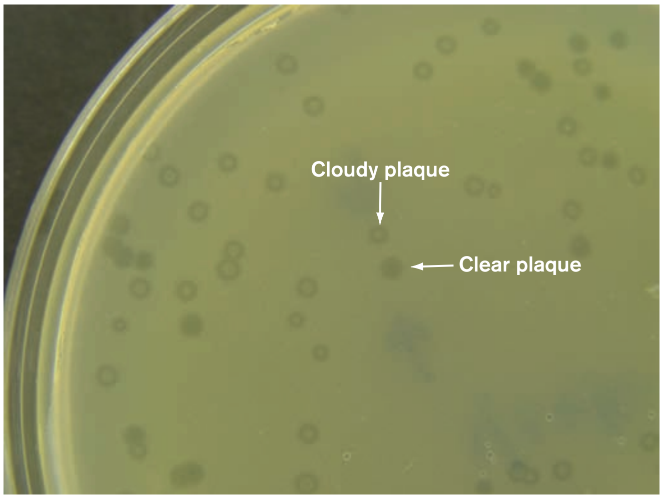
10.7 Integrated Control Circuits

The regulatory circuits outlined to this point have mostly involved single-switch mechanisms. But microbes build on these mechanisms by combining multiple switches with redundant feedback controls that can form a kind of integrated gene circuit. Integrated circuits can send a virus down alternate lifestyle paths (lysis or lysogeny), couple the genetic and biochemical control of a metabolic pathway (ammonia assimilation), or time the events of a developmental cycle such as sporulation. The deeper we delve into the regulatory workings that govern the expression of a cell's genome, the more clearly we see the hierarchy of control. Groups of simple control circuits are collectively regulated by other, more complex circuits, which, in turn, are governed by an even higher regulatory authority. One illustration of this was already presented, the role of cAMP and CRP in regulating lactose and arabinose catabolism. The *lacZYA* and *araBAD* operons are each controlled separately by dedicated regulatory switches—LacI and AraC, respectively. At a higher level, however, *both* operons are coregulated by cAMP and CRP in response to energy status (whether or not glucose is present and utilized). The systems we are about to discuss represent increasingly complex examples of nature's inventiveness and need for control.

The Phage Lambda Lysis/Lysogeny "Decision" Is to Kill or Not to Kill

Some bacterial viruses, known as temperate or lysogenic bacteriophages, have a "decision" to make after they infect a cell (discussed in Chapter 6). They can rapidly replicate intracellularly, fill the cell with progeny, and then cause the cell to lyse by destroying the cell membrane. This process is called the **lytic** life cycle of the phage.

Alternatively, lysogenic bacteriophages can remain in a dormant state after infecting a bacterial cell. This generally happens when times are good and the host grows quickly. The infecting viral DNA keeps a low profile and does not kill the host. Depending on the phage, it quietly hides by integrating into the host chromosome or masquerades as a harmless plasmid. The dormant form of the virus is called a **prophage**, and the host bacterial cell is called a **lysogen**. This lifestyle "choice" of the phage is termed **lysogeny** (Section 6.4). Lysogeny is good for the phage because if it quickly killed all the hosts in the area, the phage population could perish if no new host was found. Lysogeny can also be good for the bacterium if the prophage contains genes that contribute to bacterial virulence. However, prophages are not committed to a lysogenic existence forever. If the lysogenic cell gets into trouble (for example, by starvation or DNA damage), prophage DNA will begin replicating to produce viral progeny that kill the host and "abandon ship." The prophage switches to a lytic life cycle in the hope of finding a new, healthy host. Thus, lysogenic bacteriophages could be viewed as sleeping assassins. **Figure 10.22** illustrates the type of plaques formed by lysogenic and lytic variants of a lambdoid phage.



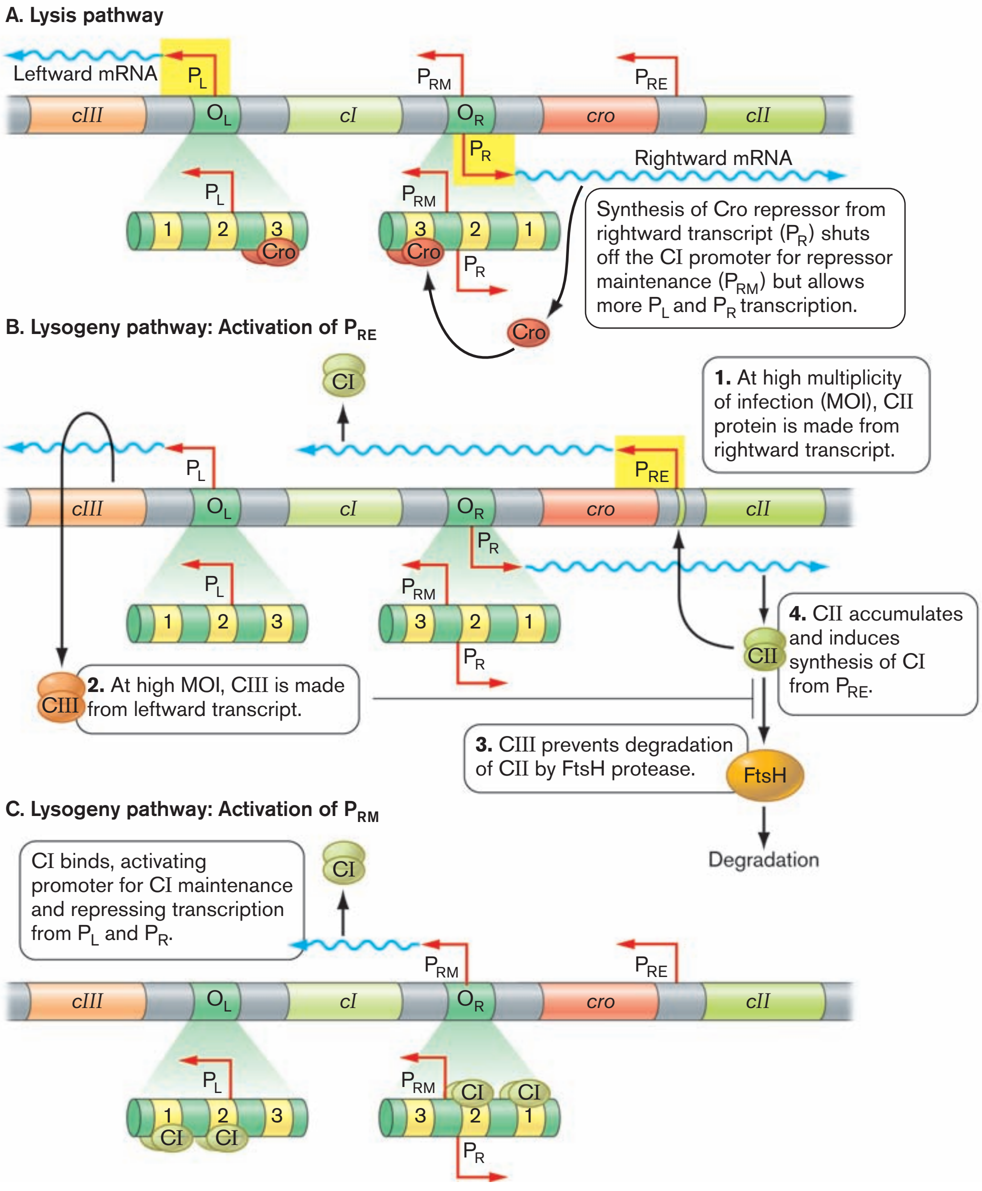
Courtesy of John Foster

Figure 10.22 Lysogenic plaques versus lytic plaques. A lambda-like phage (phage P22) was diluted and plated onto a lawn of *Salmonella enterica*. Two types of plaques are evident. Those with cloudy centers were made by P22 capable of lysogenizing the cells (cloudy plaques). The cloudy centers are due to the growth of lysogenic cells containing quiescent prophage DNA. A ring of lysis surrounds the cloudy center because low-level release of virus particles from lysogenic cells results in infection and lysis of surrounding cells. Plaques with clear centers are made by phages defective in the P22 homolog of the CI repressor (clear plaques). These phages are programmed for lysis.

The phage regulatory circuit that best illustrates this lysis/lysogeny decision is that of phage lambda, an *E. coli* virus. The decision awaits the outcome of a competition between two phage repressors, CI and Cro. If CI repressor wins, lambda DNA becomes a quiescent prophage that integrates into the host chromosome and expresses only one gene, *cI*. If Cro prevails, progeny phage are made and the cell is doomed.

It is important to understand the rationale for the lambda decision-making process before we discuss the process itself. When several lambda phages infect a single cell (a high multiplicity of infection), CI repressor tends to win and the cell becomes a lysogen. Lysogeny makes sense because the multiple infection of each cell shows that there are already more phages than there are bacteria. If progeny phage were released, there would be no other bacteria to infect. In contrast, if there are more bacteria than phage (low multiplicity infection), it makes sense for lambda to make progeny phage to infect the available hosts. So in this event, the genetic mechanisms are designed for Cro to win, initiating a lytic cycle.

The region of lambda DNA involved in the lysis/lysogeny control circuit is shown in **Figure 10.23A**. When lambda phage DNA is first injected into the cell, transcription initiates at two promoters, the leftward promoter P_L and rightward promoter P_R. Transcription from the P_L and P_R early promoters yields proteins needed for the transcription of later stage genes required for replication and capsid synthesis, but also encode the repressor Cro, as well as the proteins CII and CIII. CII protein can



A. Lysis pathway

Synthesis of Cro repressor from rightward transcript (P_R) shuts off the CI promoter for repressor maintenance (P_{RM}) but allows more P_L and P_R transcription.

B. Lysogeny pathway: Activation of P_{RE}

1. At high multiplicity of infection (MOI), CII protein is made from rightward transcript.

2. At high MOI, CIII is made from leftward transcript.

3. CIII prevents degradation of CII by FtsH protease.

4. CII accumulates and induces synthesis of CI from P_{RE}.

C. Lysogeny pathway: Activation of P_{RM}

CI binds, activating promoter for CI maintenance and repressing transcription from P_L and P_R.

Figure 10.23 The phage lambda lysis/lysogeny decision. **A.** Lysis pathway. The right and left operators, O_L and O_R, possess three binding sites each for the CI and Cro repressors. Synthesis of Cro repressor shuts off the CI promoter for repressor maintenance. Phage chooses lysis. **B.** At high MOI, CII protein is made and triggers the CI promoter for repressor establishment. CI is made. **C.** Once made, CI binds to sites 1 and 2 in the operator regions, turning on the promoter for CI maintenance while repressing the leftward and rightward promoters needed to make more phage particles. The phage chooses lysogeny.

activate transcription of the *cI* gene from the promoter for CI repressor establishment, called P_{RE}. The host protease FtsH, however, degrades CII (**Fig. 10.23B**). Thus, at low multiplicity of infection, where at most only one phage genome is injected into any one cell, CII never achieves a concentration high enough to trigger production of the repressor CI, and the phage will head toward lysis rather than lysogeny. A few other events that we will not discuss must occur before the phage is committed to replicate.

While the CI repressor is struggling to be made, the repressor Cro can bind to regions within the left and right operator regions (O_L and O_R) (**Fig. 10.23A**). These operators control transcription from the left and right promoters. Note in the figure that each operator is made up of three binding sites, each of which can bind Cro or CI. Cro binds with highest affinity to region 3, which overlaps another promoter for *cI* called the promoter for repressor maintenance (P_{RM}). Cro, even at low levels, will repress this promoter. At this point, CI, the repressor that can prevent transcription of later stage promoters, is not made and the phage has committed to lysis.

High multiplicity of infection, where multiple phage genomes infect a single cell, results in a larger amount of CII being made in part because of multiple gene copies available for transcription (**Fig. 10.23B**). In general, the more copies of a gene there are, the more of that gene's protein product can be made. The concentration of CII rises even more because its degradation by the host protease FtsH is inhibited by CIII, which is also synthesized in larger amounts at high multiplicity of infection. CIII protein binds to and inhibits FtsH activity.

Because CII is not degraded by FtsH, it will achieve a concentration that can initiate *cI* transcription from P_{RE}. The CI repressor resulting from this transcription then binds preferentially to sites 1 and 2 within the operators O_R and O_L. This shuts down transcription from the two primary phage promoters P_L and P_R (**Fig. 10.23C**). CI binding to O_{R2} also activates *cI* transcription from P_{RM}. This promoter is required to maintain long-term expression of CI because when CI binds to P_R sites 1 and 2, transcription from P_{RE} stops because CII does not accumulate. Now all transcription, except for that of the CI repressor, is terminated. The cell has committed to lysogeny.

Many breakthroughs in molecular biology have resulted from the study of phage lambda. One of the most significant was the revelation of how repressors bind to DNA and control genes. As an undergraduate student in 1960, Mark Ptashne became entranced by the bold hypothesis made by Jacob and Monod regarding regulation of cell behavior. Some vague molecule called a "repressor" controlled the expression of genes. Was it protein? Did it bind DNA? These were critical questions no one was addressing. Told that his quest was too challenging for a graduate student, Ptashne had to wait until his postdoctoral years to search for his holy grail. Using CI repressor as the model, he discovered that CI is a protein that dimerizes and, in that form, binds to a specific DNA operator site (**Fig. 10.24**). His group was the first to demonstrate what others had predicted. Ptashne and his colleagues at Harvard University also discovered within the CI repressor

the classic helix-turn-helix DNA-binding motif that is common to many DNA-binding proteins.

THOUGHT QUESTION 10.7 The plaques of normal phage lambda appear as clear rings with cloudy centers of lysogenized cells. What do you think the plaque will look like in a *cI* mutant? A *cII* mutant? A *cro* mutant?

THOUGHT QUESTION 10.8 Predict why UV irradiation can activate lambda prophage. *Hint:* What other host system is activated by UV?

Coupling Metabolic and Genetic Control: Nitrogen Regulation

Another mechanism by which levels of key compounds in the cell are regulated is to link biochemical control of a metabolic pathway (that is, whether an enzyme is active or inactive) to the genetic regulation of that pathway (which determines whether the enzyme is made or not). The assimilation of nitrogen is a classic example of coupled regulation (see Section 15.5).

All cells require nitrogen to grow. Thus, when nitrogen becomes limiting, bacteria activate pathways to gather nitrogen from the environment. The indicator of nitrogen abundance turns out to be the cellular levels of two amino acids, glutamate and glutamine. Actually, it is the intracellular ratio between alpha-ketoglutarate (the precursor of glutamic acid) and glutamine levels, but to make the discussion easier we will use glutamate/glutamine levels. Put simply, when glutamine is in excess, the cell has plenty of nitrogen; when glutamate (or alpha-ketoglutarate) is in abundance, the organism is nitrogen starved.

During times of nitrogen abundance, cells accumulate a store of nitrogen via glutamine synthetase (GlnA). Glutamine synthetase uses the energy released from ATP hydrolysis to assimilate NH_4^+ into glutamic acid and produce glutamine (**Fig. 10.25A**, step 1). However, if the cell makes too much active glutamine synthetase, then all of the cell's glutamate will be converted to glutamine, and not enough glutamate will remain for protein synthesis. To prevent this, glutamine, when present at high levels relative to glutamic acid, signals the cell to stop making GlnA and inactivate whatever GlnA is already present. Thus, the glutamate to glutamine ratio is conserved. *E. coli* uses a single coupling protein called GlnB to regulate both the transcription of *glnA* and the biochemical activity of its product, glutamine synthetase. GlnB allows cells to balance the activation/inactivation of glutamine synthetase activity with its rate of synthesis.

We will start by explaining transcriptional control of the system and then show how GlnB links transcriptional and biochemical controls. Genetic control of *glnA* transcription is managed by the products of the *ni*trogen *r*egulator genes *ntrB* and *ntrC* and a dedicated 54-kDa sigma factor, sigma N (also called sigma-54, RpoN, σ^{N}, or σ^{54}), encoded by the gene *rpoN*. NtrB and NtrC form a two-component signal transduction system. NtrB is a sensor kinase that phosphorylates the response regulator NtrC when glutamine levels are low (**Fig. 10.25A**, step 2). The phosphorylated form of NtrC (NtrC-P) induces expression of *glnA* and increases the level of glutamine synthetase in the cell (**Fig. 10.25A**, step 3). The NtrC-P regulator binds not to an operator region but to an enhancer sequence. Unlike operators, which must lie close to the promoter they control, enhancers can influence target gene expression from great distances (1 or 2 kb). Bound to its enhancer sequence, NtrC-P activates transcription of *glnA* through direct interactions with sigma N RNA polymerase bound at the *glnA* promoter resulting in a DNA loop (**Fig. 10.26**). As a result, glutamine synthetase is made, nitrogen (in the form of ammonia) is assimilated, and glutamine is produced.

NOTE: Unlike the DNA loop formed by AraC, enhancer sequences can be moved experimentally to great distances from the promoter and still affect expression of the promoter.

As already noted, a dire consequence of unrestricted glutamine production is the depletion of intracellular glutamate levels relative to glutamine levels. Ideally, when glutamine levels are in excess, the cell would stop making GlnA and would inactivate whatever GlnA is already made. That way the cell can preserve the glutamate/glutamine balance. Conversely, when glutamine levels are limiting, the cell would resume making GlnA and make sure it is active. The GlnB regulator coordinates these genetic and biochemical controls by modulating the phosphorylation of NtrC (thereby influencing transcription of *glnA*) and by altering GlnA activity.

The direction of control centers on whether or not a UMP group is attached to GlnB (uridylylation). When glutamine levels are low, GlnD protein uridylylates GlnB (**Fig. 10.25B**, step 4). GlnB-UMP allows *glnA* transcription and activates pre-existing GlnA enzyme (**Fig. 10.25B**, step 5). Conversely, when internal stores of glutamine are high relative to glutamate, GlnD removes UMP from GlnB (**Fig. 10.25B**, step 6). GlnB then halts *glnA* transcription and inactivates pre-existing GlnA enzyme.

To carry out these functions, GlnB interacts with two proteins, the NtrB sensor kinase and another protein called GlnE (**Fig. 10.25B**). GlnB (the form when glutamine levels are high) causes NtrB to dephosphorylate NtrC, which effectively halts *glnA* transcription. GlnB also compels GlnE to covalently add an AMP to GlnA (a process called adenylylation). This modification inac-

1. Glutamine synthetase assimilates nitrogen (NH_4) to make glutamine.

2. NtrB sensor kinase autophosphorylates and transfers the phosphate to the DNA-binding protein NtrC.

3. NtrC-P binds to DNA and stimulates transcription of *glnA*.

4. When glutamine is low, GlnD adds UMP to the GlnB regulator.

5. GlnB-UMP tells GlnE to remove AMP from GlnA synthetase, restoring its activity. GlnA can make glutamine.

6. GlnD, sensing high glutamine, removes UMP from GlnB.

7. GlnB tells GlnE to add AMP to GlnA, inactivating the enzyme and tells NtrB to dephosphorylate and inactivate NtrC. No transcription of *glnA* occurs.

Figure 10.25 Regulation of nitrogen metabolism. A. Genetic control. NtrB-NtrC form a cytoplasmic two-component signal transduction system that controls *glnA* transcription. **B.** Biochemical control. GlnB coordinates the function of NtrB (transcriptional control) and GlnE (metabolic control).

tivates whatever GlnA remains in the cell. The result is that ammonia is no longer assimilated and the glutamate/glutamine ratio is protected.

When glutamine levels are low, relative to glutamate, GlnB-UMP allows the phosphorylation of NtrC by NtrB. So NtrC-P is made and stimulates the synthesis of glutamine synthetase. In addition, GlnB-UMP causes GlnE protein to remove AMP from preexisting glutamine synthetase, thus activating it. The result is that transcription of *glnA* is enhanced, glutamine synthetase is activated, and ammonia is assimilated to make glutamine once again.

THOUGHT QUESTION 10.9 Predict the phenotype of a *glnB* mutant. Will it be a glutamine auxotroph or not? What about a *glnD* or a *glnE* mutant?

In this configuration, NtrC will activate transcription.

TO SUMMARIZE:

- **Bacterial genes are regulated by a hierarchy of regulators** that form integrated gene circuits.
- **Gene switches** can regulate "decision-making" processes in microbes.
- **Two repressors (CI and Cro)** made by phage lambda of *E. coli* control whether the phage travels through the lytic (Cro dominates) or lysogenic (CI dominates) pathway of replication. Both repressors bind similar phage DNA sequences but do so with different affinities. Cro prevents CI synthesis but allows expression of other genes needed for lysis. CI prevents expression of all lambda genes except its own. Multiplicity of infection determines which repressor dominates and whether the phage DNA will replicate to produce progeny or will become a prophage.
- **The study of lambda CI** repressor led to the discovery of the helix-turn-helix motif common in many DNA-binding proteins. The helices bind to appropriate sequences in the grooves of target DNA.
- **The NtrB-NtrC two-component signal transduction system** regulates nitrogen assimilation by altering transcription of the gene encoding glutamine synthetase (*glnA*).
- **The protein GlnB** links the biochemical control and genetic regulation of nitrogen assimilation.

10.8 Quorum Sensing: Chemical Conversations

A discovery that fundamentally changed the way we think about microbes was made while studying *Vibrio fischeri*, a peculiar marine microorganism that colonizes the light organ of the Hawaiian squid (*Euprymna scolopes*) (**Fig. 10.27**). As discussed at the beginning of this chapter, *V. fischeri* is bioluminescent, but only glows at high cell densities—a situation achieved naturally in the squid's colonized light organ or artificially in the test tube (**Figs. 10.27C** and **D**). What accounts for the dependence of gene expression on cell density? How do cells *know* they are crowded?

The phenomenon was originally dubbed "**quorum sensing**" because it seemed akin to parliamentary rules of order that require a minimum number of members (a quorum) to be present at a meeting in order to conduct business. In the microbial world, however, gene regulation is only loosely associated with actual cell numbers. Induction of a quorum-sensing gene system really requires the accumulation of a secreted small molecule called an **autoinducer** (usually a homoserine lactone, although gram-positive organisms are known to use short peptides). The more cells there are in a given space, the faster the critical level of autoinducer is reached.

At a certain extracellular concentration, the secreted autoinducer reenters cells and binds to a regulatory molecule. In the case of *V. fischeri*, the regulatory molecule is LuxR (**Fig. 10.28**). The LuxR-autoinducer complex activates transcription of the luciferase target genes responsible for bioluminescence. Luciferase is the enzyme responsible for light production in *V. fischeri*.

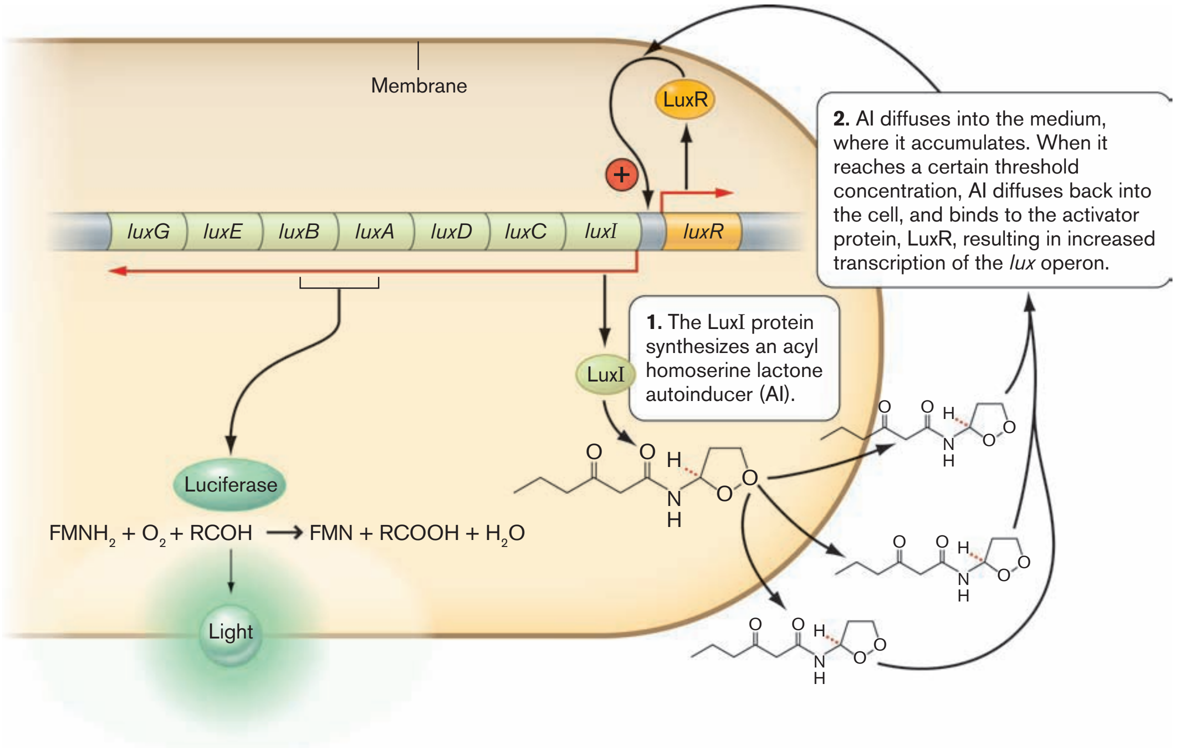
Figure 10.27 Visual demonstration of quorum sensing. **A.** The organism *Vibrio fischeri* colonizes the light organ of the Hawaiian squid (*Euprymna scolopes*). Shown is a pair mating at night. **B.** Edward Ruby, at the University of Hawaii, has studied various aspects of the symbiotic relationship between *V. fischeri* and its squid host. **C.** When colonies of the luminescent bacterium *V. fischeri* are observed in a well-lit place, the light emitted by bacteria is not visible. **D.** If the same colonies are viewed in darkness, the intensity of luminescence is remarkable.

One can bypass the apparent cell density requirement by simply adding purified autoinducer to a low-density cell culture. Many other microbes use these chemical languages to coordinate behavior of the population (**Table 10.1**). Quorum sensing is used by pathogens to time the production of virulence factors and can even be used to communicate between different species (**Special Topic 10.2**).



2. AI diffuses into the medium, where it accumulates. When it reaches a certain threshold concentration, AI diffuses back into the cell, and binds to the activator protein, LuxR, resulting in increased transcription of the *lux* operon.

1. The LuxI protein synthesizes an acyl homoserine lactone autoinducer (AI).

Figure 10.28 **Microbial communication through quorum sensing.** The *lux* system of *Vibrio fischeri* mediates that organism's bioluminescence. Synthesis and accumulation of an autoinducer (AI) triggers expression of the *lux* operon. The greater the cell number and the smaller the container, the faster AI will accumulate. The resulting luciferase enzymes catalyze bioluminescence. The luciferase reaction, catalysed by LuxA and LuxB, uses oxygen and reduced flavin mononucleotide to oxidize a long-chain aldehyde (RCHO) and in the process produces blue-green light. Other *lux* gene products are involved in synthesis of the aldehyde.

Special Topic 10.2 The Role of Quorum Sensing in Pathogenesis and in Interspecies Communications

Pseudomonas aeruginosa is a human pathogen that commonly infects patients with cystic fibrosis, a genetic disease of the lung. The organism forms a biofilm over affected areas and interferes with lung function. Key to the destruction of host tissues by *P. aeruginosa* are virulence factors such as proteases and other degradative enzymes. But these proteins are not made until cell density is fairly high, a point where the organism might have a chance of overwhelming its host. The organism would not want to make the virulence proteins too early and alert the host to launch an immune response. The induction mechanism involves two interconnected quorum-sensing systems called Las and Rhl, both comprised of regulatory proteins homologous to LuxR and LuxI of *V. fischeri*. Many pathogens besides *Pseudomonas* appear to use chemical signaling to control virulence genes. Genomic analysis has revealed homologs of known quorum-sensing genes in *Salmonella*, *Escherichia*, *Vibrio cholerae*, the plant symbiote *Rhizobium*, and many other microbes.

Some microbial species not only chemically talk among themselves, but appear capable of communicating with other species. *V. harveyi*, for example, uses two different, but converging, quorum-sensing systems to coordinate control of its luciferase. Both sensing pathways are very different from the *V. fischeri* system. One utilizes an acyl homoserine lactone (AHL) as an autoinducer (AI-1) to communicate with other *V. harveyi* cells. The second system involves production of a different autoinducer (AI-2) that contains borate. Because many species appear to produce this second signal molecule, it is thought that mixed populations of microbes use it to "talk" to each other. In the case of *V. harveyi*, specific membrane sensor kinase proteins are used to sense each autoinducer (**Fig. 1**). At low cell densities (no autoinducer), both sensor kinases initiate phosphorylation cascades that converge on a shared response regulator, LuxO, to produce phosphorylated LuxO. Phosphorylated LuxO appears to activate a repressor of the *lux* genes. Thus, at low cell densities, the culture does not display bioluminescence. At high cell density, the autoinducers prevent signal transmission by inhibiting phosphorylation. The cell stops making repressor, which allows another pro-

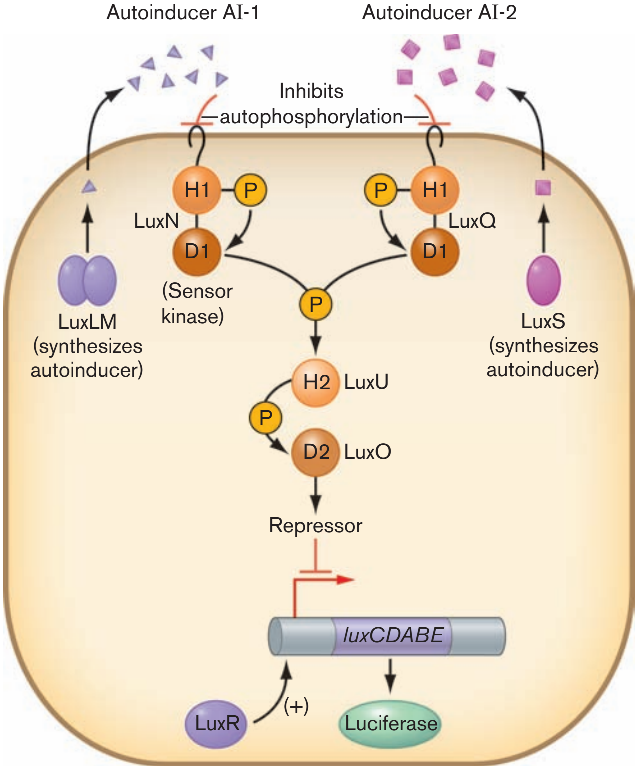

Figure 1 The two quorum-sensing systems of *V. harveyi*. In the absence of autoinducers (AI-1 and AI-2), both sensor kinases trigger converging phosphorylation cascades that end with the phosphorylation of LuxO. Phosphorylated LuxO (LuxO-P) activates a repressor that inhibits expression of the luciferase genes. As autoinducer concentrations increase, they inhibit autophosphorylation of the sensor kinases and the phosphorylation cascade. As a result, repressor levels decrease, which allows the LuxR protein to activate the *lux* operon.

This knowledge begs the question, Why would a squid want to harbor this bioluminescent microbe? Buried in the sand by day, this animal emerges at night from its safe hiding place to hunt for food. In moonlight, the squid would appear as a dark silhouette from below, marking it as easy prey for predators. It is thought that the squid camouflages itself by projecting light downward from its light organ, giving the appearance of celestial stars as perceived by predators below.

THOUGHT QUESTION 10.10 Genes encoding luciferase can be used as "reporters." What do you think would happen if the promoter for an SOS response gene were fused to the luciferase open reading frame?

THOUGHT QUESTION 10.11 What do you think would happen if a culture were coinoculated with a *V. fischeri luxI* mutant and a *luxA* mutant, neither of which produces light?

tein, LuxR (*not* a homolog of the *V. fischeri* LuxR), to activate the *lux* operon. The "lights" are turned on. Bonnie Bassler (**Fig. 2**) and Pete Greenberg (**Fig. 3**) are two of the leading scientists whose studies revealed the complex elegance of quorum sensing in *Vibrio* and *Pseudomonas* species. Other organisms, such as *Salmonella*, have been shown to activate the AI-2 pathway of *V. harveyi*, dramatically supporting the concept of cross-species communication.

A recent report by Ian Joint and his colleagues has shown that bacteria can even communicate across the prokaryotic-eukaryotic boundary. The green seaweed *Enteromorpha* (a eukaryote) produces motile zoospores that explore and attach to *Vibrio anguillarum* bacterial cells in biofilms (**Fig. 4**). They attach and remain there because the bacterial cells produce acetyl homoserine lactone molecules that the zoospores sense. Part of the evidence for this interkingdom communication involved showing that the zoospores would even attach to biofilms of *E. coli* carrying the *Vibrio* genes for the synthesis of acetyl homoserine lactone. The implications of possible interkingdom conversations are staggering. Do our normal flora "speak" to us? Do we "speak" back?

For further discussion of molecular communication between prokaryotes and eukaryotes, see Chapter 21.

10.9 Genomics and Proteomics: Tools of the Future

Most of the studies exposing the regulatory systems discussed in this chapter were accomplished by examining only a small number of genes at any one time. Now, however, new technologies enable scientists to examine thousands of genes or proteins in a single experiment.

Gene Arrays Provide Global Snapshots of Gene Expression

A pebble tossed into a pond makes a wave that spreads and ultimately disturbs the entire pond. Similarly, altering one biochemical pathway in a cell produces a wave effect that impacts, to a greater or lesser degree, all other pathways. We are just now beginning to develop the tools needed to see these molecular "waves." One powerful technique, called DNA microarrays, can simultaneously examine the expression of every gene in a cell. For an organism like *Salmonella typhi*, the causative agent of typhoid fever, this requires seeing over 4,600 genes. What is amazing is that all this can be done on a slide the size of a postage stamp.

The DNA microarray technique uses a tool called a **DNA microchip**, where DNA fragments from every ORF in a genome are affixed to separate locations on a solid support surface, producing a grid, or array (**Fig. 10.29**). The DNA fragments are generated by PCR or by in vitro chemical synthesis. The key to the technique is

Figure 10.29 DNA microarray technology. This procedure is used to determine transcript levels produced from every gene in a cell (transcriptome). It assesses the relative level of each transcript produced by cells grown in different conditions or between mutant and wild-type strains of bacteria. **A.** In the basic procedure, RNA is extracted from cultures grown under different conditions (pH 7 versus pH 4.5 in this example). The RNA molecules from the two cultures are converted to DNA with reverse transcriptase (RT), then amplified and quantitatively tagged with different-colored fluorescent tags using PCR techniques. **B.** DNA fragments of each ORF in the bacterial genome are spotted by robotics to a glass slide (DNA microchip). The tagged (fluorescent) RT/PCR mixtures are then applied to the DNA microchip and allowed to anneal. Each tagged RT/PCR fragment will only anneal to the spot corresponding to its gene. **C.** Laser scanning of the annealed chip will reveal red spots if that gene was expressed mostly under pH 4.5 conditions, green spots if it was expressed mostly at pH 7, and yellow or orange if it was equally expressed under both conditions (an equal mix of red tag and green tag).

that only one strand of a double helix is actually fixed to the slide. Heating the slide breaks the hydrogen bonds holding down the complementary strands. The released strands are washed off, leaving the tethered strands free to anneal with any other complementary DNA that approaches. Think of these strands as a thousand tiny pieces of flypaper, with each piece engineered to catch a different type of fly.

The DNA microchip can be used to analyze RNA extracted from microbes grown under two different conditions. The ultimate goal is to compare the relative expressions of each gene under the two sets of environmental conditions; for example, at a pH of 7 versus a pH of 4.5. The latter is a pH that bacteria like *Salmonella* might encounter in eukaryotic host cell vesicles. After extraction, the two RNA samples are treated separately with the enzyme reverse transcriptase, which makes a DNA called **complementary DNA**, or **cDNA**, from RNA templates. Fluorescently tagged nucleotides are used in the reaction so that the product cDNAs also carry a fluorescent tag. How much of one cDNA is made depends on how much mRNA was initially present. Different colored tags (usually red and green) are used for each sample. In the example shown in **Figure 10.29**, the cDNA from the pH 7 and pH 4.5 cultures were labeled red and green, respectively.

The microchip is then flooded with a mixture of the two fluorescently tagged batches of cDNA, allowing the individual cDNA molecules to find and bind their mates on the organized grid. This is the hybridization step. After hybridization, a laser scans the slide and a fluorescence detector reads emissions. Composite images of the two scans, one for red and one for green, are made and analyzed by computer. If a given gene is expressed equally under both test conditions, the corresponding spot on the chip will contain equal amounts of red and green, a result that produces a yellow color. If a gene is expressed more during growth at pH 7, the spot will glow green. If expressed more at pH 4.5, it will fluoresce red. The result is a comprehensive view of what has been called the cell's **transcriptome**—all the cell's expressed mRNAs (**Fig. 10.29C**).

Two-Dimensional Gels Provide a Global View of Protein Expression

If all the expressed mRNAs in a microbe make up its transcriptome, then all of the expressed proteins form its **proteome**. Unlike the DNA genome, which is fixed, the transcriptome and proteome continually change in response to a changing environment. Gene array technology can capture what happens transcriptionally, but gene arrays do not necessarily reveal which proteins are expressed because stress often causes the translation of a message to change without changing its transcription. Thus, a significant increase in the level of a protein can occur without any change in the amount of mRNA. In addition, posttranslational modifications of proteins (for example, acetylation, phosphorylation) can take place in response to different environments. The powerful technique of two-dimensional gel electrophoresis (introduced in Section 3.5), is used to capture and view fluctuations in the proteome.

The first step in the process involves isoelectric focusing (IEF), where proteins in a cell extract are sorted based on their individual charges. Every protein is adorned with ionizable side groups (amino and carboxyl) that can impart charge. The degree of protonation (ionization) of each group is affected by pH and by the dissociation constant (pK) of the group. Generally, an ionizable group will be protonated at pH values below its pK. At pH values below their intrinsic pKs, amino groups become positively charged ($R\text{-}NH_3^+$), whereas carboxyl groups are neutral (R-COOH). When the pH rises above a group's pK, the amino groups will be neutral (NH_2) and carboxyl groups become negatively charged (COO^-). Proteins have hundreds of amino and carboxyl groups in different ratios, so for each protein, there will be a specific pH, called the **isoelectric point**, where the plus and minus charges cancel out—that is, where the net charge on the protein is zero.

Isoelectric focusing takes advantage of this phenomenon. Cell proteins are applied to a gel containing an immobilized pH gradient, called an IPG strip, and are subjected to an electrical field (**Fig. 10.30**). Negatively charged proteins move toward the positive pole until they reach a pH in the gel where the charges cancel out. Without a charge, the protein does not move under the influence of the electrical field. Positively charged proteins behave similarly, but move toward the negative pole.

Proteins with very different molecular weights can share the same isoelectric point. As a result, one band on an IEF gel could contain ten proteins. The goal of the second dimension, therefore, is to further separate proteins based on their molecular weights. To accomplish this, the IEF gel is transferred to the top of a sodium dodecyl sulfate (SDS) polyacrylamide gel (**Fig. 10.30D**). SDS is a detergent that forms positive and negative ions in solution. The negatively charged ion (dodecyl sulfate) has a hydrophobic end that coats proteins, giving all of them a negative charge. Polyacrylamide is a porous gel whose pore size varies in relationship to the acrylamide concentration and the amount of cross-linking used to make it a gel. When placed in an electrical field, the proteins (which are all negatively charged by SDS) are pulled toward the positive pole, located at the bottom of the gel. Small proteins easily slip through the tiny polyacrylamide pores and race to the positive electrode. The larger proteins find it more difficult to squeeze through the pores and are slow to move. The result is a gradient of proteins ranging

The figure is the result of dual-channel image analysis of silver-stained gels. A computer assigns the color red to proteins expressed in minimal media and the color green to proteins expressed in amino-acid-supplemented media. If the proteins are expressed under both conditions, the red and green colors combine to form yellow or orange.

ment. **Figure 10.32** shows a dual-channel image analysis that compares *Bacillus subtilis* proteomes from cultures grown in a minimal glucose medium to that of cultures grown in the same medium but supplemented with a rich assortment of amino acids. The different colors indicate whether the level of a protein is higher, lower, or the same in the two cultures.

Identifying Proteins Plucked from a Two-Dimensional Gel

The true power of proteomics becomes evident when it is linked to genomics. Knowing the complete sequence of an organism's chromosome makes it easier to identify proteins following growth under any experimental condition. For example, levels of certain proteins increase when a bioremediating microbe is grown on benzene instead of glucose. How does one determine which proteins are induced? Those proteins, and the genes encoding them, can be identified from a two-dimensional gel if the organism's genome is sequenced. This procedure is shown schematically in **Figure 10.33**. The protein spot of interest is excised from the gel and digested into peptide fragments with a protease. The peptide fragment mixture is then analyzed by mass spectrometry, which determines the precise molecular weight of each fragment. Combining the molecular weight of all the fragments gives the molecular weight of the whole protein. Computer programs match the experimentally determined molecular weight of the protein (based on the sum of its peptide masses) with the calculated molecular weights of all ORFs predicted from the genome sequence. A match indicates identity.

THOUGHT QUESTION 10.12 Why might the mass of a protein excised from a gel fail to match any of the ORF molecular weights predicted by the genome sequence?

This technology has been used for many microbial applications. One fascinating example centers on the transcriptional events that occur during the developmental cycle of *Caulobacter crescentus*. This organism progresses from a nonreplicating swimming form (swarmer cell) to a sessile stalked form that can replicate to make more swarming offspring. DNA microarray and proteomic analysis have revealed several potential regulators of this complex developmental process.

Figure 10.33 Proteomic identification of proteins from a two-dimensional gel. Proteins are extracted from a bacterial culture and subjected to two-dimensional electrophoresis. Spots of interest can be cut out of the gel and digested with trypsin. The resulting peptides are analyzed by mass spectrometry. In a process called MS/MS, the mass of each peptide is determined and then selected peptides are subjected to additional fragmentation by ion spray. Each resulting peptide fragment will differ in size by one or more amino acids. Knowing the mass of each amino acid and the masses of the different peptide fragments allows one to extrapolate the sequence of the original peptide. Then the MS/MS sequences obtained for all of the tryptic peptides are compared by computer to all the predicted ORFs in a microbial genome. If one ORF contains all the peptides, a match is declared and the protein is identified.

TO SUMMARIZE:

- **The transcriptome and proteome** constitute all of a cell's mRNA molecules and proteins, respectively. Transcriptomes and proteomes change as environmental conditions change.
- **A DNA microarray chip** is used to monitor the levels of individual mRNA molecules made during growth.
- **Two-dimensional gels** separate proteins by isoelectric point and molecular weight. They offer a snapshot of the proteome at any given point of growth or under any given growth condition.
- **Mass spectrometry** can determine the exact molecular weight of a protein (or the sequence of a component peptide) taken from an otherwise anonymous spot on a two-dimensional gel. The exact molecular weight or peptide sequence is compared against the database of ORFs deduced from the genomic sequence of the organism. A successful match, therefore, determines the protein's identity.

Concluding Thoughts

The systems discussed in this chapter are but a small sampling of the known gene regulatory systems. Many more await discovery. How the cell coordinates all these systems is still a matter of conjecture. Scientists, like genetic cartographers, are now trying to map all the regulatory circuits of *E. coli,* as well as to identify novel regulatory strategies used by other organisms. The structural biology of regulatory protein-protein interactions and protein-DNA binding are certainly the research waves of the future. For though we know the "what and where" of many molecular interactions, we remain, for the most part, ignorant of *how* they occur structurally.

CHAPTER REVIEW

Review Questions

1. List regulatory mechanisms discussed in this chapter that work at the DNA level, transcription level, translational level, and posttranslational level.
2. How does lactose induce the *lacZYA* operon?
3. If *lacY* is not induced unless lactose is present, how does external lactose induce the system?
4. How does tryptophan repress the tryptophan operon?
5. Describe a two-component signal transduction system.
6. Discuss how glucose impacts the utilization of lactose as a carbon source.
7. Name a regulatory protein that can activate and repress an operon's expression. How does it do that?
8. What is DNA footprinting?
9. What is the regulatory mechanism that uses translation to control transcription? How does it work?
10. When growth of *E. coli* slows, how does the cell slow its production of ribosomes?
11. Describe four ways that sigma factor production/activity can be regulated.
12. What are small regulatory RNA molecules?
13. How do bacterial cells couple genetic control and biochemical control in terms of nitrogen assimilation?
14. What is quorum sensing?
15. Describe DNA microarrays and two-dimensional gels. Can you think of a situation where a protein could be shown to increase in response to a stress but that same stress will not increase synthesis of the mRNA encoding the protein?

Viral Molecular Biology

11.1 Phage T4: The Classic Molecular Model
11.2 The Filamentous Phage M13
11.3 A (+) Strand RNA Virus: Polio
11.4 A Segmented (−) Strand RNA Virus: Influenza
11.5 A Retrovirus: Human Immunodeficiency Virus
11.6 A DNA Virus: Herpes Simplex

Virus structure ranges from a single RNA molecule to a spore-like package containing multiple layers of protein capsid and membranes. When a virus infects a cell, its reproduction may require a genome of less than 10 genes or more than 200. Viral reproduction varies from the relatively simple lytic program of bacteriophage T4 to the elaborate multi-organelle cycle of herpes viruses. Viruses such as herpes sequester their genome within that of the host. Latent viral genomes have contributed surprisingly to human evolution.

The molecular mechanisms of viruses raise intriguing questions: How do viruses trick host cell defenses into permitting their entry and replication? How did viruses originate: as free-living cells that took up predatory lifestyles or as host cell components that went wrong? Viral molecular biology offers clues to these questions. The molecular mechanisms of viral infection reveal targets for antiviral drugs.

In the 1990s, as the AIDS epidemic spread around the globe, health care workers noticed certain individuals who remained free of HIV over many years of exposure. These people proved to have a defective gene that encodes a macrophage cell surface protein, CCR5 (**Fig. 11.1**). Individuals who carry a single copy of the gene defect, known as deletion 32 (CCR5-Δ32), possess only one functional copy of CCR5, encoded by the homologous chromosome. The CCR5-Δ32 heterozygotes show delayed onset of AIDS, and individuals with two copies of the CCR5 defect resist infection by the most common strains of HIV.

The basis of the CCR5-Δ32 resistance to HIV is that the virus envelope proteins need to recognize the specific protein sequence of CCR5 in order to attach and enter the host cell. The single CCR5 defect decreases the number of CCR5 receptor proteins and thus the efficiency of infection. The defect on both homologous chromosomes eliminates the protein and prevents virus attachment altogether. This protein-protein interaction offers hope for developing methods to prevent or cure AIDS. It may be possible to transfer the CCR5-Δ32 trait into the genome of a patient's macrophages, which will then resist HIV infection.

The HIV receptor defect is just one example of the promise of viral molecular biology for medical research and biotechnology. In Chapter 10 we discussed how molecular mechanisms such as repressors and DNA inversions regulate the function of microbial cells. Chapter 11 presents the molecular mechanisms of viral infection of cells. We assume a fundamental understanding of the nature of viruses, as presented in Chapter 6. Here we explore in greater depth the molecular basis of infection. First we consider two kinds of bacteriophages: a tailed phage and a filamentous phage. We then examine four viruses infecting humans, which include RNA and DNA genomes as well as a retrovirus. We see how all viral infection mechanisms share common themes of host recognition and co-opting cellular metabolism. At the same time, differences in genome structure dictate fundamentally different molecular requirements for infection.

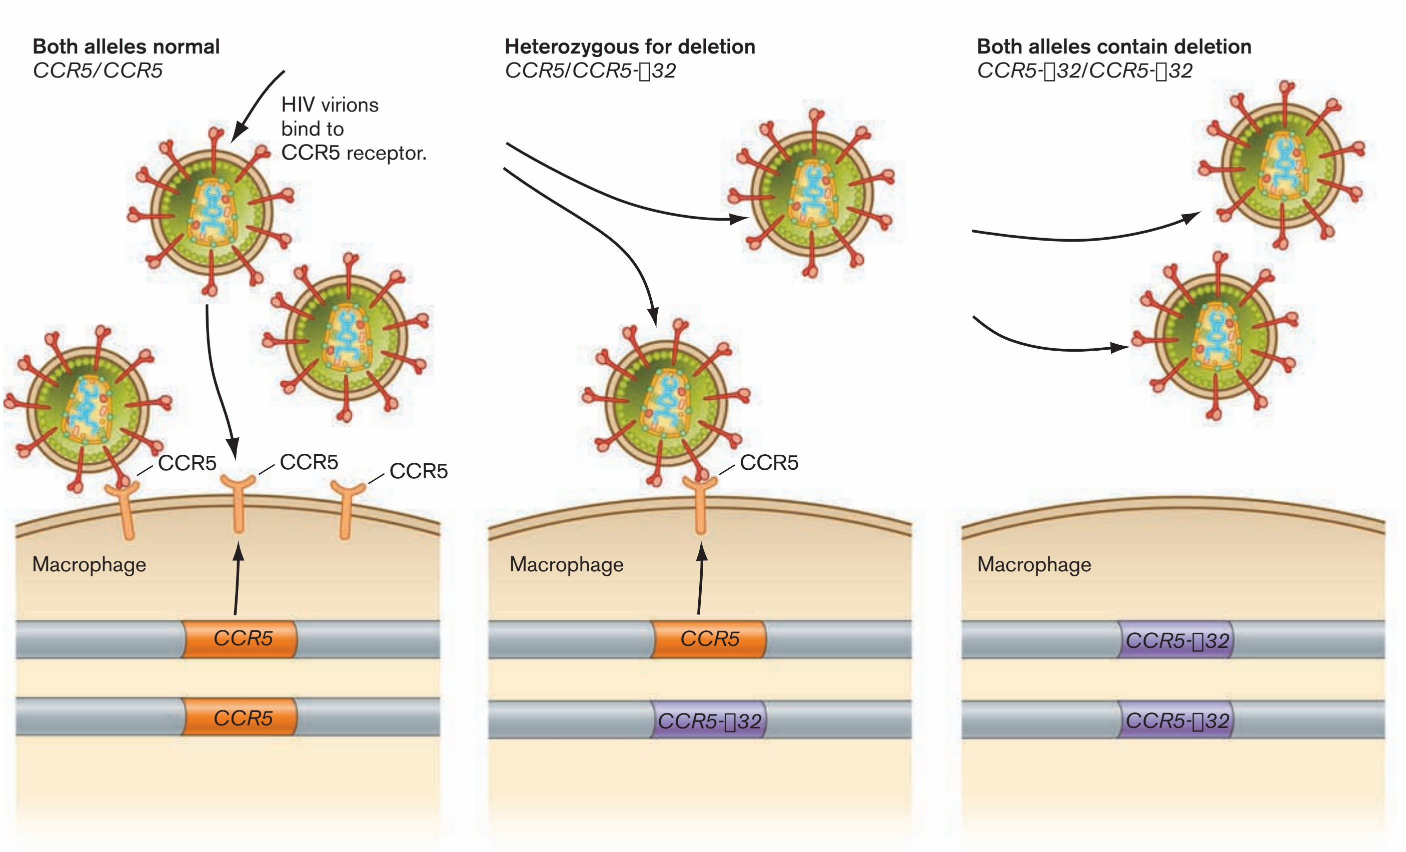

Figure 11.1 Resistance to HIV: a molecular mechanism. HIV normally binds to the CCR5 surface protein of immune cells. Individuals heterozygous for a CCR5 deletion show delayed onset of AIDS. Individuals homozygous for the CCR5 defect show full protection from the major strains of HIV, apparently because the virus fails to bind to its target host cell.

This chapter emphasizes the fundamental biology of viral infection and propagation. The consequences of viral disease for the host organism are presented in Chapter 26.

11.1 Phage T4: The Classic Molecular Model

Bacteriophages are of interest for several reasons. Historically, phages provided the first living systems simple enough to dissect at the molecular level. Phages yielded fundamental discoveries in gene regulation, including the classic case of lambda lysogeny (discussed in Section 10.7). The first model for the genetic analysis of development was a phage system, the assembly of the "tailed phage" T4 (*Myoviridae*). A different kind of phage, the filamentous phage M13 (*Inoviridae*), provided key cloning vectors for DNA sequencing in the 1970s. Today, phages provide new tools for antibacterial agents and new ways to make vaccines. They are also used to assemble wires in microscopic devices.

Here we present the replicative cycles of phages T4 and M13. These two phages offer interesting contrasts in their very different strategies of host infection.

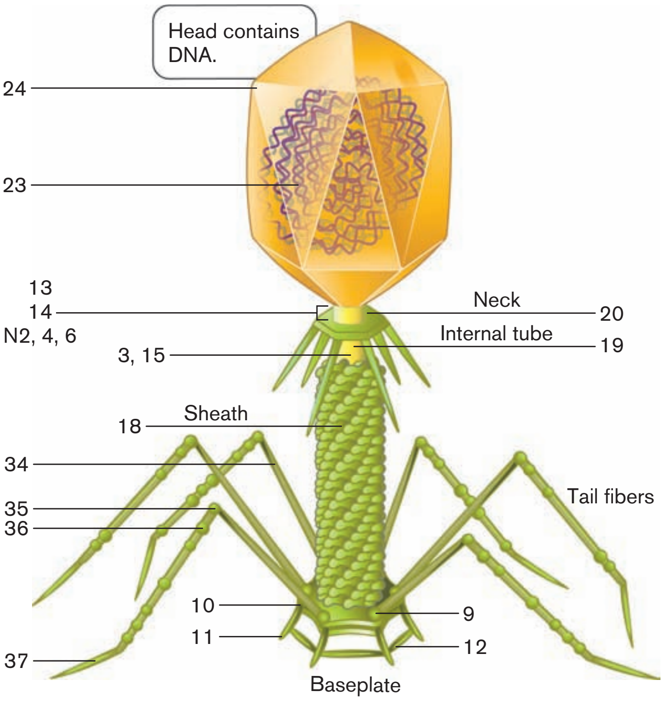

Figure 11.2 Structure of a phage T4 capsid (simplified). Proteins are assigned to specific genes (numbered) that are mapped on the chromosome in Figure 11.3.

Phage T4 Structure

Phage T4 may be the most complicated noncellular reproductive unit yet characterized. The intricate virion requires 20 gene products for assembly (**Fig. 11.2**). The T4 genome of 166 kilobase pairs (kbp) specifies 170 genes, many of which encode metabolic enzymes that duplicate host cell functions (**Fig. 11.3**). This viral genome almost looks like a cell genome in miniature. Thus, T4 has served as a model to probe the fundamental molecular processes of transcription and gene recombination as well as the global function of cells. The mutation strategies devised to dissect T4 function provided the basis for dissecting molecular development in animals.

WWW | 3-D tutorial on the T4 tail injector

The phage T4 virion contains numerous specialized protein subunits. The overall structure includes a polyhedral head, or capsid, containing its chromosome, a linear double strand of DNA (see **Fig. 11.2**) attached to a delivery device called the "tail;" hence the term **tailed phage**. The head is connected by a narrow neck tube to an internal tube that extends down within the sheath. The sheath plus the internal tube make up the tail. From the tail extend two sets of fibers, six connected at the neck and six at the baseplate. The elegant mechanical structure and function of this "molecular motor" was an early inspiration for nanotechnology.

Adsorption to Host and Delivery of DNA

Viral infection requires a molecular "fit" between a viral component and one or more molecules of the host cell surface. Phage T4 infects strains of *Escherichia coli* whose outer membrane possesses lipopolysaccharide (LPS) and the porin OmpC. The phage adsorbs (attaches) to the cell surface by contact between its tail fibers and the outer membrane (**Fig. 11.4**). Once several of the tail fibers are anchored to the outer membrane by LPS, the phage baseplate makes contact. The contact

between baseplate and cell outer membrane generates a conformational change in the tail. The outer tube of the tail, the sheath, is a helical tube of subunits of protein P18. The sheath contracts by shortening and widening, enabling the internal tube to push through, like a molecular syringe.

The internal tube of the tail is capped by the needle-like "injector," a unique trimer composed of proteins P27 and P5. The injector structure was first determined by Michael Rossman and colleagues at Purdue (**Fig. 11.5A**). Rossman's lab developed techniques of X-ray analysis and cryo EM to visualize many challenging viral structures, including whole virions such as rhinovirus (cold virus), dengue fever flavivirus, and canine parvovirus. These viral structures may now be used to test new antiviral drugs.

The P5 proteins form three intertwined strands in a "beta helix." As the sheath surrounding the internal

Figure 11.5 Injector device of phage T4. A. Michael Rossman and colleagues at Purdue University deciphered the structure of the phage T4 injector. They have also solved the structures of numerous whole viruses, such as the first rhinovirus (cold virus), dengue fever flavivirus, and canine parvovirus. **B.** Molecular model of the injector for the phage DNA. (PDB code: 1K28) **C.** Position of the injector within the baseplate, using low-resolution X-ray data. *Source:* Based on Rossman, et al. 2004. *Current Opinion in Structural Biology* 4:171–180.

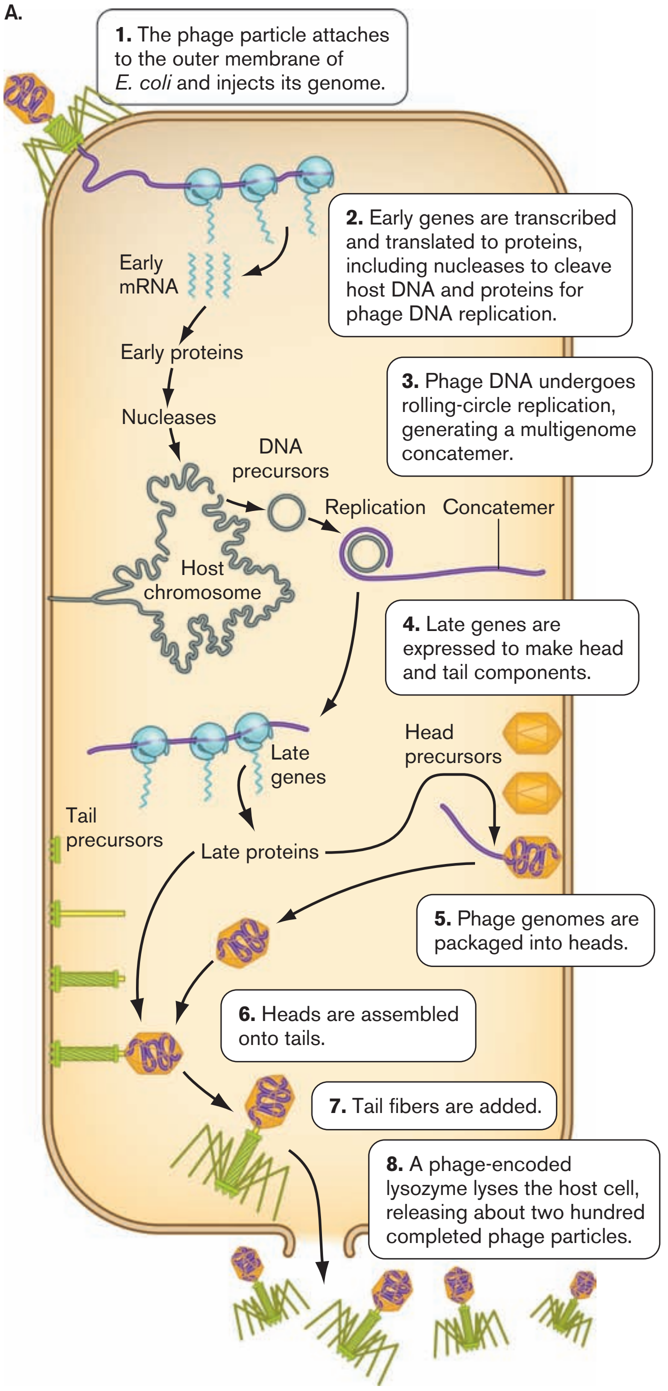
tube contracts, the injector pokes through the host outer membrane and penetrates the cell wall (**Figs. 11.5B** and **C**). The peptidoglycan surrounding the injector is then digested by protein P5, whose globular alpha-helical domain has lysozyme activity. The hole in the cell wall enables the entire tail to penetrate the cell wall and inner membrane. When the end of the tail tube penetrates the inner membrane, the phage DNA is released through it into the cytoplasm.

Virulent Replication Destroys the Host Cell

Phage T4 is fully virulent; that is, its only reproductive option is to assemble progeny virions while destroying a host cell (**Fig. 11.6A**). By contrast, other tailed phages, such as phage lambda can undergo lysogeny, the integration of their genome into that of their host cell. The integrated phage genome then replicates passively with the host. Lysogeny is described in Chapter 6, and the genetic regulation of phage lambda is presented in Chapters 7 and 10.

When phage T4 DNA enters the host cytoplasm, a set of phage genes are activated for transcription. The phage genes are transcribed by the host cell RNA polymerase and translated by the host ribosomes. These host components, however, are supplemented by phage-encoded components such as tRNAs.

Phage genes expressed early in the infectious cycle are called **early genes**. The early-gene products include proteins needed to cleave host DNA, thus halting host macromolecular synthesis. In addition, several phage DNA synthesis enzymes replace key enzymes of the host.



A.
1. The phage particle attaches to the outer membrane of E. coli and injects its genome.
2. Early genes are transcribed and translated to proteins, including nucleases to cleave host DNA and proteins for phage DNA replication.

O

Figure 11.6 Replicative cycle of phage T4. A. The phage particle attaches to the surface of *E. coli* and injects its genome. The genome is reproduced and packaged into progeny virions that are released upon lysis of the host cell. **B.** 5-Hydroxymethylcytosine replaces cytosine during DNA replication by T4-encoded DNA polymerase.

One T4 enzyme increases the rate of phage DNA replication tenfold. Another enzyme replaces cytosine with the modified base 5-hydroxymethylcytosine (**Fig. 11.6B**), which substitutes for cytosine throughout the phage chromosome. This modification of phage DNA prevents cleavage by endonucleases.

THOUGHT QUESTION 11.1 Why would phage T4 production require a tenfold higher rate of DNA replication than does the host cell? Why would the phage substitute all of its cytosine with an unusual base that requires greater energy to synthesize?

Phage T4 DNA is synthesized by rolling-circle replication (described in Chapter 7). First, the linear DNA duplex of phage T4 circularizes within its host cell by recombination between the terminally redundant ends. The circularized duplex then replicates by the rolling-circle method, generating a linear concatemer in which multiple genomes are joined end to end (**Fig. 11.7**). The concatemer serves as template to synthesize the complementary strand. Out of the linear T4 DNA concatemer, the individual genomes are packaged into head coats. Each head coat actually contains sufficient volume to pack 3% more DNA than contained in a phage genome; thus, when the DNA duplexes extending from each head coat are cleaved, each phage DNA contains 3% terminal duplication (terminal redundancy). Inclusion of the terminal duplication causes each cleavage to occur another 3% farther along the genome. Thus, every T4 DNA molecule ends up with a different terminal repeat at some point throughout the genome.

Ultimately, the **late genes** are induced to produce the capsid and tail proteins that assemble on the membrane to make mature phage. During **assembly**, the phage genomes are stuffed into heads, the filled heads are attached to tails, and finally the various tail, collar, and capsid substructures are assembled into about 200 complete phage particles per cell. At last a late gene encodes a lysozyme to digest the cell wall, releasing the phages into their surroundings. The signal for lysis and phage release remains unknown.

THOUGHT QUESTION 11.2 The phage T4 chromosome is a linear piece of DNA, yet the genomic map of T4 is circular. Why?

The temporal separation of early genes and late genes is common to the replicative cycles of all kinds of phages as well as viruses of eukaryotes. Viruses differ, however, in the size of their genomes; some, such as phage M13 (discussed shortly), contain only a small number of genes, whereas others, such as phage T4, encode products that duplicate host functions of DNA synthesis, ribosomal proteins, tRNA, as well as biosynthetic enzymes such as dihydrofolate reductase. Some phage-encoded enzymes, such as the T4 DNA polymerase, modify a cellular function to favor phage reproduction.

One hypothesis proposed for the evolution of T4 is that the phage arose by degeneration of a cellular parasite that ultimately lost its cytoplasm but retained metabolic components. An alternative hypothesis is that the phage T4 genome acquired many host genes through recombination with scraps of the host genome. The acquired genes then evolved new functions that increased the efficiency of phage assembly; for example, dihydrofolate reductase is used to assemble folate into the baseplate of the T4 injector.

Phage Particles Self-Assemble

The assembly of phage T4 particles within the host cytoplasm offers exceptional opportunities to visualize a molecular pathway. Each phage particle is assembled by convergence of three pathways involving the head coat, the tail, and the tail fibers (**Fig. 11.8**). All of these stages can be isolated and observed within infected cells by electron microscopy (**Fig. 11.9**). But with all these many steps, how did we determine the order of assembly and identify the genes responsible?

The stages of phage assembly were discovered using strains that carry mutations in various genes encoding proteins essential for development (see **Fig. 11.8**). In some cases, defective assembly leads to a bizarrely altered shape of the particle, such as a phage with a "giant head" (**Fig. 11.9A**). In other cases, a defective gene simply prevents progression in the pathway, halting assembly at an unfinished stage. For example, **Figure 11.9B** shows the phage particles found in a cell infected by a phage defective for gene 23. The unfinished particles consist of tail structures only. This occurs because gene 23 is required for assembly of the head, which must be completed before attachment to the tail. In **Figure 11.9C**, which shows phages defective for gene 19, we see only baseplates because the product of gene 19 is needed to build the tail upon the baseplate. In this case, assembled heads are found near the membrane of the cell (not shown).

Mutant 3

Figure 11.9 Developmental mutants of Phage T4. Analyzing such mutants made it possible to decipher the genetic pathway governing assembly of the structure. **A.** Mutations in developmental genes lead to variant capsid morphology such as "giant head." **B.** Gene 23 defect results in tails without heads. **C.** Gene 19 defect results in baseplates without tails. **D.** Design of experiment using temperature-dependent mutations to identify steps of assembly.

An interesting problem arises in designing an experimental strategy: How do we grow populations of phages whose particles fail to complete assembly? The answer lies in using **conditional lethal mutations**, that is, mutations that cause a lethal defect under one growth condition but permit growth under a second condition. Two classes of conditional lethal mutant strains of phage T4 were obtained through mutagenesis by Robert Edgar and Richard Epstein in the early 1960s. These two classes are:

- **Temperature-sensitive mutants.** Mutants that are temperature sensitive can grow at one temperature but fail to grow at another. For example, a point mutation may result in a protein product that is stable at 25°C but denatures at 42°C, so that the phage can reproduce at 25°C but not at 42°C.
- **Nonsense mutations countered by suppressor tRNA.** A mutant that contains a nonsense codon

(stop codon) in the middle of a gene prematurely terminates translation of the protein. Such a strain, however, may be grown in a strain of *E. coli* that makes a certain type of mutant tRNA. The mutant tRNA contains an anticodon that matches the stop codon sequence, which allows the tRNA to place an amino acid into the growing protein. This kind of tRNA is called a **nonsense suppressor** because the tRNA anticodon mutation suppresses the effect of the nonsense mutation in the phage.

Through many years of analysis of phage mutants, Edgar and Epstein and their colleagues showed that conditional lethal mutations could be used to dissect a developmental pathway as complex as that of phage T4. Their work laid the foundation for the molecular analysis of development in animals and plants and the discovery of the molecular basis of inherited diseases. With whole-genome sequences in hand, we use conditional lethal mutations and suppressor mutations to decipher how all the gene products work together. For example, genetic analysis of development in the fruit fly *Drosophila* uses temperature-sensitive mutations to dissect mechanisms of gene regulation.

TO SUMMARIZE:

- **The phage T4 virion** consists of a head containing its DNA genome and accessory proteins; a tail composed of an internal tube with a sheath; and tail fibers.
- **Adsorption of T4** occurs by binding of tail fibers to bacterial outer membrane receptors, followed by binding of the tail baseplate.
- **Injection of T4 DNA** through the internal tube leads to lytic infection. Early genes encode a DNA polymerase and a DNase to cleave host DNA.
- **Rolling-circle replication** generates progeny genomes linked in a concatemer. The concatemer is cut with an offset, so that each linear genome has a slight overlap, cut at a different position in the sequence.
- **Self-assembly of virions**, including packaging of DNA into the head, occurs in arrays beneath the inner membrane.
- **Cell lysis** is caused by a lysozyme expressed by late genes in the T4 genome.
- **The phage T4 assembly process was dissected using temperature-sensitive mutants and nonsense mutants with suppressor tRNA.** This strategy of genetic dissection was used as a model for experiments on animal development.

11.2 The Filamentous Phage M13

Filamentous phages consist of an extended, flexible tube of variable length. An exciting use of the filamentous phage M13 is to grow microscopic metal “nanowires” that conduct electricity. The wires are made using a mutant phage whose coat proteins bind metals such as gold and cobalt. Around the phage filaments form microscopic tubes of metal, which can be used in the manufacture of tiny batteries.

The filamentous phages, like the tailed phages, must construct progeny using the materials and metabolism of a host cell. Yet the means by which they achieve this goal differ greatly from those of T4. Where T4 featured remarkable complexity in its capsid, the structure of M13 is a simple helical filament (**Fig. 11.10**). Instead of the 170 genes of the T4 genome, M13 manages just as successfully with 11, including some that overlap (**Fig. 11.11**). Instead of lysing its host, M13 allows the host to continue growing, although more slowly than uninfected cells.

Filamentous Phage Structure

The M13 capsid consists of a flexible protein cylinder that is about 150 times as long as it is wide (**Fig. 11.10A**). The cylinder is assembled around a supercoiled single-stranded circle of DNA. The advantage of the filamentous structure is that it requires a relatively small number of different protein subunits encoded in the genome. Similar flexible filamentous structures have evolved independently in animal and plant viruses; compare, for example,

Figure 11.11 **The M13 phage structure and genome.** Phage M13 structure with proteins are color-coded to genes in the phage genome. *Note:* The actual phage filament is about 150 times as long as it is wide.

Ebola filovirus and tobacco mosaic virus (see Section 6.2). Filamentous animal viruses, however, show a virulent infectious cycle completely different from the slow release of filamentous phages.

Each subunit of the M13 filament consists of a short alpha-helical peptide encoded by gene 8. The protein P8 subunits have positively charged lysine residues at the internal end to bind the negatively charged DNA. The subunits extend outward at a shallow angle, looking like bunches of bananas stacked as a long tube (**Fig. 11.10B**). The tube is tipped at one end by five copies of protein P3, a much larger and more flexible protein that binds the cell surface receptor during phage adsorption (see **Fig. 11.11**). At the opposite end of the tube are proteins P7 and P9, which enable a progeny phage particle to emerge from the cell.

The simple, flexible nature of the filamentous phage has proved useful for development of the technology of **phage display**. Phage display is used in drug discovery to identify molecular interactions between protein domains. In phage display, a gene encoding a key portion of a protein domain (usually a short peptide) is cloned at the terminus of the sequence for one of the phage coat proteins, such as protein P8 or protein P3 (see **Fig. 11.11**). The recombinant phage now displays the desired protein domain on its coat, where it can be recognized by antibodies or can selectively bind to a target molecule. This technique can be used to screen a library of recombinant phages for binding partners to an antibody or to a target regulatory protein, such as a cell cycle regulator involved in tumorigenesis. Phage display is discussed further in Chapter 12.

Adsorption to Host and Delivery of DNA

Phage M13 infects only F^+ strains of *E. coli*, which possess F pili. The phage adsorbs by binding of the tip protein P3 to an F pilus (**Fig. 11.12**). The pilus contracts, bringing the phage into contact with a **coreceptor**, or secondary receptor protein, TolA. The TolA complex is an important structural anchor of the *E. coli* cell envelope. Coreceptors for host attachment are a common feature of viruses, including animal viruses such as influenza virus and HIV-1 (discussed later).

As the M13 filament contacts the cell, it transfers its DNA across the cell envelope by an unknown mechanism. Unlike phage T4, the empty M13 filament does not remain intact outside the cell. Instead, the filament subunits disassemble and insert into the inner membrane, where they eventually join the pool of newly synthesized subunits to form progeny phages. Because most M13 assembly steps involve the membrane, we know less about the details of M13 assembly than we do about assembly of T4, whose components are all cytoplasmic and therefore easier to study.

M13 Reproduction Does Not Kill the Host

As the infecting capsid dissolves in the inner membrane, the phage DNA (single-stranded circle) enters the cytoplasm. Phage DNA is replicated by host enzymes while

host cell growth continues. Replication of the single-stranded genome starts with generation of a double-stranded replicative form (**Fig. 11.13A**). The replicative form then undergoes rolling-circle replication of the (+) strand, like phage T4. The growing concatemer (multiple repeats of the minus strand) is protected by subunits of protein P5, a single-strand binding protein. As each genome length is completed, it is nicked and circularized without overhang. The circular DNA is packaged with capsid proteins at the cell membrane.

1. P4 forms export pore, plugged by P1 and P11.

2. P5 proteins on DNA are replaced by P8 and other filament proteins from the inner membrane.

3. As filament proteins assemble, the phage slides out the P4 pore. The pore is replugged by P1 and P11.

Figure 11.13 **Assembly and export of M13 progeny phages.** **A.** Replication of phage M13. Most assembly is conducted by phage proteins within the cell membrane. **B.** Assembly for export through the pore made of P4 monomers. P4 makes a channel used to export filamentous phages without lysing the bacterial host. The single-stranded DNA of the filamentous virus is coated by P8 subunits as it passes through the membrane, then passed through the P4 channel to emerge as mature, infectious phages.

The single-stranded to double-stranded transition of phage M13 was important historically because of its role in DNA sequencing. When DNA-sequencing methods were first invented by Sanger, they required a template that was single-stranded. But recombinant DNA techniques required double-stranded DNA for restriction enzyme cleavage and ligation. The most effective way to obtain large quantities of a single-strand template was to splice a gene sequence within a double-stranded M13 replicative form. The replicative form was then used to transform cells that subsequently produced M13 phages carrying single-stranded DNA. Today, a single-stranded template is no longer required for PCR-based sequencing, but M13-based vectors remain useful for special applications, such as phage display.

Filamentous Phages Self-Assemble at the Inner Membrane

The M13 genome expresses packaging proteins, including protein P8 as well as the specialized tip proteins P3, P7, and P9 (see **Fig. 11.11**). All packaging proteins insert initially into the inner cell membrane. To mediate their assembly, a pore complex forms, composed of protein P4. P4 monomers extend through all layers of the envelope and assemble in a ring to build the pore. The positive charges on the N-terminal end of P4 help attract the negatively charged DNA into the pore. The pore guides the assembly of P8 monomers (also positively charged) and other packaging proteins around the DNA (see **Fig. 11.13**). To avoid lysing the host cell, the pore is plugged by proteins P1 and P11 until phage assembly begins.

As the P5-coated chromosome enters the pore, the protein P5 subunits are replaced by the growing tube of P8 proteins. The final step of phage export involves capping with protein P3, which is needed for attachment and infection of the next host cell. The pore complex is then recapped with P1 and P11 to avoid lysis. The production of M13 phages slows growth of the host because of resource consumption, but it does not destroy the host cell; in fact, two of the phage's 11 gene products (about one-sixth of its genome) are devoted to preventing host cell lysis. The evolved strategy of M13 is to maintain its current host at minimal cost, rather than to maximize its immediate number of progeny.

THOUGHT QUESTION 11.4 Compare and contrast the reproductive strategies of phages T4 and M13.

TO SUMMARIZE:

- **The filamentous phage M13** has a filamentous capsid of variable length, able to package genomes of variable size; this is an advantage for cloning vectors.
- **Phage M13 adsorbs to F pili.** The pilus contracts, bringing the phage into contact with the host outer membrane. The filament penetrates to the inner membrane, where the filament subunits fuse and dissolve into the membrane.
- **Host enzymes replicate phage DNA and express phage genes.**
- **Phage M13 replicates without destroying the host cell.**
- **The DNA genome is a single-stranded DNA circle.** It must be replicated to a double-stranded circle for synthesis of progeny single-stranded genomes.
- **M13 virions are assembled at the inner membrane** for export through a phage-encoded pore complex.

11.3 A (+) Strand RNA Virus: Polio

Compared to bacteriophages, viruses that infect animal cells usually have the simpler task of crossing the eukaryotic cell membrane. Within the eukaryotic cell, however, the interior structure is generally more complex than that of prokaryotes. To use the cell's gene expression system, an animal virus must negotiate various cellular compartments, such as endocytic vesicles and the nucleus. Different viruses use very different strategies to manipulate the host cell.

A medically important group of viruses is the **picornaviruses** (**Table 11.1**), a class of icosahedral RNA viruses whose life cycle has some interesting parallels to that of phage T4. The picornavirus **poliovirus** is the cause of the paralytic disease **poliomyelitis**, or **polio**. The host range for infection by poliovirus is limited to humans and our closest relatives, such as chimpanzees. Closely related

Table 11.1 Picornavirus species (examples).

Genus	Virus	Disease	Host
Enterovirus	Coxsackievirus	Common cold, myocarditis	Humans
	Echovirus	Meningitis, paralysis, encephalitis	Humans
	Poliovirus (PV)	Meningitis, paralysis	Humans
Rhinovirus	Human rhinovirus (HRV)	Common cold	Humans
Aphthovirus	Foot-and-mouth disease virus (FMDV)	Foot-and-mouth disease	Cattle, swine
Hepatovirus	Hepatitis A virus (HAV)	Hepatitis	Humans
Cardiovirus	Encephalomyocardiovirus	Encephalitis, myocarditis	Mice
Erbovirus	Equine rhinotracheitis B virus (ERBV)	Rhinotracheitis (respiratory infection)	Horses

picornaviruses such as the **rhinoviruses** and coxsackievirus cause the common cold. A major veterinary concern is aphthovirus, the cause of foot-and-mouth disease in cattle and swine. In 2001, an outbreak of foot-and-mouth disease in the United Kingdom caused major economic and societal disruption.

Poliovirus is famous historically for the outbreaks of poliomyelitis that swept the United States during the first half of the twentieth century (**Fig. 11.14**). The virus enters orally from fecal sources such as contaminated water. In most cases, poliovirus infection causes a mild gastrointestinal disease, but the virus can invade motor neurons of the spinal cord and lower brain, resulting in paralysis. Tens of thousands of Americans were infected, including many young children. Many had few or no symptoms but could transmit the disease to others. About 1% became paralyzed, of whom about 15% died. Decades later, paralyzed individuals may suffer post-polio syndrome, a condition in which muscles that were previously affected by the polio infection experience atrophy and pain. Today, polio infection has nearly been wiped out worldwide, although outbreaks still occur due to low levels of vaccination in isolated communities such as the Amish and in countries of Southeast Asia and Africa.

President Franklin Roosevelt, himself a victim of the disease, established a national foundation called the March of Dimes to develop a vaccine. Support from the March of Dimes led Jonas Salk and colleagues at the University of Pittsburgh to develop the first vaccine against polio in 1952. The spectacular success of the March of Dimes set the pattern for future public support for research on more challenging diseases, such as cancer and AIDS.

Despite the success of the polio vaccine, questions remain. The vaccine is not perfect; could better vaccines avoid the one-in-a-million deaths actually caused by the vaccine? What is the cause of the post-polio syndrome that affects some former polio victims 30–40 years after their illness? Are there positive applications of poliovirus, perhaps as a gene therapy vector or even as a treatment for brain tumors? To address these questions an understanding of the virus and its host cell at the molecular level is required.

Poliovirus Structure and (+) Strand RNA Genome

The structure of poliovirus is so compact and symmetrical that it was crystallized early in the twentieth century. Its three-dimensional structure was modeled by X-ray crystallography and by digital reconstruction based on cryo EM. Like many viruses, the capsid is fundamentally icosahedral (20-sided) (discussed in Chapter 6). Its form can be visualized as 60 triangular faces, each composed of proteins VP1, VP2, and VP3 (**Fig. 11.15A**). The three proteins arise from one long "polyprotein" or polypeptide translated as a unit, then cleaved into three pieces. The polyhedral form enables a small number of genes to encode a relatively large capsid. For this reason, capsids of icosahedral symmetry are common among animal and plant viruses, including, for example, the rhinoviruses (cold viruses), aphthovirus (foot-and-mouth disease), herpes viruses, and rice yellow mottle virus.

Each group of three triangular faces forms a pentamer. Beneath the pentamers of VP1, VP2, and VP3 lie subunits of a fourth protein, VP4. VP4 subunits coat the interior, strengthen the structure, and help package the RNA genome.

The RNA genome of poliovirus consists of a coding (+) strand. Its 3′ OH end has a poly-A tail, like eukaryotic mRNA, but its 5′ OH end is capped with a special viral protein, VPg.

Virus Attachment and Genome Entry

The poliovirus attaches to the host at a species-specific receptor protein location. The virus can only infect host cells that contain a **poliovirus receptor (PVR)**, a cell membrane protein found only in humans and close relatives such as chimpanzees. The structure of PVR protein suggests host

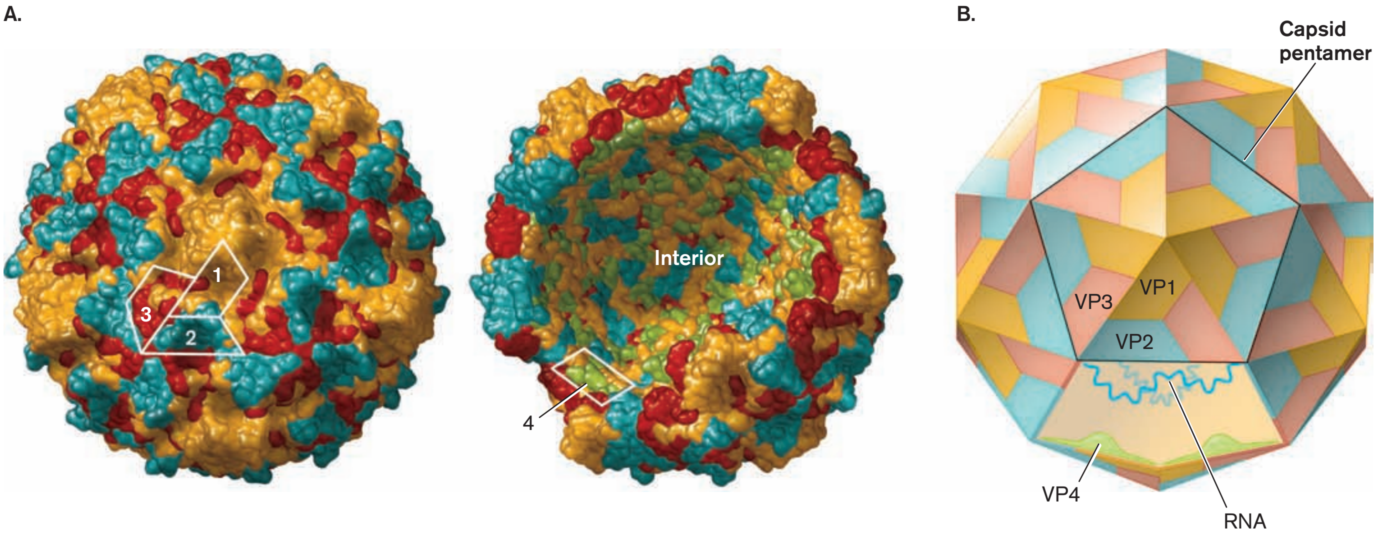

Figure 11.15 Poliovirus structure. A. Digital reconstruction of the poliovirus capsid based on TEM. *Left:* The icosahedral structure is composed of external capsid proteins VP1 (yellow), VP2, (blue), and VP3 (red). The three proteins form a structural unit, five of which form a pentamer (B). *Right:* Beneath the pentamer, VP4 subunits (green) coat the interior. The interior normally contains the RNA chromosome (not shown). (PDB code: 1ASJ) **B.** Schematic of capsid proteins forming a pentamer.

function related to inflammation or cell adhesion, but the details are unknown. A transgenic mouse expressing a recombinant human gene for PVR can be infected by poliovirus, generating all the major symptoms of poliomyelitis. The polio mouse was the first example of a transgenic animal created as a model system for a human disease.

Poliovirus receptors diffuse freely within the host cell membrane. PVR can bind the polio virion at any vertex of the capsid pentamer (a pentamer is shown in **Fig. 11.15B**). PVR actually binds to adjacent VP2 and VP3 proteins surrounding the VP1 subunits, as shown in **Figure 11.16**. When poliovirus attaches to a cell, multiple receptor molecules diffuse near it and eventually bind to several faces of the capsid. As the poliovirus receptors bind, the membrane forms a cup around the capsid. Unlike other viruses, such as influenza virus, poliovirus requires only the earliest stage of endocytosis; the virion delivers its RNA to the cytoplasm immediately after internalization beneath the cell membrane. Thus, poliovirus infection is insensitive to drugs such as bafilomycin A1, which prevents infection by viruses that enter cells through endosomes.

As the poliovirus interacts with the poliovirus receptors, its pentamer structures shift so as to extrude the N-terminal ends of the five VP1 peptides (**Fig. 11.16**). The five VP1 molecules of the pentamer poke through the cell membrane together, generating a pore through which the chromosome passes into the cytoplasm. The transfer of the poliovirus chromosome parallels that of phage T4 in that the nucleic acid is injected across the cell membrane through a viral device while the capsid proteins are left outside.

The viral chromosome, a (+) strand RNA with a protein VPg attached to the 5′ end, is said to be uncoated.

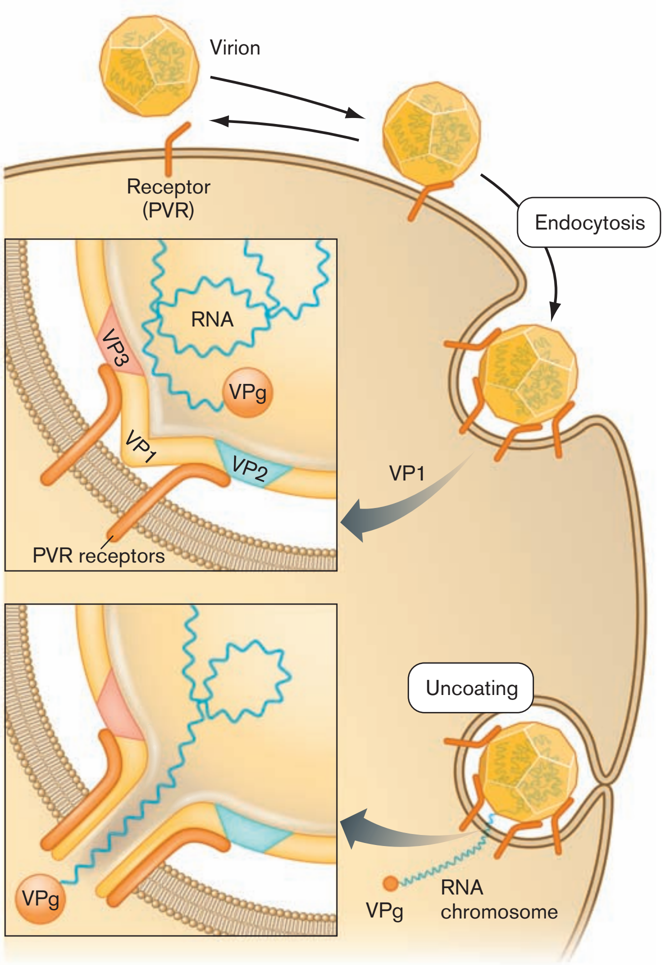

Figure 11.16 Poliovirus attachment to the host cell. The poliovirus binds PVR at the VP2 and VP3 subunits. A conformational change in the VP1 subunits allows insertion of genome.

The uncoated genome is now ready to direct formation of progeny virions.

Gene Expression and Replicative Cycle

The uncoated viral RNA has two distinct roles in producing progeny virions: (1) mRNA translation by host ribosomes and (2) template replication of progeny RNA genomes. These two processes occur in separate compartments within the host cells.

Translation to make peptides. In the cytoplasm, the RNA is translated to make three large precursor peptides, P1, P2, and P3 (**Fig. 11.17A**). All three peptides are

eventually cleaved by one of two viral proteases (products 2A and 3C) to generate a total of 11 different protein products. The P1 precursor forms the repeating unit of the isosahedral capsid; each unit is ultimately cleaved into four peptides. The P2 precursor is cleaved to form a two-subunit protease and an RNA-membrane interaction protein. The P3 subunit is cleaved to form RNA-dependent RNA polymerase, the Vpg primer for RNA synthesis, and another protease.

The capsid proteins ultimately arise from cleavage of P1. Cleavage, however, does not occur immediately (**Fig. 11.17B**). Instead, the peptide P1 (including sequences V4–V2–V3–V1) first folds into the tertiary structure of the capsid's major repeating unit. The repeating unit is called the 5S structural unit, referring to its size in Svedberg units of sedimentation rate. After folding together, each 5S unit then undergoes proteolysis at the junctions between the four subunits (V1 through V4). The 5S units then join together in groups of five to form pentamers, 12 of which ultimately assemble around a viral RNA chromosome.

RNA genome replication. In the overall cycle of replication (**Fig. 11.18**), the RNA chromosome serves as mRNA for peptide translation (step 1) and also as a template for RNA synthesis by RNA-dependent RNA polymerase (translated from the genomic RNA as part of precursor peptide P3). A theoretical problem is: How do the two molecular machines (ribosomes and RNA polymerase) avoid colliding with each other? The problem is solved by containing the chromosome and polymerase within special vesicles formed out of the ER, induced by the poliovirus (step 2). The virus-induced vesicles contain no ribosomes, so only RNA synthesis occurs.

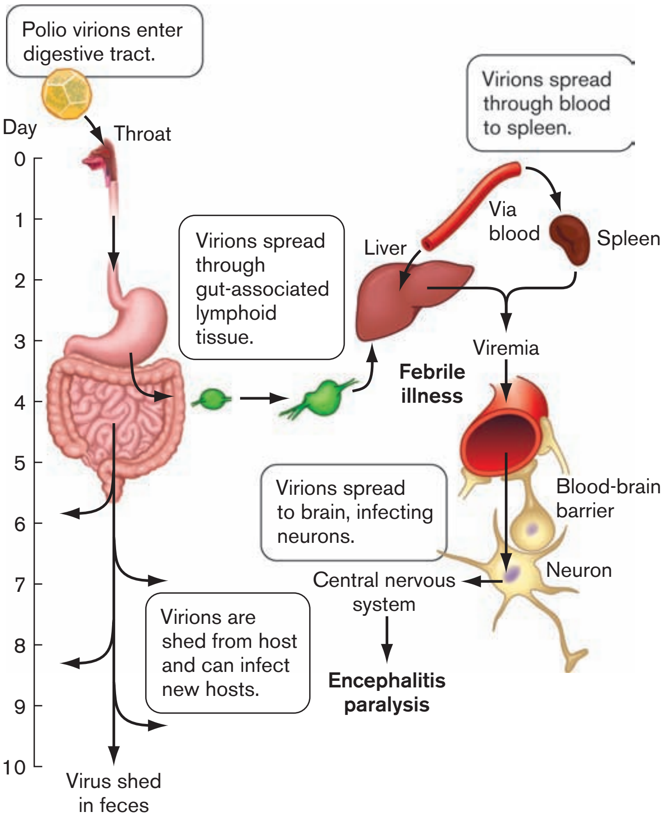
Within the virus-induced vesicles, the (+) strand RNA is bound to the vesicle membrane by protein 2C (step 3) and protein 3AB (step 4). Protein 3AB primes RNA synthesis, then it is cleaved to form VPg. The (+) strand RNA first serves as template to synthesize (–) strands of RNA (step 5). The (–) strands then serve as templates to make new (+) strands (step 6). For each process of RNA synthesis, the template RNA is bound at the membrane by protein 2C. The daughter strand synthesis is primed by a tyrosine-OH of protein 3AB, which binds to the 3′ end of the template. Protein primers are unique to viruses; in uninfected host cells, all DNA synthesis is primed by the 3′ OH end of RNA. Protein primers, however, are common in many kinds of viruses.

After synthesis of (+) strand RNA is complete, the membrane-bound 3AB protein is cleaved, leaving the 3B portion (now designated VPg) attached to the 5′ OH end of the RNA. Polioviral RNA synthesis is extremely efficient, generating about 50,000 copies per host cell. The (+) strand RNAs exit the ER (step 7), where some of them serve as mRNA for further translation to peptides, while others are packaged into capsids (step 8) to complete the poliovirus particles.

Viral Exit and Dissemination

How mature polio virions exit the cell is poorly understood, but their release is rapid and destroys the cell. Rapid, destructive release of virions is typical of species with nonenveloped capsids. The cytopathic effects of release are compounded by the host's immune response, which includes inflammation that further damages cells.

Animal viruses, unlike bacteriophages, require a means of transmission not only from cell to cell but also from host to host. To complete its infectious cycle, the animal virus may need to infect several different kinds of cells in different tissues. Poliovirus initially infects epithelial cells of the gut lining (**Fig. 11.19**). Some of the progeny virions remain in the gut, sustaining infectious cycles for weeks or months. In most cases, the infection remains confined to the gut; but in some cases, virions move to the gut-associated lymphoid tissue, leading to



Polio virions enter digestive tract.

dissemination throughout the lymphatic system and associated organs. Large numbers of virus are released into the blood, a condition known as **viremia**. Viremia facilitates dissemination across the blood-brain barrier, leading to infection of neurons. The destroyed neurons cannot be regrown; thus, nerve loss results in paralysis.

Throughout the course of infection, polio virions continue to be released from the host via the digestive tract. The process of viral release is known as **virus shedding**. Poliovirus can be shed from the gastrointestinal tract for several weeks after symptoms have ended, thus enhancing transmission to the next host.

TO SUMMARIZE:

- **Poliovirus**, a picornavirus, is icosahedral. Its genome consists of single-stranded (+) strand RNA.
- **Polio virions attach to poliovirus (PVR) receptors.** Conformational change in the capsid allows DNA insertion for uncoating in the cytoplasm.
- **Poliovirus RNA is replicated in the ER by RNA-dependent RNA polymerase.** Genome replication is primed by virus-encoded protein primer 3AB, which is cleaved to 3B (VPg).
- **(+) strand RNA serves as a template for (–) strand RNA.** The (–) strand RNA then serves as template for (+) strand RNA, which is either translated to proteins or encapsidated into progeny virions.
- **RNA for polio gene expression is exported** to the cytoplasm for translation by host ribosomes. Virions are packaged in the cytoplasm and exported by an unknown mechanism.
- **Poliovirus enters the body through the gastrointestinal tract.** In severe cases, the virus disseminates through the lymph and blood, crossing the blood-brain barrier to infect neurons and cause paralysis.

11.4 A Segmented (–) Strand RNA Virus: Influenza

Some viruses package a (–) strand RNA genome, whose replication involves a more complex replicative cycle than that of (+) strand RNA viruses. Influenza A virus, an orthomyxovirus, is one of the most common life-threatening viruses in the United States. Each year, influenza A infects approximately 10% of the U.S. population, causing about 20,000 deaths annually. The elderly are most susceptible, but in an epidemic year, mortality rises among young people.

Influenza shows a cyclic appearance of extremely virulent strains that cause pandemic mortality, such as the famous pandemic of 1918, which infected 20% of the world's population and killed more people than World War I. The 1918 strain arose as a mutant form of an influenza strain infecting birds. In 2006, a similar avian influenza strain emerged as a potential source of the world's next influenza pandemic. As of this writing, however, the avian strain has not yet mutated to a form readily transmitted between humans.

Highly virulent strains of influenza usually result from reassortment between distantly related strains. The reassortment process is enhanced by a particular feature of their molecular biology, namely, the **segmented genome**. A segmented genome of a virus consists of multiple separate nucleic acids, like the multiple chromosomes of a eukaryotic cell. The influenza genome consists of eight separate linear (–) strands of RNA, which can combine from different strains to generate a novel hybrid strain.

WWW | CDC page on influenza virus

Influenza Virion Structure and Genome

The influenza virion, unlike that of polio, has no geometrical capsid (**Fig. 11.20A**). Its RNA chromosome segments are loosely contained by a shell of **matrix proteins** (M1). Matrix proteins enclose the core or capsid, supplementing its connection to the membrane envelope (**Fig. 11.21A**). The envelope derives from the phospholipid membrane of the host cell, which incorporates viral proteins such as hemagglutinin (HA) and neuraminidase (NA). These viral envelope proteins peg the membrane to the enclosed capsid, maintaining its structure. Thus, mutations in the gene encoding neuraminidase produce aberrant virions with highly irregular shapes (**Fig. 11.20B**). Neuraminidase can be blocked by the antiviral agent Tamiflu (oseltamivir), the main drug available to treat influenza.

Figure 11.21 Influenza A: structure and genome. A. Diagram of virion structure showing envelope (tan), envelope proteins, matrix protein (green), RNA segments with attached polymerase, and the nuclear packing protein NS2. **B.** Genome of influenza A includes eight RNA segments, each encoding one protein. Each (–) strand segment must be transcribed to a (+) strand mRNA with a host-derived 5′ cap and viral RNA polymerase, and 3′ poly-A tail. Two of the segments (7 and 8) undergo additional processing to express two additional proteins (M2 and NS2).

The matrix shell contains the eight RNA segments, which are noncoding (–) strands (**Fig. 11.21B**). The RNA segments are coated with **nucleocapsid proteins (NP)**. The term "nucleocapsid" refers generally to proteins coating a viral genome and packaged within or as part of the viral capsid. Each NP-coated RNA segment also possesses a bound RNA-dependent RNA polymerase complex. Thus, unlike poliovirus and most bacteriophages, the influenza virion contains more than its genome; it also contains its own RNA polymerase enzyme, bound to each RNA segment and poised for synthesis. During infection each (–) strand RNA segment must be transcribed to a (+) strand mRNA for eukaryotic translation.

THOUGHT QUESTION 11.5 Why does influenza virus have to provide its polymerase ready-made, whereas poliovirus does not?

NOTE: In figures of this chapter, AAA-OH$^{3'}$ represents a poly-A tail consisting of a variable number of adenine nucleotides with a 3′ hydroxyl end.

The segmented genome of influenza poses a major problem for virus assembly: Given that viral infection requires all eight segments, how does the assembly mechanism package exactly eight segments, one of each? In fact, the segments are packaged at random, resulting in a vast majority of defective particles. The fraction of influenza particles observed to be capable of infection is consistent with random packaging of any eight segments into a capsid. The theoretical fraction of infectious virions would be given by the following equation:

$$\frac{8!}{8^8} = \frac{8 \times 7 \times 6 \times 5 \times 4 \times 3 \times 2 \times 1}{16{,}777{,}216} \approx \frac{1}{416}$$

One in 400 may sound tremendously inefficient, but if 10,000 virions are produced, there will be more than enough infective particles to propagate the virus. Furthermore, animal viruses require a relatively small number of progeny to ensure infecting the neighboring cells of a multicellular tissue, as compared to phages or viruses of single-celled organisms. Thus, influenza virus may avoid

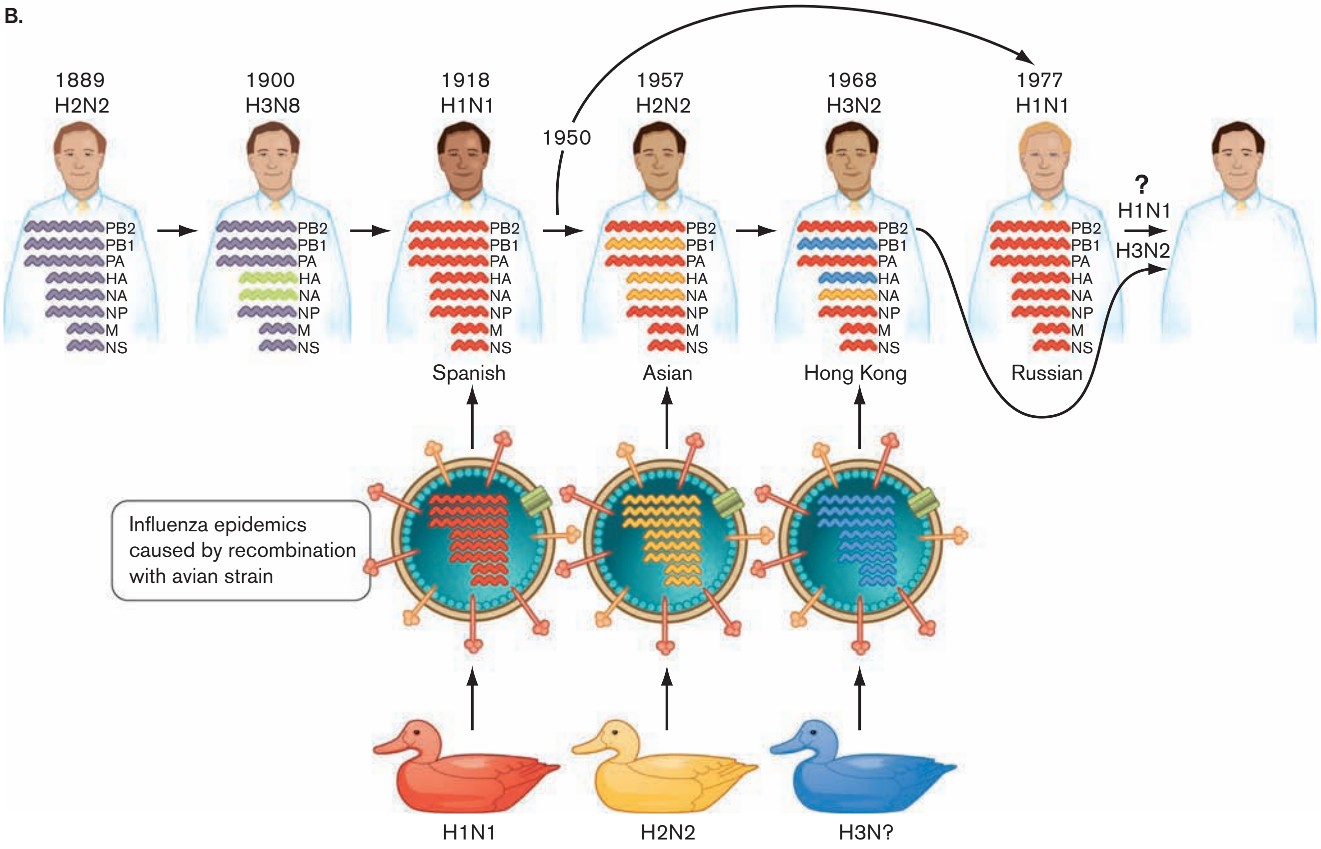
James Gathany/CDC

Figure 11.22 Reassortment between human and avian strains generates exceptionally virulent strains. A. The reconstructed strain of the 1918 Pandemic Influenza Virus is studied by Dr. Terrence Tumpey, microbiologist at the Centers for Disease Control and Prevention, Atlanta. The 1918 strain may hold clues to combatting the "avian influenza" strain today. **B.** Major epidemics of exceptionally virulent strains arise from reassortment with chromosomal segments from strains that evolved within ducks or swine, agricultural animals that live in proximity to humans. The segments are labeled as in Figure 11.21. The 1918 pandemic may actually have derived all eight segments from an avian strain. The 1957 strain incorporated avian segments 2, 4, and 5; subsequently, the 1968 strain replaced segments 2 and 4 with those of yet another avian strain. The numbers following H and N refer to different alleles of the genes encoding hemagglutinin and neuraminidase, respectively.

B.



the energetic expense of an accurate packaging mechanism for its segmented genome.

THOUGHT QUESTION 11.6 Explain why the expression ($8!/8^8$) approximates the proportion of infective particles of influenza virus. What assumption might be changed to make the proportion greater or less?

The key advantage of a segmented genome is that it facilitates recombination between two strains coinfecting the same cell. Coinfection can generate an instant new strain that evades a host immune system. Even strains that infect animals such as ducks or swine may reassort their segments with those of a human virus (**Fig. 11.22**). Influx of genes from a distantly related strain can sharply increase virulence and mortality. Major epidemics of exceptionally virulent influenza arise from reassortment with chromosomal segments from strains that evolved within ducks or swine, agricultural animals that live in close proximity to humans.

Figure 11.22B shows how various combinations of human and avian genome segments led to new allelic combinations of the envelope proteins hemagglutinin (H numbers) and neuraminidase (N numbers). These variant envelope proteins can foil the immune system; for example, a human immune system is unlikely to have developed antibodies against an avian envelope protein. Based on sequence analysis, the 1918 pandemic virus may actually have derived all eight segments from an avian strain. Subsequently, the 1957 virulent strain incorporated avian segments 2, 4, and 5, whereas the 1968 virulent strain replaced segments 2 and 4 with those of yet another avian strain.

Overall, the opportunities for reassortment among influenza strains make it difficult to generate vaccines and predict which strains to vaccinate against in a given flu season. Nevertheless, alert clinicians and effective public health reporting enable physicians to predict lesser epidemics and protect many people by vaccination, as discussed in Chapter 28. The rarer pandemics involving exceptionally virulent avian-human recombinant strains remain a major challenge to public health.

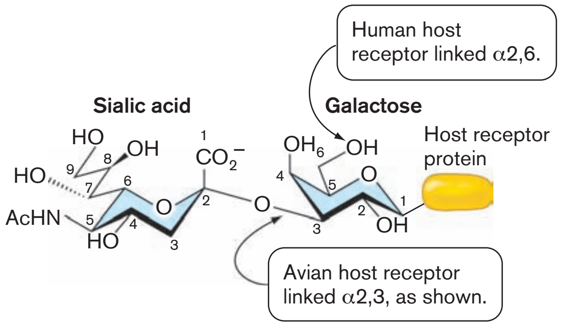


Figure 11.23 **Sialic acid in influenza receptor.** The avian host receptor polysaccharide contains sialic acid with an α2,3 bond to galactose, whereas the human receptor in the upper respiratory tract has an α2,6 bond.

Attachment and Entry to the Host Cell

An influenza virion attaches to a cell when its hemagglutinin envelope protein binds to a host cell receptor protein that contains polysaccharide terminating with sialic acid. The precise structure of the host receptor binding the hemagglutinin may determine whether a strain such as avian influenza H5N1 will spread directly between humans. For example, the sialic acid connection in the receptor polysaccharide can involve different OH groups of the sugar galactose: a linkage to the OH-3 (α2,3) or to the OH-6 (α2,6) (**Fig. 11.23**). The influenza strain H5N1 recognizes mainly the α2,3-linked protein, found in birds. In humans, the upper respiratory tract contains mainly α2,6-linked receptors; α2,3-linked receptors are found only deeper within the lungs. Thus, avian influenza strain H5N1 is rarely transmitted between humans. However, more rapid transmission could arise from a mutation in the avian hemagglutinin that binds the receptor, leading to an influenza pandemic.

The hemagglutinin complex consists of a trimer of subunits, each of which has an N-terminal **fusion peptide**. A fusion peptide is a portion of an envelope protein that changes conformation so as to facilitate envelope fusion with the host cell membrane.

Before membrane contact, the fusion peptides are buried within the core of the hemagglutinin (HA) trimer (**Fig. 11.24**). The HA C-terminal domains each bind a sialic acid receptor in the host membrane. When the virion is taken up by endocytosis, the endocytic vesicle fuses with a lysosome and its interior acidifies. The lowered pH induces a conformational change shifting the C-terminal ends back and the N-terminal fusion peptides outward to face the vesicle membrane. The peptides extend into the membrane, where they mediate fusion between viral and host membranes. The fusion process expels the contents of the virion into the host cytoplasm, where the RNA segments become uncoated. Unlike poliovirus, which injects only its chromosome with an attached peptide, influenza virus releases several enzymes and structural proteins along with its genetic material.

Replicative Cycle of Influenza A

The replication of influenza virus is more complex than that of poliovirus because the viral components travel in and out of the nucleus. In addition, envelope proteins require transport through the ER and Golgi to the cell membrane (**Fig. 11.25**). By contrast, for poliovirus no envelope is assembled.

Figure 11.25 Replication of influenza virus. HA-mediated attachment and uptake (1) leads to release of NP-coated RNA segments in the cytoplasm (2). The (–) strands enter the nucleus (3), where the viral polymerase makes (+) strand RNA (4). RNA synthesis is primed by "capped" fragments of host mRNA, obtained by "cap snatching." The (+) strand RNA segments return to the cytoplasm (5) for translation to viral proteins (6, 7). Additional (+) strand RNA is made to serve as a template for (–) strands, primed by NP protein (8, 9). Proteins MI, NS1, and NS2, as well as newly synthesized RNA-dependent RNA polymerase components (PA, PB1, and PB2), return to the nucleus to bind the progeny (–) strand segments (10). Protein-packaged RNA segments then return to the cytoplasm (11) where the capsid assembles (12). Envelope proteins (M2, NA, and HA) are synthesized at the ER (6), where they are glycosylated by host enzymes and transferred to the Golgi (13) for export to the cell membrane (14). At the cell membrane, the packaged (–) RNA segments are enveloped by host membrane containing the envelope proteins (15).

After the influenza virion undergoes endocytosis (step 1) and release into the cytoplasm (step 2), all the viral (–) RNA segments with their prepackaged primers and polymerases are released. Each NP-coated RNA segment individually passes through the nuclear pores into the nucleus (step 3). In the nucleus, each viral polymerase attached to a genomic (–) RNA segment synthesizes (+) strand RNA for mRNA (step 4) or for templates to synthesize progeny (–) strand RNA segments (steps 8, 9). The processes of mRNA synthesis and template synthesis for progeny genomic RNA are primed differently.

Synthesis of (+) strand mRNA. The prepackaged RNA-dependent RNA polymerase uses each (–) strand RNA segment to synthesize mRNA (**Fig. 11.25**, step 4). The mRNA synthesis is primed by a 5-methylguanine-"capped" RNA fragment (labeled C). The influenza polymerase had obtained the cap fragments from the previous host by cleaving them from host nuclear pre-mRNA, a process quaintly known as "cap snatching." The (+) strand mRNA molecules return to the cytoplasm (step 5) for translation to all types of viral proteins. Segments encoding envelope proteins attach to the ER for ultimate transport to the host cell membrane (step 6). The nucleocapsid RNA-packaging protein (NP), as well as newly synthesized RNA-dependent RNA polymerase components, subsequently return to the nucleus (step 7). Other genome-packaging proteins (M1 and N2) also return to the nucleus.

Synthesis of (+) strand and (–) strand genomic RNA. Back in the nucleus, the original (–) strand RNA segments now serve as templates for RNA synthesis primed *not* by cap snatching, but instead by one of the subunits of nucleocapsid protein NP (step 8). The NP-primed (+) strand RNA then becomes coated with the newly made NP subunits imported from the cytoplasm. The NP-coated (+) strand serves as template to synthesize (–) strand RNA (step 9), which also becomes coated with NP (step 10).

The NP-coated (–) RNA associates with a newly made polymerase for a future cycle of viral replication. The RNA is then complexed with matrix protein (M1) and nuclear packaging protein (N2), proteins that were imported from the cytoplasm earlier. At last, the fully packaged (–) RNA segments exit the nucleus to the cytoplasm (step 11), where they approach the cell membrane for packaging into progeny virions (step 12).

Envelope synthesis and assembly. The envelope proteins synthesized at the ER include hemagglutinin (HA) and neuraminidase (NA). Within the ER lumen, these proteins are glycosylated by host enzymes, then transferred to the Golgi (step 13) for export to the cell membrane (step 14). Within the cell membrane, the envelope proteins assemble around a group of (–) RNA segments complexed with their matrix and packaging proteins, completing the virion particle (step 15). The virion buds out (step 16) by an unknown mechanism. The net result is a massive release of virions that destroys the host cell.

TO SUMMARIZE:

- **Influenza virus** causes periodic pandemics of respiratory disease. New virulent strains arise through recombination of human and avian strains.
- **The influenza virus consists of segmented (–) strand RNA.** Each segment is packaged with nucleocapsid proteins. Segments from different strains recombine through coinfection.
- **Capsid and matrix proteins** enclose the RNA segments of the influenza virus. The matrix is enclosed by an envelope containing spike proteins.
- **Spike proteins mediate virion attachment.** The spike proteins include a fusion peptide that undergoes conformational change to cause fusion between viral envelope and host cell membrane. For influenza, the virion is internalized by endocytosis.
- **Lysosome fusion with endosomes** triggers viral envelope fusion with the endosome membrane. The viral genome and proteins are then released into the cytoplasm. Viral (–) strand RNA segments are uncoated and enter the nucleus.
- **Influenza mRNA synthesis is primed by capped RNA fragments**, cleaved from host mRNA. The viral mRNAs return to the cytoplasm for translation.
- **Genomic RNA synthesis is primed by the nucleocapsid protein (NP).** First, (+) strand RNA is synthesized as a template for (–) RNA strands, which are then packaged in newly made nucleocapsid protein and exported to the cytoplasm.
- **Envelope proteins** of influenza virus are synthesized at the ER for transport to the cell membrane.
- **Influenza viral assembly** occurs at the cell membrane, where capsid, matrix, and (–) strand RNA components are packaged into envelope.

11.5 A Retrovirus: Human Immunodeficiency Virus

So far we have discussed (+) strand RNA viruses, which need to generate a (–) strand intermediate as a template both for (+) strand mRNA and for progeny genomes; and (–) strand viruses, which can generate mRNA directly but need to make a (+) strand template to generate progeny virions. Another major class of RNA viruses is **retroviruses**. Retroviruses are so called because they reverse the normal order of synthesis to copy their RNA into a double-stranded DNA, which is then integrated into the host genome. As introduced in Chapter 6, the RNA-to-DNA synthesis requires a key enzyme, reverse transcriptase (RT), the target of the major anti-AIDS drug azidothymidine (AZT). Retroviruses form a large family of viruses that infect animals; for examples, see **Table 11.2**.

www | Reverse Transcriptase Tutorial, Biomolecules at Kenyon

The most famous of the retroviruses is **human immunodeficiency virus (HIV)**, the causative agent of **acquired immunodeficiency syndrome (AIDS)**. In 2005, according to the United Nations, nearly 40 million people globally were estimated to be living with HIV. That year, the AIDS epidemic claimed more than 3 million lives, and close to 5 million people became newly infected with HIV.

www | UNAIDS

Besides HIV, several other retroviruses have significant historical importance and human impact. **Rous sarcoma virus (RSV)** was the first virus demonstrated to cause cancer. Indeed, the DNA insertion mechanism of retroviruses is ideally suited to alter host gene regulation, either by decoupling a host gene from its regulatory sites or by insertion of an oncogene (an altered host gene that causes cancer). Another retrovirus, **feline leukemia virus (FeLV)** is a major veterinary pathogen. FeLV remains America's number one killer of outdoor cats, despite the availability of an effective vaccine. Related to FeLV is primate T-lymphotrophic virus (PTLV-1), formerly called human T-cell leukemia virus (HTLV). PTLV-1 was the first virus shown to involve reverse transcription, discovered by American virologist Robert Gallo in 1980. Gallo's studies laid the foundation for the discovery by French virologist Luc Montagnier of HIV and its role in AIDS.

Human Immunodeficiency Virus Causes AIDS

HIV-1 is a **lentivirus,** a genus of retroviruses that evolved from viruses infecting African monkeys. Two strains are recognized: HIV-1, the cause of most infections at present, and HIV-2, a strain that appears to have evolved from simian immunodeficiency virus (SIV). The virus is transmitted through blood and through genital or oral-genital contact. The HIV life cycle is that of a "slow virus" that can hide in the host cell for many years, with only gradual production of virions. Eventually, however, the virus destroys the body's T leukocytes, leaving the host defenseless against many organisms that normally would be harmless.

The first cases of AIDS in the United States were reported in 1981. Twenty-six years later, HIV infects over a million Americans, and more than half a million have died of AIDS. Worldwide, HIV infects one in every 100 adults, equally among women and men. In the developed countries, treatment effectively prolongs the life of people with AIDS; but treatment is too expensive for the majority of those infected worldwide. Countries in southern Africa have already experienced population decline. In Swaziland, for example, 40% of adults test positive for

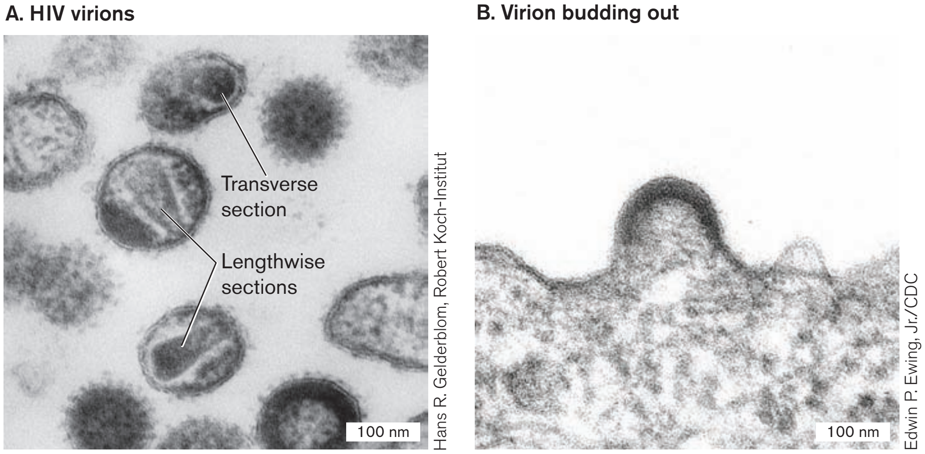
Figure 11.26 **HIV discovery, in fact and film.** **A.** The film *And the Band Played On* depicts the first decade of the AIDS epidemic. In this scene, French scientists observe HIV grown in T-lymphocyte tissue culture. **B.** Luc Montagnier and Robert Gallo signing agreement to collaborate on development of an AIDS vaccine, 2002.

HIV. Despite all we know, AIDS continues to grow in North America and Europe, and particularly high rates of increase are seen in Eastern Europe and central Asia. As of this writing, there is no cure and no vaccine.

A historical view of AIDS in the United States emerges in the book *And the Band Played On* by Randy Shilts, adapted as an award-winning film in 1993 (**Fig. 11.26A**). The book and film show how American society failed for many years to grasp the significance of AIDS because the syndrome first appeared in societal groups considered marginal (homosexual men and certain ethnic immigrants), although it spread to all social classes. Also, the virus proved extremely difficult to detect and grow in culture. The discovery of HIV sparked controversy in the scientific community, as Gallo failed to acknowledge his use of a virus-producing cell line from Montagnier, the first to isolate HIV-1. Since that time, the two scientists and many others have collaborated to develop a test for HIV-1 infection and to search for a vaccine (**Fig. 11.26B**).

The lack of a cure for AIDS should not surprise us, since only a small number of effective antiviral drugs have been found. But why can we find no vaccine when safe and effective vaccines were obtained long ago for major killers such as smallpox and polio and even for the feline retrovirus FeLV? The answers to this question are complex. They include:

- **High mutation rate.** The mutation rate of all retroviruses is exceptionally high because of the high error rate of reverse transcriptase. In addition, the lentiviruses (including HIV) appear to have evolved selectively high mutation rates for envelope proteins that are exposed to the immune system.
- **Complex regulation of replication.** The lentiviruses express a greater number of regulator proteins



Hans R. Gelderblom, Robert Koch-Institut

than other retroviruses. These complex regulatory options may enable HIV to hide itself more effectively within host cells than other retroviruses such as FeLV.

While a cure remains elusive, studying the molecular biology of HIV has led to successful treatments that greatly extend the life span and improve the quality of life for infected individuals.

HIV Structure and Genome

The structure of HIV as visualized by TEM consists of an electron-dense **core particle** (or capsid) surrounded by a phospholipid envelope (**Fig. 11.27A**). In some sections, the core appears round, whereas other sections cut longitudinally reveal an elongated shape, like a cone or cylinder. The thickening of the membrane around the core indicates the presence of **spike proteins**, which peg the membrane to the matrix, as in influenza virus. The envelope forms around the core by budding out of the host cell membrane (**Fig. 11.27B**), a process that does not rapidly lyse the cell but has other devastating consequences for cell function. The conical core is composed of capsid subunits (CA) whose arrangement is partly icosahedral (**Fig. 11.28A**). The capsid subunits enclose two identical copies of the RNA genome plus reverse transcriptase and other enzymes.

Figure 11.28 **HIV-1 structure and genome.** **A.** Internal structure of virion, color-coded to match the genome. In the genome sequence, the staggered levels indicate three different reading frames. Each virion contains two copies of the RNA genome plus multiple copies of reverse transcriptase (RT) and protease (PR) enclosed within a conical capsid (CA subunits plus subunits of a host protein, cyclophilin A). The capsid is surrounded by a matrix (MA subunits), which reinforces the host-derived phospholipid membrane, pegged by spike proteins (SU, TM). The genome also encodes six accessory proteins that are expressed within the infected host cell and regulate the replicative cycle. **B.** Flossie Wong-Staal, pioneering AIDS researcher at University of California, San Diego, was the first to clone the HIV genome. Wong-Staal now pursues gene therapy approaches to AIDS prevention and develops lentiviral gene vectors.

Each virion contains two copies of the RNA genome, coated with nucleocapsid proteins (NC) similar in function to those of influenza virus (**Fig. 11.28A**). For priming, each RNA is complexed with a tRNA derived from the previously infected host cell. The primed and packaged RNA is contained within the capsid or core composed of capsid subunits (CA). The capsid also contains about 50 copies of reverse transcriptase (RT) and protease (PR), as well as a DNA integration factor (IN). Unique to strain HIV-1, subunits of a host chaperone named cyclophilin A are incorporated into the structure, about one for every ten capsid subunits. An HIV-1 mutant that fails to incorporate cyclophilin A can attach to a host cell and insert its capsid, but the capsid fails to come apart, and infection is halted.

The capsid is surrounded by a matrix (MA subunits), which reinforces the host-derived phospholipid membrane. The membrane is pegged by spike proteins composed of the envelope subunits TM and SU. As in influenza virus, the spike proteins play crucial roles in host attachment and entry.

The genome of HIV was first cloned for molecular study by Flossie Wong-Staal, now at the University of California at San Diego (**Fig. 11.28B**). Born in China in 1947, Wong-Staal immigrated to the United States, then worked with Gallo on the early discoveries of HIV. Wong-Staal now pursues gene therapy approaches to combat HIV infection and is developing retroviral vectors for human gene therapy.

The HIV genome encodes three main open reading frames: *gag*, *pol*, and *env*. The *gag* sequence encodes capsid and nucleocapsid proteins; *pol* encodes reverse transcriptase (RT), integrase, and protease; and *env* encodes envelope proteins. During infection, each reading frame is transcribed and translated as a "polyprotein;" then, at subsequent stages, the polyprotein is cleaved by proteases to form the mature products. The three polyprotein reading frames are found in all retroviruses, but each retroviral species processes their products differently.

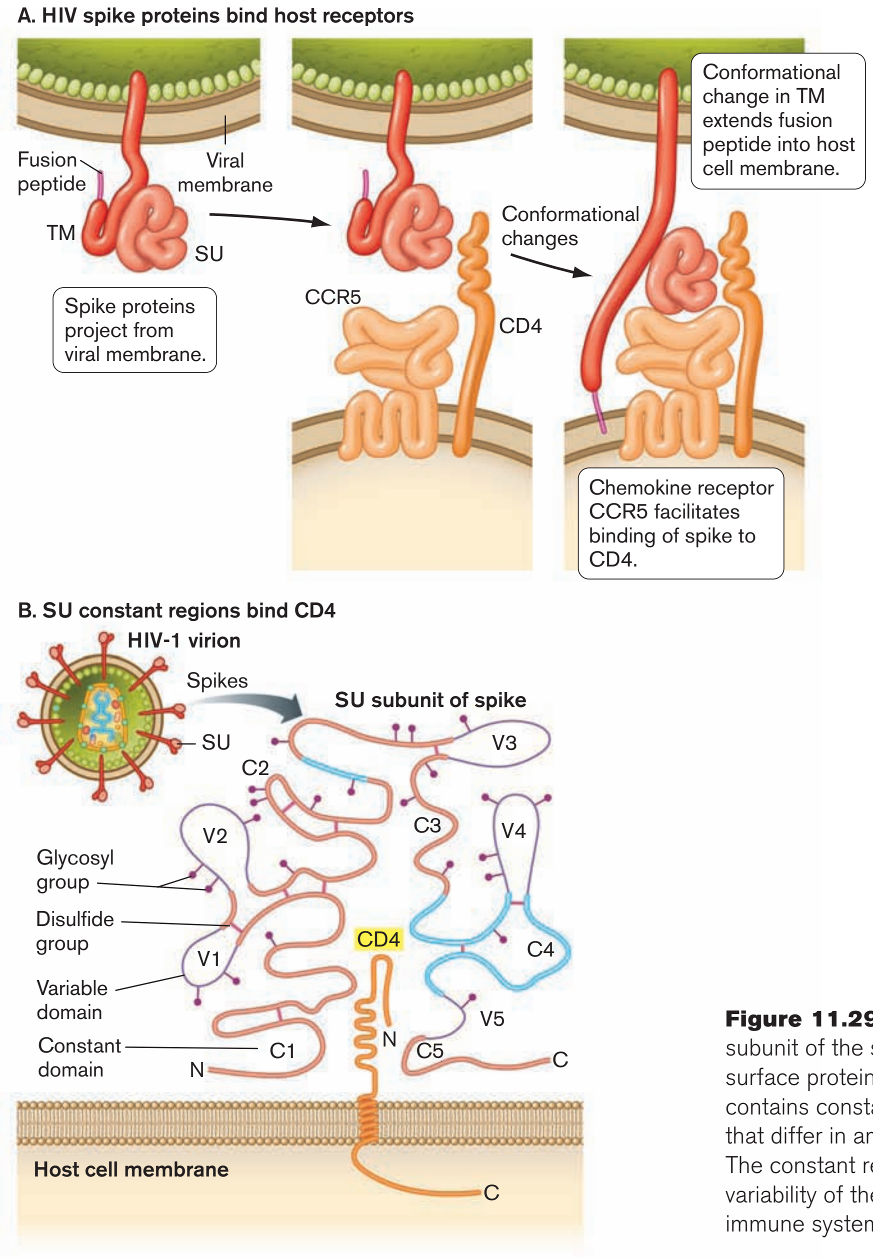
In HIV-1, the *gag* and *pol* sequences overlap, and *env* overlaps with genes encoding **accessory proteins**, a term for proteins that modify and regulate retroviral infection. The accessory proteins are expressed within the infected host cell and regulate the replicative cycle (**Table 11.3**). For example, Tat protein activates transcription of the viral genome. The HIV-1 genome encodes at least six accessory proteins—a greater number than any other retrovirus. They are major targets for research and drug discovery aimed at preventing HIV proliferation.

Table 11.3 Accessory proteins of HIV-1.

Protein	Function	Effect of mutation
Vif	Virion component: • Associates with cytoplasmic filaments • Required for infectivity of progeny virions	Virions produced are noninfective
Vpr	Virion component: • Transcription factor, activates HIV transcription during G_2 phase of cell cycle; arrests T-cell growth • Imports DNA across nuclear membrane; avoids need to infect rapidly dividing cells in which mitosis dissolves the nucleus	Lower production of virions
Nef	Virion component: • Internalizes and degrades CD4 receptors • Controls signal transduction to downregulate immune response by T cells • Enhances infectivity of virus particle • Accelerates progression from infection to disease syndrome (AIDS)	Slower progression to AIDS
Vpu	Membrane protein: • Degrades CD4, releasing bound spike proteins • Promotes virion assembly and export	Host cell dies early; lower production of virions
Rev	Nuclear phosphoprotein, combines with host cell proteins: • Stabilizes certain mRNAs in nucleus • Export of mRNA out of nucleus into the cytoplasm • By promoting mRNA export, induces shift from latent phase to virion-producing phase	Failure of infection
Tat	Transcription factor: • Binds TAR site on nascent RNA to activate transcription • Associates with histone acetylases and kinases to activate transcription of integrated viral DNA	Failure of chromosome replication

HIV Attachment and Entry to the Host Cell

Like other viruses, HIV needs to recognize specific receptor molecules on the surface of its target cells. The primary receptor for HIV is the CD4 surface protein on CD4 T lymphocytes (T cells). The normal function of CD4 surface proteins is to connect the T cell with an antigen-presenting cell, which activates the T cell to turn on production of antibodies (discussed in Section 24.5). Note, however, that CD4 proteins appear on many other cell types, such as microglia (macrophage-like cells in the central nervous system) and Langerhans cells (immune cells of the epidermis). Their presence may make other cells susceptible to infection by HIV.



A. HIV spike proteins bind host receptors

Spike proteins project from viral membrane.

Conformational change in TM extends fusion peptide into host cell membrane.

Chemokine receptor CCR5 facilitates binding of spike to CD4.

B. SU constant regions bind CD4

Figure 11.29 HIV attachment to host cell. A. The SU subunit of the spike complex attaches to the receptor, CD4 cell surface protein. **B.** The region of SU that binds the CD4 receptor contains constant regions (C1–C5) and variable regions (V1–V5) that differ in amino acid sequence in different HIV-1 isolates. The constant regions directly interact with the CD4 receptor. The variability of the V regions enables the virus to evade the host immune system.

Spike proteins mediate membrane fusion. The binding of HIV to CD4 receptors involves the envelope spike protein SU (**Fig. 11.29A**). Spike proteins are the main external proteins accessible to the host immune system. The binding of SU to CD4 requires several crucial domains of the SU peptide sequence (constant domains C1–C5; **Fig. 11.29B**). The constant domains show the same sequence in most isolates of HIV. In contrast, the variable domains of SU (V1–V5) show highly variable sequences. Apparently, the viral genome tolerates a wider range of variation in parts of the protein not directly involved in receptor binding. Variations in the nonbinding domains helps the virus evade the host immune system.

HIV attachment to the cell membrane requires a fusion peptide rearrangement similar to that of influenza virus. When SU binds to CD4, the spike transmembrane component (TM) unfolds and extends its fusion peptide into the host cell membrane (see **Fig. 11.29A**). In addition, SU binds to secondary receptors in the membrane called **chemokine receptors (CCR)**. After attachment of the spike protein SU to receptors and the insertion of the TM fusion peptide, the HIV-1 envelope fuses with the plasma membrane.

Chemokine receptors such as CCR5 participate in cell signaling for host defenses (discussed in Chapter 24). The requirement for CCR attachment varies among different strains of HIV. Some chemokine receptors are found on neurons, and their involvement in HIV infection may be responsible for the neurological disorders seen in AIDS. As described at the beginning of the chapter, people with a defective gene for CCR5 are resistant to infection by HIV-1. Researchers used this knowledge to develop a transgenic therapy for HIV-1-positive volunteers. From the HIV-infected individuals, CD4 T cells were removed and placed into culture. The genome of the cultured T cells was engineered to contain a defective CCR5 gene; thus, the T cells no longer expressed CCR5 on their surface. The CCR5-negative T cells were then returned to the volunteers, where they produced a resurgence of HIV-1-resistant T cells in the blood. The transgenic therapy may prove useful in maintaining the immune systems of HIV-positive patients. It may not, however, prove useful for all strains of HIV, and it does not cure the infection. Nevertheless, it represents hope for future molecular research to overcome AIDS.

After the HIV envelope fuses with the cell membrane, the HIV core directly enters the cytoplasm. The HIV entry mechanism differs from that of influenza virus, in which endocytosis and lysosome fusion are required to open the capsid and release the genome into the cell. The HIV core (composed of CA and the host-derived cyclophilin A) dissolves, releasing the twin RNA genomes along with associated viral enzymes into the cytoplasm.

THOUGHT QUESTION 11.7 How do attachment and entry of HIV resemble attachment and entry of influenza virus? How do attachment and entry differ between these two viruses?

Retroviral RNA Genome

The twin RNA genomes each possess a 5′ "cap" and a 3′ poly-A "tail" that probably enable them to mimic host nuclear mRNA. Each RNA is hybridized to a tRNA primer for DNA synthesis. The primer is a lysine-specific tRNA from the previous infected cell (**Fig. 11.30**). The primer might be expected to hybridize at the 3′ end of the template, where its 3′ OH "points" toward the opposite end, positioned to synthesize all the way down. Surprisingly, however, the 3′ OH end of the tRNA actually binds near the 5′ end, where initially it can only generate a brief sequence. These early sequences bind key regulatory factors for transcription and for DNA insertion into the host genome.

Figure 11.30 Structure of the RNA dimer. The RNA dimer packed in the virion includes two host tRNA molecules, each hybridized so as to present a 3′ OH for priming synthesis of DNA. The primer hybridizes so near the 5′ end of the chromosome that only a short piece of DNA can be synthesized (see Figure 11.28). The capped 5′ end of the RNA forms several hairpin loops containing control sequences: TAR, to bind Tat protein, which induces transcription; a signal for 3′ polyadenylation; PBS, the primer-binding site for host tRNA; DIS, site of contact for RNA dimer; a splice site to generate shortened transcripts for *env* and for accessory protein genes; a signal required for core packaging; and the AUG start codon for the *gag* transcript.

THOUGHT QUESTION 11.8 Compare and contrast the priming of chromosome replication in HIV with the priming mechanisms of poliovirus and influenza virus.

Reverse Transcriptase Copies RNA to Double-Stranded DNA

The defining component of a retrovirus is **reverse transcriptase (RT)**, the enzyme that synthesizes the double-stranded DNA copy of the genome (**Fig. 11.31A**). Reverse transcriptase is the target of the first clinically useful drug to treat HIV infection, the nucleotide analog **azidothymidine (AZT)**. The reverse transcriptase complex actually possesses three different activities:

- **DNA synthesis from the RNA template.** Synthesis of DNA is first primed by the host tRNA, which was hybridized to the chromosome within the virion.
- **RNA degradation.** After DNA synthesis, the template RNA is gradually removed through an RNase activity of the RT complex. Removal of RNA enables replacement of the entire original RNA template by DNA.
- **DNA-dependent DNA synthesis.** To make the DNA complementary strand replacing the RNA, the RT needs to use the newly made DNA as its template. Thus, RT has the rare ability to use either DNA or RNA as template.

The RT complex is shown in **Figure 11.31A**. The RNA template with its short RNA primer is threaded

Figure 11.31 Reverse transcription of the HIV genome and integration into host DNA. **A.** The RNA template with its short RNA primer is threaded through the RT complex between the "thumb" and "fingers," a configuration typical of other RNA polymerases. The RT complex adds successive deoxynucleotides from dNTPs, starting at the 3′ OH end of the RNA primer (as in regular DNA synthesis). As DNA elongates, the RNA template is cleaved from behind. **B.** The tRNA primer (1) initiates a short sequence of DNA complementary to the 5′ end of the HIV chromosome (2). The corresponding template is then degraded. The original RNA template has repeated ends (r), so the exposed DNA end (extended tRNA primer of the second copy) then hybridizes to the 3′ end (3). DNA elongation now extends along the rest of the chromosome (4), up to the polymerase-binding site for mRNA transcription (PBS). DNA completion is followed by degradation of the remaining RNA template. Complementary DNA is then synthesized up to the PPT-U3 junction (5). The completed double-stranded DNA copy of the HIV genome, plus a short repeat of the 5′ end (U3 R U5), circularizes (6) and integrates into the host chromosome (7), mediated by integrase (IN). The repeat of the 5′ end generates a long terminal repeat (LTR) flanked by short repeats of host sequence.

through the RT complex between the “thumb” and “fingers,” a configuration typical of other RNA polymerases (discussed in Chapter 8). The RT complex adds successive deoxynucleotides from dNTPs starting at the 3′ OH end of the RNA primer. As DNA elongates, however, the RNA template is cleaved from behind by the RT complex. Thus, the new DNA actually replaces preexisting RNA sequence. This “destructive replication” is unique to retroviruses. The details are important, as they suggest possible targets for new antiviral drugs.

WWW | Reverse Transcriptase tutorial, Biomolecules at Kenyon

Initiation of reverse transcription. **Figure 11.31B** outlines the entire process of reverse transcription in HIV-1, from primed RNA template to integration of duplex DNA. First, the host-derived tRNA primer initiates synthesis of a DNA strand complementary to the RNA chromosome. DNA synthesis is directed toward the 5′ end of the HIV chromosome, generating a short segment (step 1). The original RNA template for this short segment is then degraded, leaving only the DNA extension off the tRNA primer (step 2).

The new DNA primes the second template. The original RNA template had repeated ends (labeled r, lowercase for RNA), and the exposed DNA copy of the 5′ end has a complementary sequence (R, uppercase for DNA). The R DNA from the second tRNA extension hybridizes to the 3′ end of the original RNA (step 3). From the hybridized DNA, elongation now extends along the rest of the chromosome (step 4), up to the polymerase-binding site for mRNA transcription (pbs). DNA completion is followed by degradation of the remaining RNA template, except for occasional short fragments to serve as primers, such as the polypurine tract (ppt). A complementary DNA strand is then synthesized through the PPT primer, leaving a nick ahead (step 5).

DNA integration into the host genome. The final step of genome processing requires integration into host DNA. The double-stranded DNA copy of the HIV genome (plus a short repeat of the 5′ end) circularizes (step 6). The circular molecule then integrates into the host chromosome by site-specific recombination (step 7), mediated by the HIV integrase protein (IN), generating an integrated viral genome, or **provirus**. The provirus contains a repeat of the 5′ end at its 3′ end; this pair of repeats is called a **long terminal repeat (LTR)**. Proviral sequences can now be expressed, directing production of progeny virions.

An alternative to virion production is that the integrated HIV genome can lie dormant, like the lambda prophage in *E. coli* (discussed in Chapter 6). The viral genome is replicated passively within the genome of its host cell, hiding for many years with only infrequent production of virions. The few virions shed by the patient, however, can infect an unsuspecting individual who shares sexual or blood contact.

Replicative Cycle of HIV

The steps of HIV replication are outlined in **Figure 11.32**. The main points of viral entry and replication are typical of retroviruses. HIV, however, has an exceptionally large number of accessory proteins that govern the level of virus production and the duration of the quiescent phase, when the integrated chromosome replicates with the host cell.

Synthesis of HIV mRNA and progeny genomic RNA. After the HIV virion attaches to the host receptors, its envelope fuses with the host membrane (step 1). Unlike influenza virus, the HIV core dissolves in the cytoplasm directly, without endocytosis (step 2). The RNA chromosomes are then reverse-transcribed to make double-stranded DNA (step 3). The double-stranded DNA enters the nucleus through a nuclear pore (step 4), a key step facilitated by Vpr accessory protein. Vpr enables infection of nondividing cells, which only lentiviruses can do; other retroviruses, such as those causing lymphoma, must infect dividing cells, in which the nuclear membrane dissolves during mitosis.

Upon entering the nucleus, the DNA copy of the HIV genome integrates its sequence as a provirus at a random position in a host chromosome (step 5). Within the nucleus, full-length RNA transcripts are made by host RNA polymerase II, including a 5′ cap and a 3′ poly-A tail (step 6). Some of the RNAs exit the nucleus (step 7) to serve as mRNA for translation of polyproteins. Polyproteins are translated in alternative versions, such as Gag-Pol. Other full-length RNA transcripts exit the nucleus to form RNA dimers for progeny virions (step 8). Still other RNA transcripts within the nucleus are cut and spliced to complete the *env* gene sequence for translation of envelope proteins (step 9).

The Env (envelope) proteins are made within the endoplasmic reticulum (ER) (step 10). They pass through the Golgi for glycosylation and packaging (step 11) and are exported to the cell membrane (step 12). At the membrane, Env proteins plug into the core particle as it forms from the RNA dimers plus Gag-Pol peptides (step 13).

Virion assembly and exit. The assembly and packaging of core particles into virions (step 14) is mediated by Vif, one of the unique HIV accessory proteins. As the virion buds off, the protease (PR) cleaves the Gag-Pol peptide to complete the maturation of the core structure containing Gag subunits as well as RNA polymerase (RT) (step 15). The Gag subunits now form the conical core structure. Proteases that cleave Gag-Pol offer important drug

1. The HIV virion attaches.

2. The virion fuses to the membrane and releases its core in the cytoplasm.

3. The core dissolves, and the RNA chromosomes are copied/replaced to make double-stranded DNA.

4. The double-stranded DNA enters the nucleus through a nuclear pore.

5. The viral DNA integrates in a host chromosome.

6. Full-length RNA transcripts are made.

7. Some RNA transcripts exit the nucleus for translation of Gag and of Gag-Pol.

8. RNA transcripts exit the nucleus to form RNA dimers for progeny virions.

9. Some RNA transcripts are spliced to translate Env proteins (SU-TM).

10. Env proteins (SU-TM) are translocated into the ER.

11. Glycosylation and packaging of the Env proteins occur in the Golgi.

12. Env proteins are exported to the cell membrane.

13. The membrane-bound Env proteins assist the packaging of the RNA dimers plus Gag-Pol peptides into the core.

14. Core particles assemble and are coated with envelope.

15. As the virus buds off, the PR protease cleaves the Gag-Pol peptide in order to complete the maturation of the core (Gag subunits) and the RNA polymerase (Pol).

If spike proteins bind to CD4 CCR receptors of a neighboring cell, cell fusion allows core particles to enter a new cell.

Figure 11.32 **HIV replicative cycle.** The HIV virion attaches its receptor and fuses with the host cell membrane, releasing its contents in the cytoplasm to undergo a replicative cycle. ⏯

targets, which have led to the development of anti-HIV drugs known as **protease inhibitors**.

An alternative to viral budding is cell fusion, mediated by binding of Env in the membrane to CD4 receptors on a neighboring cell. The two cells then fuse, and HIV core particles can enter the new cell through their fused cytoplasm. The fusion of many cells can create a giant multinucleate cell called a syncytium. Cell fusion with formation of syncytia enables HIV to infect neighboring cells without exposure to the immune system.

The intricate scheme in **Figure 11.32** actually omits many functions of HIV accessory proteins that enhance the virulence of HIV infection (**Table 11.3**). Accessory proteins are the subject of intensive research. Mutation of genes for accessory proteins often decreases virulence; thus, these proteins are important potential targets for chemotherapy. For example, the Nef accessory protein accelerates progression from HIV infection to AIDS, so a drug that inactivates Nef might prevent the onset of AIDS.

Retroelements in the Human Genome

Suppose that an integrated HIV genome were to mutate and lose the ability to produce progeny. What would happen to its genome? The integrated genome would be "trapped" within a cell; and over many generations in its host, it would inevitably accumulate more mutations.

In fact, the human genome shows evidence for numerous remains of decaying retroviral genomes, collectively known as retroelements (**Fig. 11.33**). Some retroelements are **endogenous retroviruses**, sequences that contain all the genomic elements of a retrovirus, including *gag*, *env*, and *pol* genes, yet never generate virions. Presumably, they lost this ability by mutation. Other elements known as **retrotransposons** retain only partial retroviral elements but may maintain a reverse transcriptase to copy themselves into other genomic locations. An example of a retrotransposon is the well-known Alu sequence, a short sequence found in about a million copies in the human genome. In some cases, a retrotransposon such as Alu can interrupt a key human gene, leading to a genetic defect such as a defective lipoprotein receptor associated with abnormally high cholesterol level and heart failure. Still other retroelements, known as LINEs (long interspersed nuclear repeats) and SINEs (short interspersed nuclear repeats), show more vestigial remnants of retroviral genomes. Amazingly, about half the sequence of the human genome appears to have originated from viruses and retroelements. The origin of viruses, including their interaction with cellular evolution, is explored in **Special Topic 11.1**.

Lentiviruses for Gene Therapy

How could a virus as deadly as HIV be used to improve human health? In fact, the exceptional ability of lentiviruses to deliver their own DNA to human cells makes them promising candidates for gene therapy. Lentiviruses are particularly promising for their ability to infect nonmitotic cells. Research is focused on engineering lentiviral vectors that can transfer a recombinant gene to a host cell but fail to generate progeny virions.

TO SUMMARIZE:

- **Human immunodeficiency virus (HIV)** causes an ongoing epidemic of acquired immunodeficiency syndrome (AIDS). There is no cure, although molecular biology has led to drugs that extend life expectancy.
- **HIV is a retrovirus** whose RNA genome is reverse-transcribed into double-stranded DNA, which integrates into the DNA of the host cell.
- **The HIV core particle** contains two copies of its RNA genome, each bound to a primer (host tRNA) and reverse transcriptase (RT). The core, or capsid, is surrounded by an envelope containing spike proteins.
- **HIV binds the CD4 receptor** of T lymphocytes with coreceptor CCR5. Following virion-receptor binding and envelope-membrane fusion, HIV virions are released into the cytoplasm.
- **DNA is synthesized in the nucleus from the retroviral RNA**, primed by the tRNA, and synthesized by reverse transcriptase. **RNA degradation**

allows formation of a double-stranded DNA. The retroviral **DNA integrates** into the host genome.

- **Retroviral mRNAs are exported to the cytoplasm** for translation. Envelope proteins are translated at the ER and exported to the cell membrane.
- **Retroviral assembly occurs at the cell membrane**, where virions are released slowly, without lysis. Alternatively, the accumulation of retroviral proteins in the cell membrane leads to cell fusion, forming syncytia.
- **Accessory proteins regulate virion formation** and the latent phase, in which double-stranded DNA persists without reproduction of progeny virions.
- **Ancient retroviral sequences** persist within animal genomes, including the human genome.

11.6 A DNA Virus: Herpes Simplex

Many important viruses of humans and other animals contain genomes of double-stranded DNA (**Table 11.4**). DNA viruses include the causative agents of well-known diseases such as smallpox, chickenpox, and infectious mononucleosis (mono). Most DNA viruses are considerably larger than RNA viruses and encode a wider range of viral enzymes; for example, the vaccinia genome encodes nearly 200 different proteins. The complexity of viruses such as vaccinia and herpes approaches that of small prokaryotic cells—a fact with interesting implications for viral evolution (see **Special Topic 11.1**).

Replication of viral DNA occurs by mechanisms similar to replication of prokaryotic and phage genomes, either bidirectionally from an origin of replication (as in bacteria) or by the rolling-circle method (as in phages such as T4). As for cellular genomes, DNA replication requires more than a polymerase; enzymes such as helicase, primase, and single-stranded binding proteins are also needed. Viral species differ as to the source of their replication components. SV40 and Epstein-Barr virus rely entirely on cellular components, whereas poxviruses rely entirely on viral components for DNA replication. Other species, such as adenovirus and papillomavirus, combine viral and cellular components.

Herpes Simplex Virus Infects the Oral or Genital Mucosa

An important example of a DNA virus is **herpes simplex virus (HSV)**. Strains HSV-1 and HSV-2 cause one of the most common infections in the United States. Approximately 60% of Americans acquire herpes simplex, usually HSV-1, in epithelial lesions commonly known as cold sores. About 30–60% acquire genital herpes, usually HSV-2, through sexual contact (oral or vaginal). Genital herpes

Vaccinia virus		Cowpox	Cattle, humans
Other poxviruses		Monkeypox	Monkeys, camels, birds

Special Topic 11.1 How Did Viruses Originate?

The origin of viruses remains a mystery. Did viruses evolve within cells? Or could they possibly have predated cells? Unlike cellular organisms, viruses are too small to have left fossil traces that we can detect. Viral genomes show evidence of so much horizontal transfer that lineages are impossible to trace back over time. Unlike cells, which all possess ribosomal RNA genes with a common ancestor, all virus species share no one gene in common. No viral sequence data point to a first common ancestor, nor to a common means of origin.

Three theories are proposed to explain the origin of viruses (**Fig. 1**).

Reductive Evolution

Reductive evolution leads to gradual loss of unselected traits. For example, pathogens such as *Helicobacter* and *Mycoplasma* have lost many genes encoding metabolic functions and stress responses that are unnecessary when the host organism provides these functions. Suppose such a cell were to become an intracellular parasite, increasingly dependent on host functions. Ultimately, it might lose all but a few metabolic genes, losing functions for genome replication with the rest of its functions provided by the host.

Some viruses show signs of degeneration from ancestral cells. Phage T4, the poxviruses, and herpes viruses possess large genomes of 80–200 genes. Their virions include enzymes and other proteins that provide some of the virus's own metabolic functions. The size of a poxvirus approaches half a micrometer—well within the size range of prokaryotic cells (**Fig. 2**). A vaccinia particle actually looks like a miniature cell, with its multilayered envelope containing a DNA chromosome surrounded by enzymes.

Recently, an even larger "cellular virus" was discovered, called the Mimivirus because it mimics a cell (discussed in Chapter 6). Originally discovered within amebas, the Mimivirus was at first mistaken for a bacterium. In fact, Mimivirus consists of a giant icosahedral particle with a diameter of

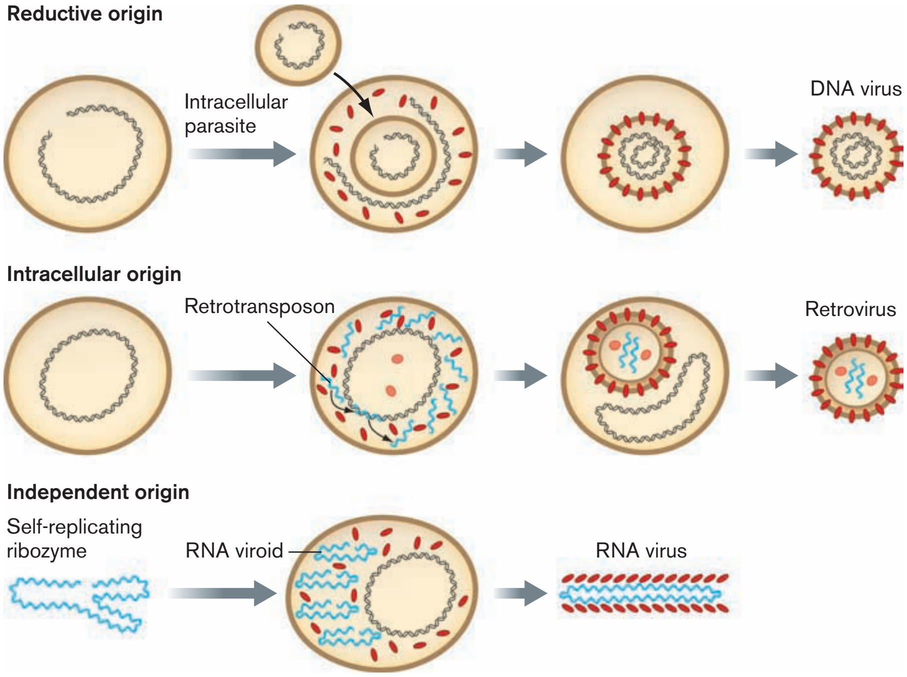

Figure 1 Theories of viral origin. Three theories have been proposed to account for the origin of viruses. According to the theory of reductive origin, viruses evolved by degenerative evolution from intracellular parasitic cells. According to the theory of intracellular origin, viruses evolved from functional parts of cells that acquired an ability to reproduce themselves uncontrolled by the cell. The theory of independent origin holds that viroid nucleic acids could have evolved outside of cells during the RNA world and acquired the ability to infect cells.

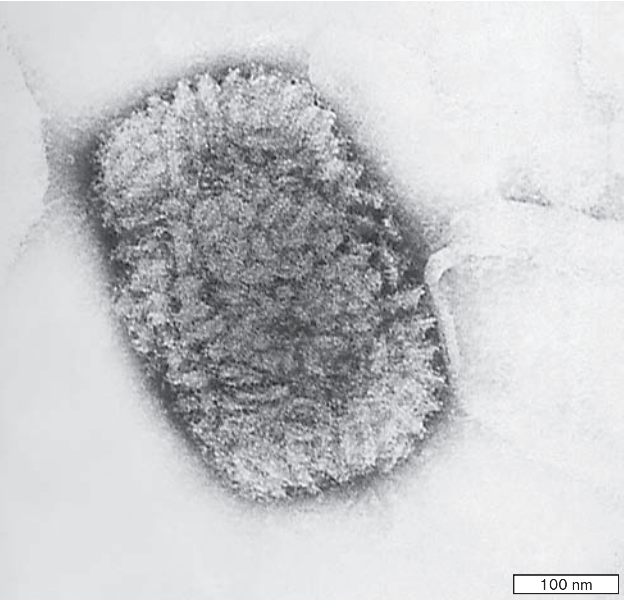
400 nm. Its genome is a circle of double-stranded DNA, about 1.2 megabases (Mb). The genome was sequenced by Jean-Michel Claverie and colleagues at the Institut de Biologie Structurale et Microbiologie, Marseille. It includes 1,262 open reading frames—a greater number than the genomes of several prokaryotes, such as mycoplasmas. It is the first viral genome known to include protein translation components such as aminoacyl-tRNA synthetases and elongation and termination factors. Mimivirus may represent a "missing link" between bacteria and viruses.

Intracellular Origin

Other viruses, particularly retroviruses, support the idea of intracellular origin. Retroviruses require reverse transcriptase to convert their RNA information to DNA. When retroviruses were first discovered, reverse transcriptase was considered an anomaly because no such enzyme had been reported in host cells. We have since discovered specialized reverse transcriptases in both plant and animal cells. In retrospect, we now believe that a reverse transcriptase must have existed very early in the evolution of all cells because something had to copy the information from the ancient "RNA world" cell into the DNA of modern genomes.



Fred Murphy/Sylvia Whitfield/CDC

Figure 2 Large cell-like viruses. Support for reductive origin of some viruses can be seen in the size and complexity of viruses such as vaccinia, the infective agent of cowpox.

In animal cells, a native type of reverse transcriptase called telomerase serves to replicate the ends of linear chromosomes. The sequence of telomerase shows homology with that of known reverse transcriptases of retroviruses. Mammalian genomes show repeated elements of DNA that have arisen from mistaken reverse copying of host RNA molecules back into the DNA genome. One can imagine that mutation of a cellular reverse transcriptase might lead to intracellular evolution of a retrovirus.

Independent Origin

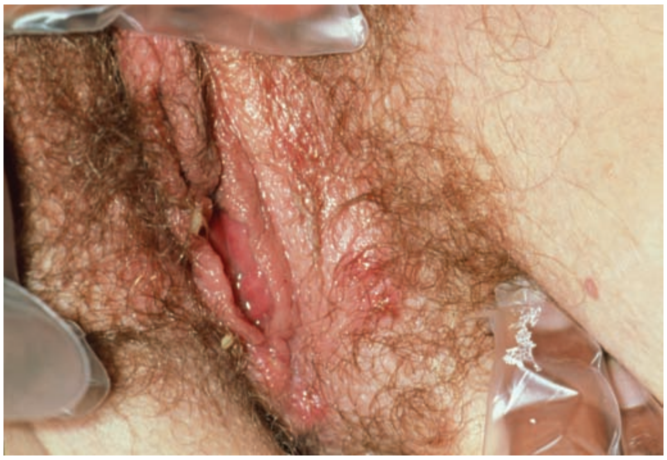
Some of the simpler viral elements might have evolved by themselves in the RNA world, first as free-living entities, later as stowaways within host cells. Perhaps the best clue for such an origin is that of the viroid ribozymes that infect plant cells. Viroids are self-contained RNA molecules that possess catalytic function. Present-day viroids rely entirely on host cell metabolism; but one could imagine that viroids might have evolved from an ancestral RNA molecule that managed its own self-replication.

An intriguing possibility is that some viruses not only originated as independent cells, but were the first to evolve DNA, and they contributed DNA to all living cells. The viral origin of DNA is proposed by evolutionary biologists, including Patrick Forterre, at the University of Paris-Sud in Orsay, France. The earliest cells are believed to have had genomes of RNA, the simplest nucleic acid. These RNA-world cells may have been parasitized by viruses that evolved DNA chromosomes to avoid cleavage by host cellular enzymes. If a viral DNA chromosome became latent in a host cell (as do herpes viruses, for example), it might eventually acquire genes from the host genome through recombination events. Any host gene transferred to the DNA chromosome would be favored in evolution because DNA is more stable than RNA. Eventually, according to this hypothesis, the entire host genome would end up transferred to the DNA chromosome, and all cells would have genomes of DNA (as indeed cells do today). The hypothesis of viral origin of DNA remains unproven but inspires exciting research to test its implications.

The origin of viruses has important implications for the principles of evolution, including origins of the earliest cells. In addition, the medical importance of studying viral origins is that it yields insights into virus function, suggesting pharmacological applications. For example, ribozymes are being studied for possible use in therapeutic regulation of cancer gene expression.

causes recurrent eruptions of infection in the reproductive tract (**Fig. 11.34**). Many of those infected are unaware of symptoms, but they can still transmit the disease to others.

Herpes simplex virus typically infects cells of the oral or genital mucosa, causing ulcerated sores. The primary infection is epithelial, followed by latent infection within neurons of the ganglia. A common site of infection is the trigeminal ganglion, which processes nerve impulses between the face and eyes and the brain stem.



P. Marazzi/Clinical Images, AHMF

Figure 11.34 Genital herpes infection. Lesions of the vulva caused by HSV-2 infection.

The latent infection of the ganglia later leads to new outbreaks of virus, often triggered by stress such as menstruation, sunlight exposure, or depression of the immune system. Progeny virions travel back down the dendrites to the epithelia, causing lytic infection. In the trigeminal ganglion, herpes reactivation can lead to eye disease or lethal brain infection. In most cases, herpes symptoms can be controlled by antiviral agents such as acyclovir (discussed in Chapter 26). There is no cure or prevention of future outbreaks. In pregnant women, HSV can be transmitted to the fetus, with serious complications for the child.

Herpes simplex virus is closely related to varicella-zoster virus (VZV), the cause of chickenpox, also an epithelial infection. Varicella, too, can hide in ganglial neurons, emerging decades later to cause skin lesions called shingles.

Herpes Virus Structure

The herpes virion comprises a double-stranded DNA chromosome packed within an icosahedral capsid (**Fig. 11.35A**). The capsid is surrounded by **tegument**, a collec-

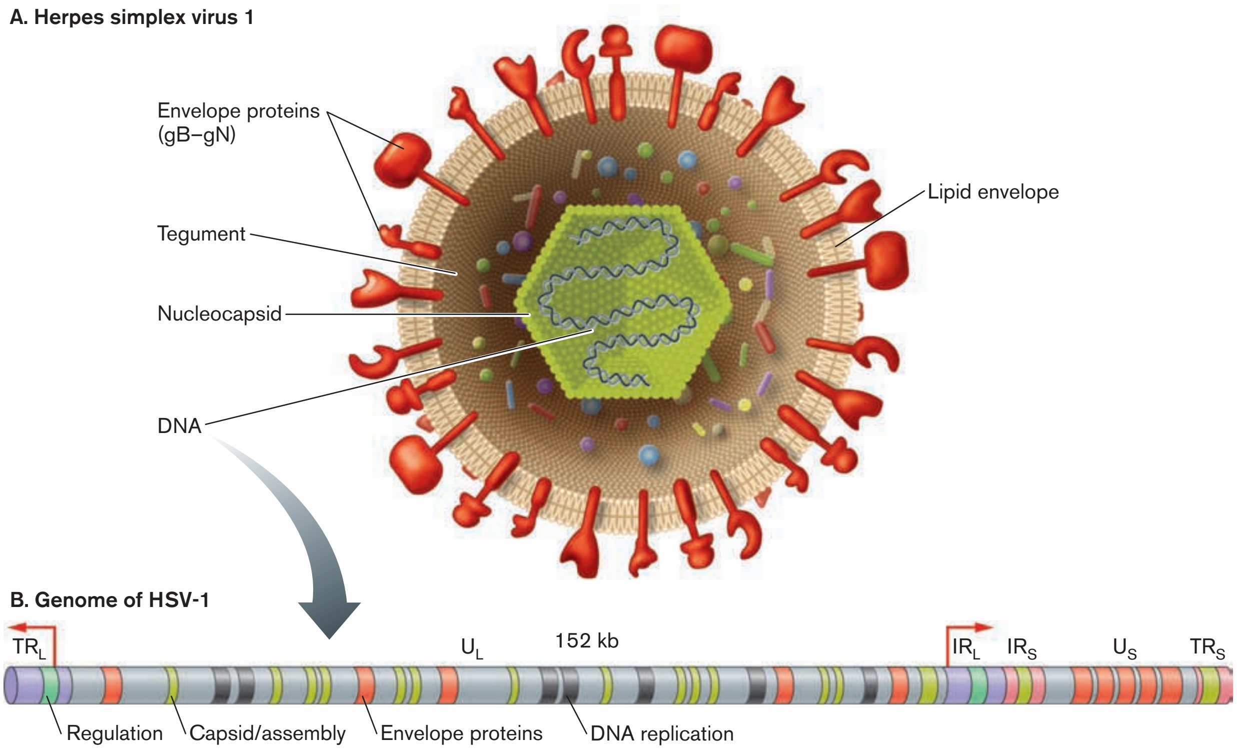


Figure 11.35 Herpes simplex virus 1: virion and genome. A. HSV-1 virion consists of a double-stranded DNA chromosome packaged within an icosahedral capsid. The capsid is surrounded by tegument, a collection of 15 different kinds of virus-encoded proteins. The tegument is contained within a host-derived membrane envelope including several kinds of envelope proteins. **B.** The genome of HSV 1 spans 152,000 base pairs, encoding more than 70 gene products. The HSV sequence consists of two segments, long (U_L) and short (U_S). Each segment contains a unique region (U_L or U_S) flanked by two inverted repeat regions, terminal (TR_L or TR_S) and internal (IR_L or IR_S) where the two segments meet.

tion of about 15 different kinds of virus-encoded proteins. The tegument is contained within a host-derived membrane envelope with several kinds of spike proteins. The HSV-1 genome spans 152 kbp, encoding more than 70 gene products (**Fig. 11.35B**). The sequence includes two unique segments, long (U_L) and short (U_S), each flanked by a terminal repeat (TR_L or TR_S) and an internal repeat (IR_L or IR_S). Within the host, the genome circularizes, so the genetic linkage map appears circular.

Attachment and Entry of Herpes Simplex

Unlike poliovirus and HIV, the herpes virion can bind to several alternative receptor molecules in the host cell membrane, such as a homolog of tumor necrosis factor receptor called HveA or intercellular adhesion molecules called nectins (**Fig. 11.36**, step 1). As in the case of HIV, the entire herpes capsid enters the cytoplasm (step 2); but unlike HIV, whose capsid dissolves, the herpes capsid travels down a scaffold of microtubules (step 3) to the nuclear membrane. During this stage, the virion host shut-off factor (Vhs) degrades host mRNA, while the virion protein VP16 protects viral mRNA. At a nuclear pore, the herpes chromosome is inserted into the nucleus (step 4). The DNA then circularizes (step 5) to form a plasmid-like intermediate.

The herpes genome now takes one of two alternative directions: expression of mRNA for proteins of the infectious cycle or expression of mRNA encoding LAT proteins to maintain latency (step 6). If the latent course is taken, the DNA circle can persist within the cell for decades before switching to lytic infection. Latent infection most commonly occurs in nerve cells, such as those of the trigeminal ganglion.

Replication of Herpes Simplex Virus

In the nucleus, herpes DNA is transcribed to mRNA by host RNA polymerase II (**Fig. 11.36**). If mRNA for lytic infection is produced, it leaves the nucleus to be translated by ribosomes. Many different mRNAs are produced and exported, including those required for early and intermediate stages of infection (step 7). The translated proteins return to the nucleus for packaging within capsids.

To generate progeny genomes, the circular DNA is replicated by viral enzymes including DNA polymerase, single-strand binding protein, and a proofreading endonuclease (step 8). Additional enzymes are provided by the host cell. Replication occurs by the rolling-circle method, generating a concatemer similar to that of phage T4. Unlike T4, however, the herpes DNA is eventually cut into segments defined by the terminal repeat sequences.

The newly synthesized DNA expresses late-stage mRNA (step 9), which exits the nucleus for translation. Translated envelope proteins are inserted into the ER membrane, through which they migrate to the nuclear membrane (step 10). Other late proteins reenter the nucleus for assembly into capsids containing DNA genomes (step 11). The envelope may form from the nuclear membrane (step 12), although some evidence supports formation in the ER or Golgi. The virions are then transported through the ER (step 13) to the Golgi, and ultimately to the cell membrane (step 14). Finally, the cell membrane releases mature virions through exocytosis. Rapid release destroys the cell, causing the characteristic sores of herpes infection.

THOUGHT QUESTION 11.9 Compare and contrast the fate of the HSV chromosome with that of the chromosome of HIV.

TO SUMMARIZE:

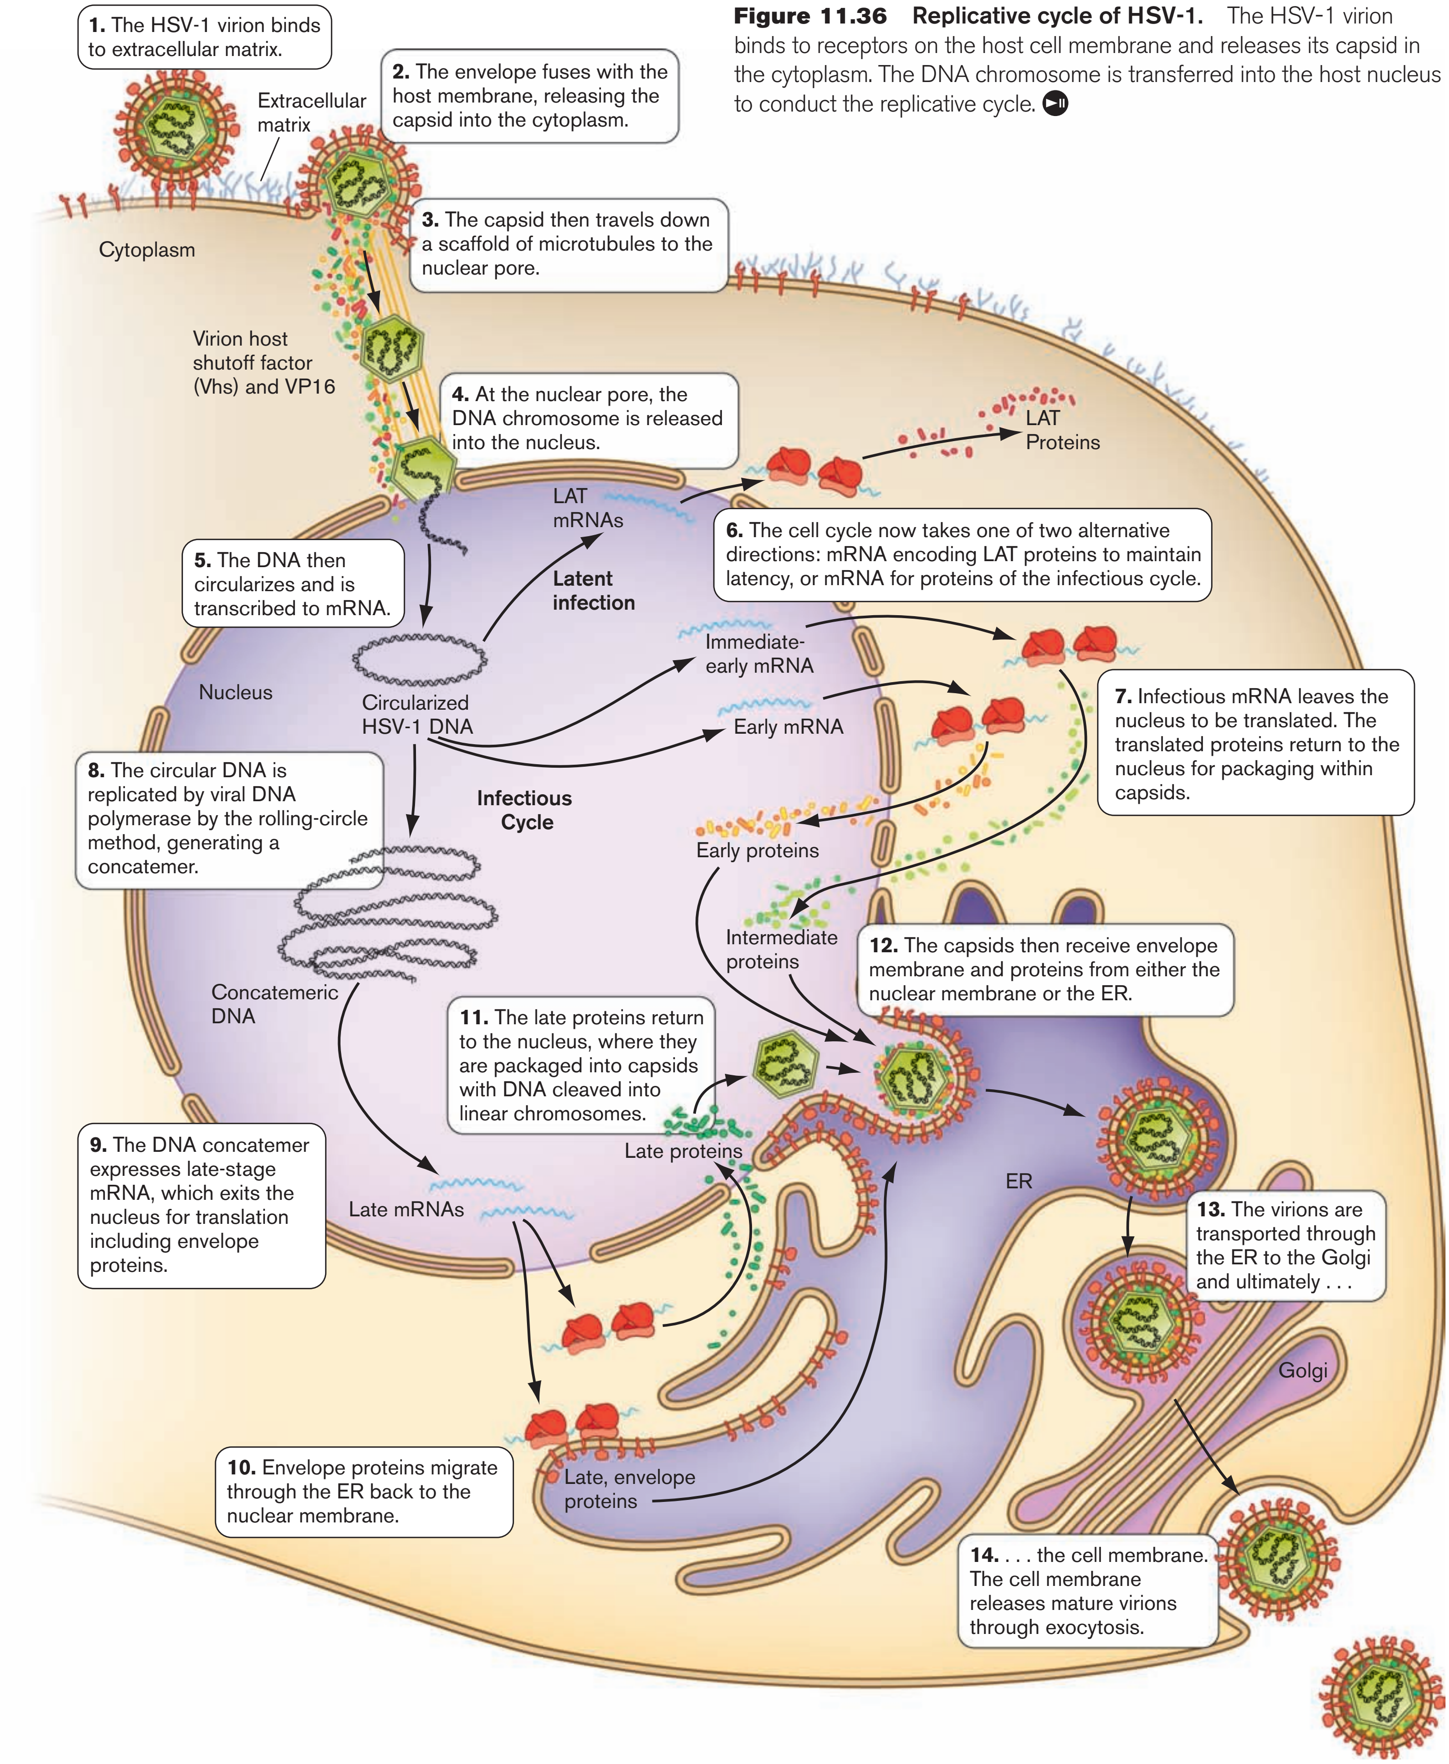
- **Herpes simplex** causes recurring eruptions of sores in the oral or genital mucosa. Initial transmission is by oral or genital contact, followed by eruptions from reactivated virus latent in ganglial neurons.
- **The herpes virion** contains a double-stranded DNA genome, packed in an icosahedral capsid. The capsid is surrounded by numerous matrix proteins and by an envelope.
- **HSV attachment** may involve several alternative receptors. **A microtubular scaffold** transports the herpes virions to the nucleus, where the DNA genome is inserted. The DNA circularizes for transcription.
- **DNA genomes of HSV** are synthesized by the rolling-circle method, using viral DNA polymerase supplemented by viral and host-generated components.
- **Infectious mRNA expression** leads to production of capsid, matrix, and envelope proteins for assembly of HSV. Alternatively, **LAT protein expression** leads to latent infection, usually in nerve cells, where the DNA persists silently for months or years.
- **HSV assembly** occurs at the nuclear membrane or other membranes. The virions are released from the cell by exocytosis. Rapid release leads to mucosal pathology.

Viral Infection Mechanisms: Commonalities and Diversity

In considering the mechanisms of viral infection, a picture emerges of interesting commonalities as well as intriguing diversity:

- **Viral infection requires host membrane receptors.** Different viruses evolve to take advantage of different cell membrane proteins in order to recognize and gain entry into host cells. Mutation of host receptors confers resistance to the virus.

Figure 11.36 Replicative cycle of HSV-1. The HSV-1 virion binds to receptors on the host cell membrane and releases its capsid in the cytoplasm. The DNA chromosome is transferred into the host nucleus to conduct the replicative cycle.



1. The HSV-1 virion binds to extracellular matrix.

Latent infection
5. The DNA then circularizes and is transcribed to mRNA.
6. The cell cycle now takes one of two alternative directions: mRNA encoding LAT proteins to maintain latency, or mRNA for proteins of the infectious cycle.
Immediate-early mRNA
Nucleus
Circularized HSV-1 DNA
Early mRNA
7. Infectious mRNA leaves the nucleus to be translated. The translated proteins return to the nucleus for packaging within capsids.
8. The circular DNA is replicated by viral DNA polymerase by the rolling-circle method, generating a concatemer.
Infectious Cycle
Early proteins
Intermediate proteins
12. The capsids then receive envelope membrane and proteins from either the nuclear membrane or the ER.
Concatemeric DNA
11. The late proteins return to the nucleus, where they are packaged into capsids with DNA cleaved into linear chromosomes.
Late proteins
ER
9. The DNA concatemer expresses late-stage mRNA, which exits the nucleus for translation including envelope proteins.
Late mRNAs
13. The virions are transported through the ER to the Golgi and ultimately . . .
Golgi
10. Envelope proteins migrate through the ER back to the nuclear membrane.
Late, envelope proteins
14. . . . the cell membrane. The cell membrane releases mature virions through exocytosis.

- **Viruses recruit host cells to replicate their genomes.** Viral genomes are remarkably diverse, including RNA or DNA, single- or double-stranded, linear or circular. Replication within the host cell occurs by a variety of methods, with varying dependence on viral and host enzymes.
- **Virus particles (and their genomes) range in size from a few components to assemblages approaching the complexity of cells.** The advantage of simplicity is the minimal requirement for resources. The advantage of complexity is the fine-tuning of infection mechanisms for evading host defenses.

Concluding Thoughts

The study of viral molecular biology raises intriguing questions about the nature of viral replication and about viral origins (see **Special Topic 11.1**). Research in virology offers hope for new drugs and cures for humanity's worst plagues, as well as devastating diseases of agricultural plants and animals. At the same time, it is sobering to note that despite the enormous volumes we now know about viruses such as HIV and influenza, the AIDS pandemic continues to grow, and we face the likely emergence of a new deadly flu strain. Molecular research can succeed only in partnership with epidemiology and public health (discussed in Chapter 28).

CHAPTER REVIEW

Review Questions

1. How does phage T4 attach to its correct host cell and insert its genome for replication?
2. How does phage M13 maximize its reproductive options while avoiding loss of its host cell?
3. How does poliovirus compartmentalize the expression and replication of its genome? How are the products coordinated to complete viral assembly?
4. How do influenza virions gain access to the host cytoplasm? Explain the role of fusion peptides.
5. How does influenza virus manage the replication and packaging of its segmented genome? What is the consequence of genome segmentation for virus evolution?
6. How does HIV provide ready-made components for replication of its genome? How does reverse transcriptase convert the single-stranded RNA genome to double-stranded DNA?
7. What is the role of protease in HIV replication? What is the significance of protease for AIDS therapy?
8. How did ancient retroviruses participate in evolution of the human genome?
9. How does herpes virus compartmentalize the expression and replication of its DNA genome?
10. Compare and contrast the needs of DNA genome replication with those of RNA genome replication.

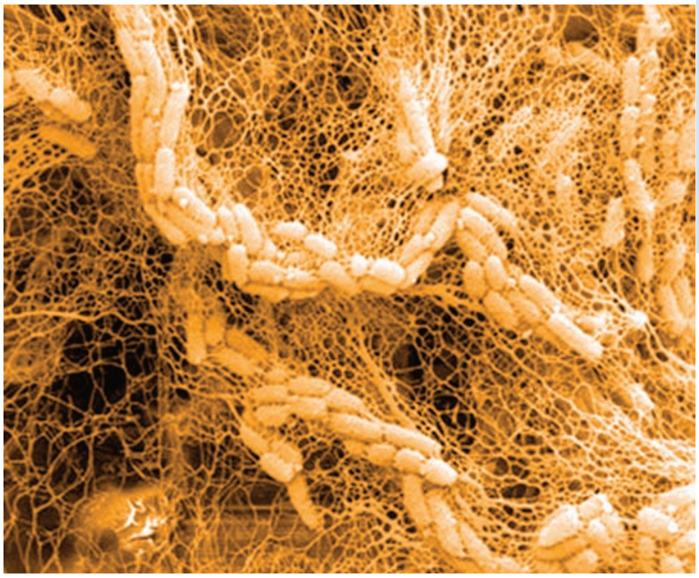
Molecular Techniques and Biotechnology

12.1 Basic Tools of Biotech: A Research Case Study
12.2 Genetic Analyses
12.3 Molecular Analyses
12.4 "Global" Questions of Cell Physiology
12.5 Biotechniques of Artificial Evolution
12.6 Applied Microbial Biotechnology

Technologies that are developed to answer basic questions in biology often yield useful consumer products. This is especially evident in today's world of genetic engineering, where the term *biotechnology* has become ubiquitous. The science of biotechnology uses living organisms or their products to improve human health. Although we think of it as a new field, the earliest biotechnologists actually lived about 10,000 years ago. They learned to use yeast to make bread and alcohol. They also unwittingly used naturally existing bacteria to make cheeses and yogurts. The field changed little over the millennia, until about 60 years ago, when the Scotsman Alexander Fleming discovered antibiotics. That watershed event, along with unraveling the structure of DNA and deciphering the genetic code, ushered in the modern high-tech era of biotechnology. We have since learned a great deal about the molecular biology of the microbes our ancestors used. Now, through gene-splicing techniques, we can force bacterial cells to produce human hormones; make fruits and vegetables produce vaccines; and create biochemical pathways to synthesize therapeutic molecules that never before existed.



Scanning electron micrograph of an *Alcanivorax borkumensis* SK2 mutant overproducing polyhydroxyalkanoate during growth on n-octadecane (0.8 to 1.2 micrometers in length). Disrupting the acyl-coenzyme A thioesterase gene results in the overproduction and extracellular deposition of this biotechnologically important biopolymer used in sutures, cardiovascular patches, skin substitutes, and dozens of other applications.

Today's farmers must spray huge amounts of antifungal agents on their crops to combat potato blight disease—the cause of the famous Irish potato famine that wiped out 30% of the Irish population in the nineteenth century. Spraying plants as many as 25 times a season with chemicals, the typical U.S. potato farmer spends about $250 per acre to fight the disease—a huge incentive to find less expensive means of prevention. But the problem may be solved by biotechnology. Scientists discovered a wild Mexican potato that was completely resistant to *Phytophthora infestans*, the cause of potato blight disease. Although the Mexican potato had no commercial value (it is not edible), the gene conveying resistance was genetically engineered into commercial potato breeds, making them utterly resistant to the fungus. This discovery may eventually improve the health of potato crops (research is ongoing) and will certainly contribute to our understanding of disease resistance in plants. This is but one example of how biotechnology can potentially improve human existence.

Of course, with technological power comes a sobering responsibility, for if nature has taught us anything, it has taught us that it cannot be tampered with without cost. For instance, what would happen if an *Escherichia coli* that produced human growth hormone managed to colonize the human gut? Or, worse yet, one that was engineered to make botulism toxin. While these possibilities may seem unlikely, future advances in biotechnology must be guided by serious considerations of bioethics and an eye for unintended consequences.

We begin our discussion of biotechnology by explaining the techniques of modern molecular biology that are used to probe the inner workings of microbes. A research case history will illustrate how many of these techniques are applied to a single problem. Other applications will be discussed at the end of the chapter.

12.1 Basic Tools of Biotech: A Research Case Study

Biotechnology encompasses numerous molecular techniques developed over the last few decades. We need to understand these techniques to fully appreciate the potential of biotechnology. Some of these techniques were described in earlier chapters: DNA sequencing was introduced in Section 7.6; gene array technology and the two-dimensional PAGE analysis of proteomes were covered in Section 10.9. In this chapter, we present several other essential molecular tools in the context of a basic research question concerning a remarkable microbial stress response that allows *E. coli* to survive in the highly acidic conditions of the human stomach.

Few microbes that grow at neutral pH can survive at pH 2, a degree of acidity equivalent to 10 mM HCl. In the stomach, such a highly acidic environment kills most ingested pathogens, but strains of the intestinal bacterium *E. coli*, such as enterohemorrhagic *E. coli* O157:H7, can survive at pH 2 for hours. This means that a person needs to ingest only a few cells of *E. coli* to become colonized or infected. Thus, the organism is said to have a low infectious dose. What makes *E. coli* so special? The molecular tools that we will describe here helped reveal the novel mechanisms of acid resistance used by this microbe and the regulatory networks that control them. Our story of these acid resistance mechanisms begins with the discovery of acid-sensitive *E. coli* mutants that failed to survive at pH 2.

Investigating acid resistance in *E. coli* called for various techniques to determine which genes were defective in the acid-sensitive mutants and computer-assisted analysis of those genes to gain insight into their possible function (see Section 12.2). In Section 12.3, we will see how regulation of each gene was investigated by looking at their RNA transcripts (Northern blots) and protein products (Western blots). We will describe methods used to purify possible regulatory proteins and strategies used to prove that proteins regulating acid resistance bind to target DNA sequences. We will also discuss techniques that allow us to map protein-protein interactions in the cell, design novel vaccines to immunize against disease, and even carry out evolution in the test tube.

12.2 Genetic Analyses

Transposons Inactivate and Mark Target Genes

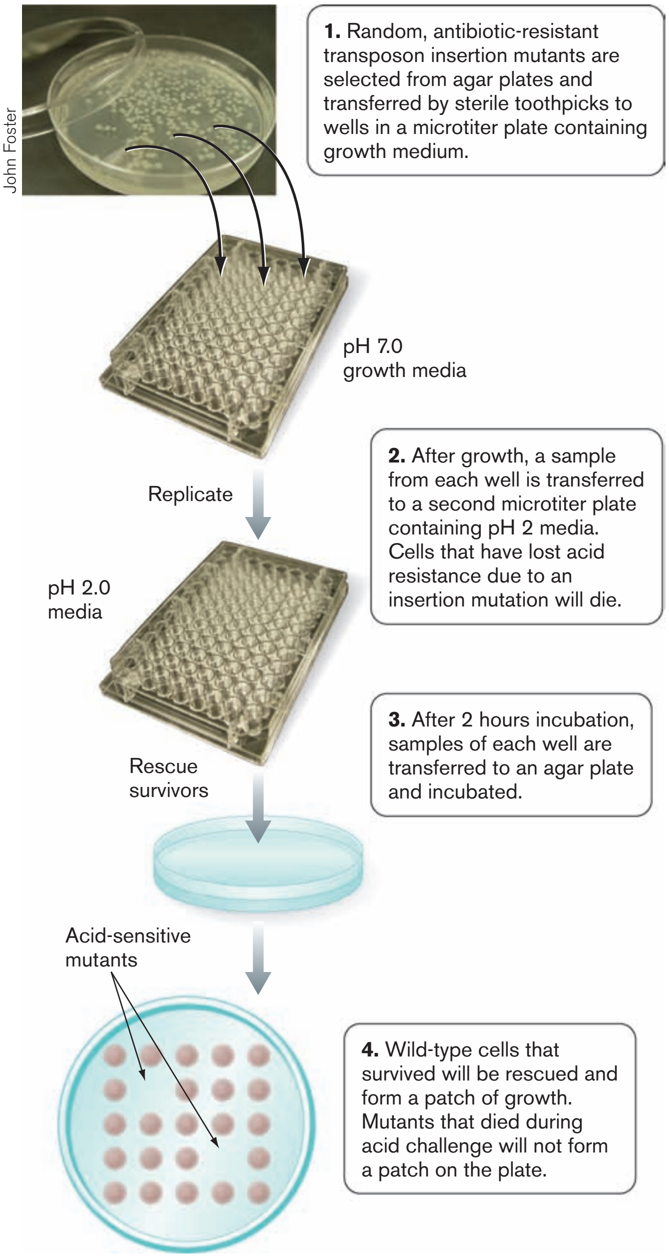
An early step commonly taken to gain insight into a biological process involves isolating mutants defective in that process. Such was the case with *E. coli* acid resistance. The initial goal was to inactivate relevant genes and tag them with an antibiotic resistance marker. In other words, a known gene whose product confers resistance to an antibiotic (that is, an antibiotic resistance gene) is inserted into the middle of a target gene sequence. This process inactivates the target gene and marks the mutation with antibiotic resistance. As a result, the mutant cell becomes antibiotic resistant.

Once constructed, the insertion mutation can be moved from one strain of *E. coli* to another by transduction. Transduction is the process whereby bacteriophage package bacterial DNA segments into capsids, rather than phage DNA, and then transfers the host DNA to another cell. Transducing phage is grown on the mutant bacterial strain (the donor) that contains the tagged host gene. Some of the progeny phage in the resulting lysate will contain the tagged gene. The phage lysate is then mixed with antibiotic-sensitive cells (the recipient) and the mixture plated onto agar medium containing the antibiotic. The only way a colony can develop is if a phage particle containing the marked (antibiotic resistance) gene attaches to a recipient cell and introduces the mutant gene into the cytoplasm. There the donor DNA can recombine into the recipient's genome in exchange for the wild-type gene. The recipient's genome remains identical in all other aspects except it now contains the mutant gene and is resistant to the antibiotic.

To generate mutations in genes needed to confer acid resistance, researchers infected a population of *E. coli* with bacteriophages containing a tetracycline resistance transposon. The bacteriophage was a mutant that fails to replicate in most strains of *E. coli*, so for an infected cell to become tetracycline resistant, the transposon had to "hop," or transpose, out of the phage DNA and into the host chromosome (see Section 9.6). Because target sequences are randomly selected during transposition, each tetracycline-resistant cell contained a transposon inserted into a different gene. As each cell grew into a colony, the colony was picked with a sterile toothpick and transferred into a well of a microtiter plate containing growth medium (**Fig. 12.1**).

After about 10,000 colonies were transferred to microtiter dishes and grown, a multipronged replicator device (a square with 48 metal prongs arranged in 6 rows of 8) was used to transfer small amounts of each culture to new microtiter plate wells that contained a pH 2 medium. After several hours of incubation, the multipronged replicator was again used to sterilely transfer a sample of the pH 2 culture from each well to an agar plate. Most of the insertion mutants survived at pH 2 and were able to form colonies on agar. These insertions occurred in genes unimportant for acid resistance. A few mutants, however, were killed. The transposon in these acid-sensitive mutants had inserted into a gene required for acid resistance, rendering it inactive. The acid-sensitive mutants were retrieved from the original growth medium microtiter plates and subjected to further analysis.

THOUGHT QUESTION 12.1 In this postgenomic era, how might you generally design a strategy to construct a strain of *E. coli* that cannot synthesize histidine?



John Foster

1. Random, antibiotic-resistant transposon insertion mutants are selected from agar plates and transferred by sterile toothpicks to wells in a microtiter plate containing growth medium.

2. After growth, a sample from each well is transferred to a second microtiter plate containing pH 2 media. Cells that have lost acid resistance due to an insertion mutation will die.

3. After 2 hours incubation, samples of each well are transferred to an agar plate and incubated.

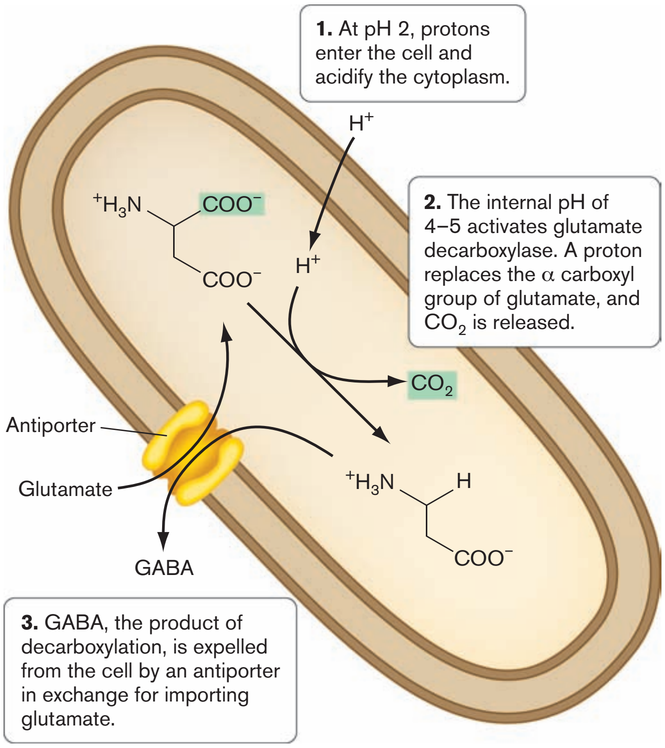
4. Wild-type cells that survived will be rescued and form a patch of growth. Mutants that died during acid challenge will not form a patch on the plate.

Figure 12.1 **Selection for acid-sensitive mutants.** Mutagenesis with transposons led to the discovery of several *E. coli* genes involved in acid resistance. The technique is applicable to many other biochemical systems.

DNA Sequencing of Insertion Sites and Computer Analysis

Once mutants in a project are identified, it is important to know in what genes the insertions occurred. Subsequent bioinformatic analysis of the gene may then link function to phenotype. In our example, an oligonucleotide primer (a short, single-stranded DNA molecule) that anneals to one end of the transposon was used to sequence across the insertion joint and into the adjacent *E. coli* DNA. The DNA sequences obtained were subjected to computer-based homology searches with the sequenced genome of *E. coli*. The matches obtained indicated that insertions occurred in four genes. Two of these genes encode isoforms of glutamate decarboxylase (the isoforms differ by only a few amino acids), which converts glutamic acid to gamma-aminobutyric acid (γ-aminobutyric acid), known as GABA; a third gene produces a glutamate/GABA antiporter; and a fourth gene encodes a putative DNA-binding protein with no known function, although it was annotated as a possible regulator.

The nature of the gene's functions suggests how the system might protect cells submerged in acid (**Fig. 12.2**). When *E. coli* is placed into a pH 2 environment, the cytoplasmic pH falls to dangerously low levels. Glutamate



1. At pH 2, protons enter the cell and acidify the cytoplasm.
H+
2. The internal pH of 4–5 activates glutamate decarboxylase. A proton replaces the α carboxyl group of glutamate, and CO2 is released.

Antiporter
Glutamate
+H3N
H
COO−
GABA
3. GABA, the product of decarboxylation, is expelled from the cell by an antiporter in exchange for importing glutamate.

Figure 12.2 Proposed model of acid resistance in *E. coli*. DNA sequence data identified the location of the transposon insertions leading to acid sensitivity. The genes identified included two isoforms of glutamate decarboxylase and a putative antiporter that brings glutamate into the cell in exchange for the decarboxylation product gamma-aminobutyric acid (GABA), which is transported out of the cell. The combined action of decarboxylase and antiporter would remove H^+ from the cell.

decarboxylase removes a carboxyl group from glutamate and replaces it with a proton from the cytoplasm, thereby decreasing acidity and elevating cytoplasmic pH. But to continue draining protons from the cytoplasm, *E. coli* must bring in more glutamate. The glutamate/GABA antiporter does this by bringing in glutamate in exchange for expelling the decarboxylation end product, GABA.

Exploring Gene Regulation: Reporter Fusions

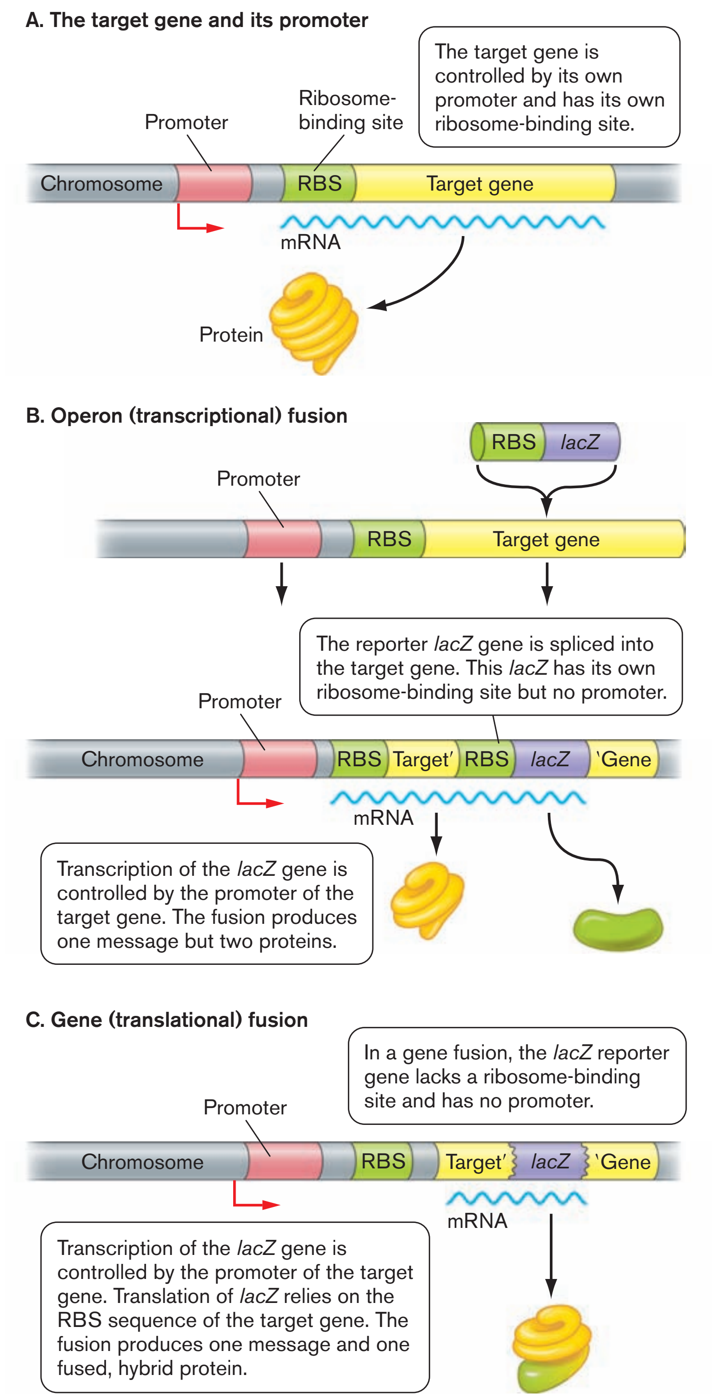
Another important question in our example was whether any of the acid resistance genes were regulated in response to changes in the environment. Are they always expressed, and is the cell ever-ready to encounter acid stress? Or does the cell have sensing mechanisms that anticipate when it might encounter life-threatening low pH and only then express acid resistance genes? Several experimental strategies can be used to determine if a given gene is regulated in response to changes in the environment. Recall that the cell can control production of a protein at several levels. The cell can regulate transcription, translation, and the stability of the mRNA or protein. How do microbiologists differentiate between these possibilities or determine if there is any regulation in the first place?

One technique used to examine gene regulation involves linking (or fusing) the promoter of the gene of interest to what is called a **reporter gene**, such as *lacZ* (beta-galactosidase) or *gfp* (green fluorescent protein). Reporter genes encode proteins whose activities are easily assayed. The result is called a **reporter fusion**. Reporter fusions facilitate monitoring the expression of genes whose products are difficult to measure directly. In the case of *lacZ*, beta-galactosidase (β-galactosidase) converts the substrate *o*-nitrophenyl galactoside (ONPG) to a yellow product that is easily measured with a spectrophotometer.

Two general types of reporter fusions are used to investigate gene regulation in bacteria: **operon fusions** and **gene fusions**. Operon fusions will only reveal transcriptional control of the target gene, whereas gene fusions expose both transcriptional and translational controls. Both types of fusions involve linking a reporter gene lacking its own promoter to the 3′ end of a target gene that still possesses its promoter (**Fig. 12.3**). The result is an artificial operon. Because there is only one promoter, only one mRNA transcript is made encompassing the target and reporter gene transcripts. The 5′ end of the newly engineered polycistronic mRNA will contain the target gene transcript followed at the 3′ end by the reporter gene transcript. When the reporter gene is inserted into the middle of the target gene, as shown in Figure 12.3, the downstream part of the target gene is not transcribed because of a transcriptional terminator located at the end of the reporter.

In both types of fusions, any factor that controls expression of the target gene promoter will also control the production of the reporter. The difference between operon fusions (also known as transcriptional fusions) and gene fusions (also known as protein or translational fusions) is whether the reporter gene carries its own ribosome-binding site. In an operon fusion, the reporter gene carries its own ribosome-binding site, but in a gene fusion, it does not. Because the reporter gene in an operon fusion maintains its own ribosome-binding site, translation of the reporter message occurs independently of the fused, target gene's message. As a result, operon fusions will only reflect transcriptional control at the promoter, not control at the level of translation.

In a gene fusion the reporter is missing *both* its promoter and ribosome-binding site. So for the reporter protein to be synthesized, the reporter gene must be fused to the target gene in the proper codon reading frame (**Fig. 12.3C**). Now, not only will the mRNA messages from the target and reporter genes be fused, but the peptides of the truncated target gene and the reporter gene will also be linked. In this case, anything controlling the transcription *or* translation of the target gene will also control reporter protein levels.



A. The target gene and its promoter

The target gene is controlled by its own promoter and has its own ribosome-binding site.

B. Operon (transcriptional) fusion

The reporter *lacZ* gene is spliced into the target gene. This *lacZ* has its own ribosome-binding site but no promoter.

Transcription of the *lacZ* gene is controlled by the promoter of the target gene. The fusion produces one message but two proteins.

C. Gene (translational) fusion

In a gene fusion, the *lacZ* reporter gene lacks a ribosome-binding site and has no promoter.

Transcription of the *lacZ* gene is controlled by the promoter of the target gene. Translation of *lacZ* relies on the RBS sequence of the target gene. The fusion produces one message and one fused, hybrid protein.

Figure 12.3 Transcriptional and translational fusions. Aspects of a gene's regulation can be monitored by fusing a second gene, one that produces an easily assayed protein, to the gene under study. **A.** The gene targeted for construction of a reporter fusion. **B.** Construction of an operon fusion. **C.** Construction of a gene fusion. The *lacZ* open reading frame must be fused in-frame to the amino-terminal end of the target gene.

Each type of fusion can be constructed in vitro using plasmids and then transferred into recipient cells in a manner that will promote exchange of the reporter fusion for the resident gene. Once constructed, these fusions allow the researcher to monitor how different growth conditions influence the transcription or translation of the gene. They can also be used to test whether mutations in known or suspected regulators affect expression of the gene. In addition, these fusions provide convenient phenotypes (for example, lactose fermentation or fluorescence) that can be exploited in mutant hunts to screen for new regulators.

In our acid resistance example, a strain engineered to have a *gadA-lacZ* fusion would highly express that gene when growing on pH 5.5 agar media. If that medium contained X-Gal, a chemical indicator of LacZ activity, the colonies would appear dark blue. β-galactosidase cleaves a bond in the colorless X-Gal molecule and releases a blue chemical that stays in the colony. One can then search for regulatory genes required to activate *gadA* by subjecting the *gadA-lacZ* strain to random transposon mutagenesis and plating the insertion mutants onto pH 5.5 X-Gal medium. The medium includes an antibiotic that only allows growth of insertion mutants whose transposons contain an antibiotic resistance gene. An insertion into a gene encoding a positive regulator of *gadA-lacZ* will then produce a white ($LacZ^-$) colony, distinguishable from the blue $LacZ^+$ colonies.

THOUGHT QUESTION 12.2 You have monitored expression of a gene fusion where *lacZ* is fused to the glutamate decarboxylase gene, *gadA*. You find that there is a 50-fold increase in expression of *gadA* (as measured for β-galactosidase) when the cells carrying this fusion are grown in media at pH 5.5 as compared to cells grown at pH 8. What additional experiment must you do to tell if the control is transcriptional or translational?

TO SUMMARIZE:

- **Transposons** can be used to mutate genes and mark the defective gene with antibiotic resistance.
- **The location of a transposon insertion** can be determined by sequencing from the end of the transposon across the insertion junction. The junction sequence is examined by online comparative BLAST analysis to identify the gene in the genome.
- **Annotations of the gene** may provide clues as to the function of the protein.
- **Regulation of a gene** can be determined by fusing that gene to an easily assayed reporter gene.
- **Operon fusions** reflect transcriptional control of the subject gene.
- **Gene fusions** (also called translational fusions) reflect transcriptional and translational control.

12.3 Molecular Analyses

There are many situations and numerous organisms in which creating a fusion is not possible. One must then use more direct measures to monitor changes in mRNA or protein levels. This section will describe the Northern, Southern, and Western blot procedures that accomplish these goals and will describe methods to examine protein-DNA interactions as well as rapidly purify proteins.

Northern Blots Help Visualize Specific mRNA Messages

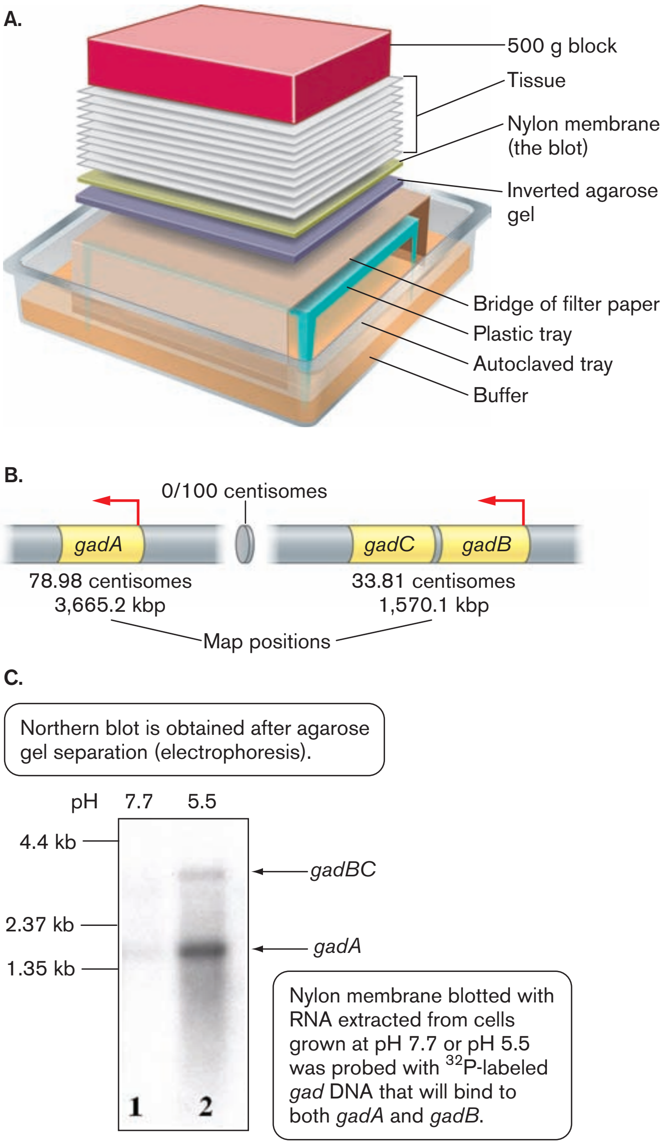
Edwin M. Southern, in the 1970s, invented a method, now called the **Southern blot**, for identifying a particular sequence of DNA in a complex mixture of DNA fragments. Scientists later used a similar technique to examine RNA fragments and named their method the **Northern blot** in counterpoint to the Southern blot.

Northern blots are used to analyze the presence, size, and processing of a specific RNA molecule in a cell extract. In the Northern blot technique, RNA is extracted from the cell. Special precautions must be taken to avoid contaminating these preparations with RNases that are ubiquitous to the laboratory environment. The RNA is then fractionated by electrophoresis on an agarose-formaldehyde gel. Formaldehyde helps keep the RNA denatured and unkinked by preventing base pairing, so the molecules can be separated by size. The separated fragments are transferred by simple capillary action onto a nylon or nitrocellulose membrane, creating the blot.

The diagram in **Figure 12.4A** illustrates how buffer is drawn up through the agarose gel and then through the facing membrane. RNA (or DNA) travels with the buffer out of the gel and is deposited on the membrane in exactly the same pattern as it was displayed in the gel. Once transferred, the RNA is fixed to the membrane by UV cross-linking.

Once the RNA is transferred, the membrane is hybridized (or "probed") with a small DNA fragment specific for a given mRNA. This is done under conditions that allow annealing between the DNA probe and matching RNA fragment in a process called **hybridization**. The probe can be labeled with radioactivity, a fluorescent dye, or biotin. The biotin is detected later by a chemiluminescent enzyme assay. RNA fragments to which a radiolabeled probe has bound are visualized by exposing the membrane to X-ray film, followed by photographic development of the film, otherwise known as **autoradiography**. Alternatively, the membrane is subjected to phosphoimaging. (A phosphoimager is a machine that records the energy emanated as light or radioactivity from gels or membranes.)

The molecular weights of bands visualized by autoradiography or phosphoimaging can be determined by comparing their locations on the gel with the locations of standard RNA molecular weight markers run in a parallel lane. This technique can be used to determine the presence of any given mRNA. By estimating the size of the transcript, the method can also be used to evaluate whether two adjacent genes are transcribed as an operon.



Northern blot is obtained after agarose gel separation (electrophoresis).

Nylon membrane blotted with RNA extracted from cells grown at pH 7.7 or pH 5.5 was probed with ^{32}P-labeled *gad* DNA that will bind to both *gadA* and *gadB*.

Figure 12.4 Northern blot to view mRNA levels. Northern blots can be used to monitor the quantity and breakdown of RNA. **A.** Apparatus to perform Northern blot. Capillary action draws buffer through the gel and carries the RNA upward to the membrane, which binds the RNA. **B.** Organization of genes responsible for acid resistance in *E. coli*. Genes *gadA* and *gadB* encode isoforms of glutamate decarboxylase. Gene *gadC* encodes the putative antiporter. Map positions are given in centisomes and kpb. **C.** Northern blot illustrates that *gadB* and *gadC* are transcribed as an operon, while *gadA*, located elsewhere in the genome, is transcribed separately. The data also illustrate that *gadA* and *gadBC* mRNA accumulate after growth at pH 5.5, probably due to increased transcription. *Source*: From Zhuo Ma, et al. 2003. *Molecular Microbiology* 49:1309–1320.

In our example, how are the *E. coli* acid resistance genes regulated? **Figure 12.4B** shows that the *gadA* gene is located at a position on the genome different from those of the *gadB* and *gadC* genes, which together form an operon. The Northern blot in **Figure 12.4C** reveals that when cells are grown under acidic conditions (low pH), the *gadA* gene and the operon *gadBC* are both induced. The RNA gel was probed with a fragment of DNA that can bind mRNA from either the *gadA* or *gadB* gene. Because *gadB* and *gadC* form an operon, a longer mRNA molecule appears. The RNA bands are more intense in the lane from acid-grown cultures (pH 5.5) than in the lane from cultures grown at high pH (pH 7.7). The results suggest that the transcription of these genes is induced by acid. A current alternative procedure for quantitating levels (but not sizes) of specific RNA molecules is real time quantitative PCR, which is discussed in Section 12.4.

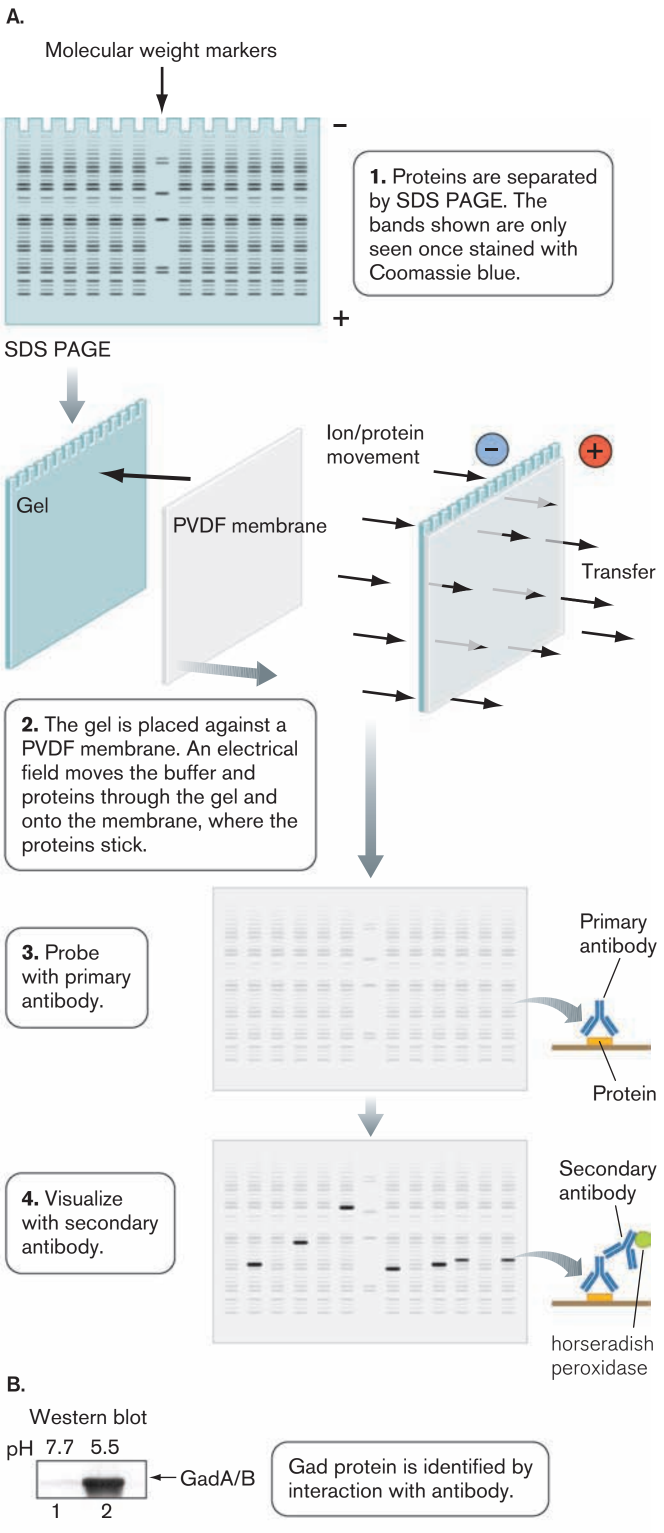
Southern Blots Help Visualize Specific DNA Sequences

The Southern blot technique for DNA uses a probing strategy similar to that of Northern blots to detect the presence of specific bands of DNA. The basic difference between the Southern and Northern blot techniques is the starting material. Southern blots begin with restriction endonuclease digestion of genomic DNA to produce discrete DNA fragments that are then separated by electrophoresis in an agarose or acrylamide gel. The DNA fragments are denatured to single strands then blotted onto a membrane. A DNA probe is generated from one bacterial species by PCR, although other techniques can be used, and labelled with a radioactive or nonradioactive tag. This probe is hybridized to the DNA blot and the hybridized bands visualized by autoradiography or phosphoimaging. Standardized double-stranded DNA markers are used to help determine sample fragment sizes. Southern blotting is used, for example, to detect the presence of specific genes among different species or strains of a single species.

Western Blots Help Visualize Proteins

An alternative approach to examining gene regulation is to detect the protein products themselves; the technique used is called the **Western blot**. Antibodies that specifically bind a given protein can be used to detect those proteins within a complex mixture of different proteins. To carry this out, the protein extract is subjected to SDS polyacrylamide gel electrophoresis (discussed in Section 10.9). The protein bands are electrophoretically transferred from the gel to a membrane made of polyvinylidene fluoride (PVDF), which tightly binds proteins (**Fig. 12.5A**). The membrane is then probed with a primary antibody directed against the specific protein. These antibodies are made by injecting the protein into animals and then extracting the serum after a few months.

Depending on the source of the primary antibody (mouse, rabbit, or other), the membrane is then probed with



1. Proteins are separated by SDS PAGE. The bands shown are only seen once stained with Coomassie blue.

2. The gel is placed against a PVDF membrane. An electrical field moves the buffer and proteins through the gel and onto the membrane, where the proteins stick.

3. Probe with primary antibody.

4. Visualize with secondary antibody.

Gad protein is identified by interaction with antibody.

Figure 12.5 Western blot analysis. Specific proteins within a mixture of many proteins can be identified by Western blot. **A.** The Western blot procedure. **B.** Western blot analysis of glutamate decarboxylase content of *E. coli* grown at pH 7.7 versus pH 5.5. The production of the protein is induced by growth under acidic conditions. *Source*: From Zhuo Ma, et al. 2003. *Molecular Microbiology* 49:1309.

a secondary antibody that specifically binds to the primary antibody (for example, anti-mouse IgG antibody). This secondary antibody may be tagged with horseradish peroxidase, for instance. The result is an antibody "sandwich" in which the primary antibody binds the target protein and the secondary antibody binds the primary antibody. Adding hydrogen peroxide, which is oxidized by horseradish peroxidase and luminol (a chemical that emits light when oxidized) sets off a luminescent reaction wherever an antibody sandwich has assembled. The light emitted can then be detected by autoradiography or phosphoimaging. Only protein bands to which the primary antibody has bound will be detected. The technique is used to determine if, and at what levels, specific proteins are present in a cell extract.

In our acid resistance example (**Fig. 12.5B**), Western blot analysis was performed to detect glutamate decarboxylase protein. The blot shows that the level of this protein is increased—that is, induced by growth under acidic conditions. Thus, the acid-induced increase in mRNA from transcription (as shown by the Northern blot) correlates with an increase in translated protein (as shown by Western blot).

THOUGHT QUESTION 12.3 What would you conclude if the Northern blot of the *gad* genes showed no difference in mRNA levels in cells grown at pH 7.7 and pH 5.5 but the Western blot showed more protein at pH 5.5 than at pH 7.7?

DNA Mobility Shifts

Once a gene encoding a putative transcriptional regulatory protein is identified by sequence annotation, proof of function requires a demonstration that the protein will bind to a DNA sequence present in the target promoter area. One approach is to add purified protein to the putative target DNA fragment and see if the protein causes a shift in the electrophoretic mobility of that fragment in a gel. An example of this method, as applied to our acid resistance problem, is illustrated in **Figure 12.6A**. Linear DNA molecules travel in agarose or polyacrylamide gels at an inverse rate relative to their size; larger molecules travel more slowly than smaller ones. If a protein binds to a DNA molecule, the complex is larger than the DNA alone and will travel even more slowly in the gel. This method of analyzing protein-DNA binding is called the **electrophoretic mobility shift assay (EMSA)** or gel shift (first introduced in Section 10.2).

In our research example, one of the genes that affected acid resistance (*yhiE*) was annotated in the database as a potential transcriptional regulator. The encoded protein was purified and tested by EMSA for its ability to bind to a DNA sequence conserved within the promoter regions of the two potential targets, *gadA* and *gadBC*. As shown in **Figure 12.6B**, the purified YhiE protein, renamed GadE because of its role in regulating glutamic acid decarboxylase expression, did bind the *gadA* sequence and retarded its mobility. Thus, GadE appears to be a true regulator of the acid resistance genes. It appears to work in collaboration with the GadW protein shown in Special Topic 10.1, Figure 2.

Purifying Proteins in One Step

How do researchers purify proteins today? In the past, protein purification was a long, complex process involving

Protein-DNA interactions can be monitored by EMSA. **A.** Diagrammatic representation of EMSA showing slowed mobility of a hypothetical DNA-protein complex in a polyacrylamide gel. **B.** Gel shift experiment showing that the GadE regulatory protein binds to a radiolableled promoter fragment of *gadA*. Lane 1, radiolabeled target DNA only; Lanes 2 and 3 contain target DNA and GadE protein. Lane 4 is the same as Lane 3 but includes excess unlabeled promoter fragment. The unlabeled fragments effectively outcompete labeled fragments for the protein, so no shift in the radiolabeled fragment is seen. This provides a check on the specificity of the binding.

numerous columns and time-consuming assays. Now, a desired protein with a known sequence can be purified in only a week or so. The trick is to take the gene encoding the protein and fuse it to a DNA sequence encoding a peptide tag that has a strong binding affinity to some small ligand molecule. The target ligand is attached to beads, and the cell extract containing the tagged protein is passed over the beads. Only the tagged protein, also called a fusion protein, will bind to the beads. The other proteins will pass through the column. This technique allows researchers to essentially "fish" the tagged protein from a complex mixture of proteins present in a cell extract.

There are several commonly used peptide tags. One tag is a series of six histidines, called a His_6 tag, which tightly binds to nickel. A commercially available plasmid used to make His-tagged proteins is shown in **Figure 12.7A**.

The gene of interest is cloned into one of the His-tagged vectors, creating a gene fusion.

Transformed *E. coli* is grown and the culture is induced to produce His_6-tagged fusion protein constituting up to 30% of the cellular protein.

The crude cell extract is poured over a nickel column. The fusion protein binds to the nickel while all other proteins flow through. The fusion protein is then eluted in purified form with imidazole.

The His tag is cleaved from the purified fusion protein by a specific protease.

The protein of interest is separated from the His-tag peptide by passing the mixture over another nickel column, which retains the His-tag peptide.

Figure 12.7 Tagging proteins for easy purification. There are several different strategies for tagging proteins. **A.** His_6 tag vector. The vector contains a promoter from the T5 phage, tandem *lacO* operators to repress expression of the inserted gene unless isopropyl thiogalactoside (IPTG) is added, a ribosome binding site (RBS), a start ATG codon, a sequence encoding 6 histidine residues, and a multicloning site to insert the desired ORF. The translational reading frame of the His codons and the codons of the ORF must be the same to create a protein fusion. **B.** Purification of the fusion protein on a nickel column. **C.** SDS polyacrylamide gel electrophoresis of fractions from the purification of His_6-GadB. Source: C. From Zhuo Ma, et al. 2003. *Molecular Microbiology* 49:1309.

These plasmids typically include an inducible promoter to control when the fusion protein is produced. To purify the protein produced, nickel-coated beads are loaded into a column, and then a crude extract containing the tagged protein is added to the top (**Fig. 12.7B**). Proteins that do not bind to the nickel (that is, those without the His_6 tag) are eluted with buffer. The tagged protein molecules that did bind are then eluted from the column with an elution buffer containing imidazole. Imidazole has a stronger affinity for the nickel and will displace the His_6-tagged protein from the beads. Analysis of the progressive purification of GadB by the His_6 tag fusion method is shown in **Figure 12.7C**.

The other commonly used tag is maltose-binding protein (MBP), which binds to amylose. The MBP-GadE protein in our research example (Fig. 12.6) was made by genetically fusing maltose-binding protein to the amino terminus of GadE.

Primer Extension Analysis Identifies Transcriptional Start Sites

For many genes, transcription can occur from multiple promoters to produce transcripts of different sizes. The transcripts all *end* at the same terminator but *begin* at different defined nucleotides located upstream of the struc-

1. Cell transcription produces mRNA.

2. Labeled oligonucleotide primer complementary to mRNA is added to purified RNA.

3. Reverse transcriptase is added to extend the primer until the 5′ end of the mRNA. This produces a cDNA product of a specific size.

4. The cDNA product is electrophoresed next to a DNA sequence ladder generated from initial DNA using the same primer.

Sequence is actually of the bottom DNA strand, but lane assignments are reversed to reflect the top strand sequence corresponding to the mRNA.

Figure 12.8 Primer extension analysis to determine transcriptional start sites. **A.** Top sequence represents the DNA sequence of an imaginary promoter. The mRNA product is shown below. After separating the RNA from DNA, a DNA oligonucleotide primer that binds to the mRNA at a defined place is added, followed by a reverse transcriptase reaction. Reverse transcriptase produces a cDNA primer extension product that ends at the beginning (5′ end) of the mRNA. The product is run in a polyacrylamide gel next to a sequencing ladder of the original DNA made with the same primer used in the reverse transcriptase reaction. The primer extension product will migrate at the same position as the base that represents the start site of transcription. **B.** Primer extension (lane on far right) showing the transcriptional start site of the *gadA* gene (arrow) involved in *E. coli* acid resistance. **C.** The sequence of the promoter is shown with −10, −35, and transcriptional start site marked. Lowercase letters indicate bases that differ from consensus −10 and −35 sequences. Note that the first base of the mRNA transcript is marked C (cytosine). This corresponds to a G (guanosine) in the gel sequence ladder (panel B). This is because the DNA sequence obtained using the primer is actually that of the strand complementary to the message. *Source:* De Biase, et al. 1999. *Molecular Microbiology* 32:1198.

tural gene. These different promoters are useful because they can respond to different cell signals (for example, high temperature vs. acidic pH vs. nitrogen limitation).

To begin the search for upstream promoter sequences, we need to define where each transcript begins. If there are different transcriptional start sites, there are multiple promoters. One method to determine transcript length is called **primer extension** (**Fig. 12.8**). Knowing the sequence of the gene, the researcher designs a single DNA primer that will anneal to the mRNA of interest near to the suspected start site. The primer is used in a reverse transcription reaction (reverse transcriptase makes DNA from RNA) that extends the primer to the 5′ end (the start) of the message. This produces a complementary DNA (cDNA) of a precise length. The cDNA is radiolabeled by using radioactive nucleotides in the reaction mix.

The key to using the primer extension technique is that the same primer is also used in a DNA-sequencing reaction with the template DNA (see **Fig. 12.8A**). The cDNA primer extension fragment is then run on a polyacrylamide gel alongside a DNA-sequencing reaction of the gene fragment. The size of the primer extension cDNA fragment will be identical to the size of one of the "rungs" on the DNA sequence ladder. That "rung" represents the base in the sequence that correlates to the transcriptional start site. The cDNA from the transcripts of genes that have multiple promoters will produce primer extension fragments of varying sizes that comigrate with different-sized sequencing fragments.

Primer extension analysis of one of the *E. coli* acid resistance genes, *gadA*, is illustrated in **Figure 12.8B**. The primer extension analysis indicates that the transcript begins opposite a G in the sequence of the complementary DNA strand. This corresponds to a C in the sense strand of DNA shown in **Figure 12.8C**. The sense strand has the same sequence as the mRNA. Thus, the promoter sequences for *gadA* reside at –10 and –35 bp from the transcript start site. Once the promoter is identified, we can begin to search for nearby DNA sequences that control expression of the promoter.

DNA Protection Analysis Identifies DNA-Protein Contacts

An electrophoretic mobility shift assay will identify fragments of DNA to which a transcriptional regulatory protein will bind, but it does not actually reveal which nucleotides in the sequence are bound. A first step in determining potential DNA-protein contacts on DNA is to see what bases the binding protein can protect from nuclease digestion. The protected bases represent what is called the "footprint" of the binding protein.

Because a regulatory protein covers DNA at its binding site sequence, an enzyme that might attack the sequence cannot get close enough to do damage. Deoxyribonuclease I (DNase I), one of many different types of DNases, is one such enzyme. It cleaves phosphodiester bonds between bases. **Figure 12.9** presents the fundamental method that uses DNase I to determine the protective "footprint" a regulatory protein leaves on a DNA sequence. In this method, DNase I is added to a DNA fragment at a concentration that can nick each molecule only once during the time of incubation. When the DNA is later denatured by heat, arrays of single-stranded fragments are produced, each fragment being of a different size, depending on where the nick occurred. Because only one end of one strand of the DNA is labeled, only those fragments containing that label will be seen following polyacrylamide gel electrophoresis and autoradiography.

The bases protected by a hypothetical protein are shown in **Figure 12.9A** and **B**, while **Figure 12.9C** presents the actual footprint of GadX, another regulator of *E. coli* acid resistance. The regulatory protein GadX covers a region around the promoter of *gadA* and *gadB* (only *gadA* is shown). The region is immediately upstream of the promoter. It is thought that both regulatory proteins GadE (previously described) and GadX communicate with RNA polymerase at the promoter, allowing it to transcribe the acid resistance genes.

DNA protection assays do not definitively show contact points between protein and DNA. Areas of the protein only have to be close enough to the DNA to hinder nuclease access. Protein-DNA interaction sites can be better defined by other, more difficult methods that cause a cross-link between amino acids of the protein and the specific bases they contact in the DNA. Nevertheless, the DNA protection assay remains a very useful tool.

THOUGHT QUESTION 12.4 Another regulator of glutamate decarboxylase (Gad) production does not affect the production of *gad* mRNA but is required to accumulate Gad protein. What two regulatory mechanisms might account for this phenotype?

Two-Hybrid Analysis Reveals Protein-Protein Interactions

Many cellular proteins interact with and influence the function of one or more other proteins in the cell. For example, anti-sigma factors help control the timing of sporulation in *Bacillus* by interacting with sigma proteins. Protein-protein interactions, therefore, constitute an essential aspect of the normal workings of a living cell. Unraveling the various interactions between individual proteins is an invaluable way of understanding protein function.

It is important to probe protein-protein interactions in vivo, where the proteins actually work. An ingenious tool to measure in vivo protein-protein interaction is the two-hybrid system. Two-hybrid analysis can be used to mine for unknown "prey" proteins that interact with a known "bait" protein.

While there are many types of two-hybrid techniques, a classic example is the **yeast two-hybrid system** (**Fig. 12.10**). Yeast two-hybrid analysis involves fusing genes encoding two potentially interacting proteins to separated components of the yeast GAL4 transcriptional factor (**Fig. 12.10A**). The GAL4 transcription factor is composed of two domains: an activation domain and a sequence-

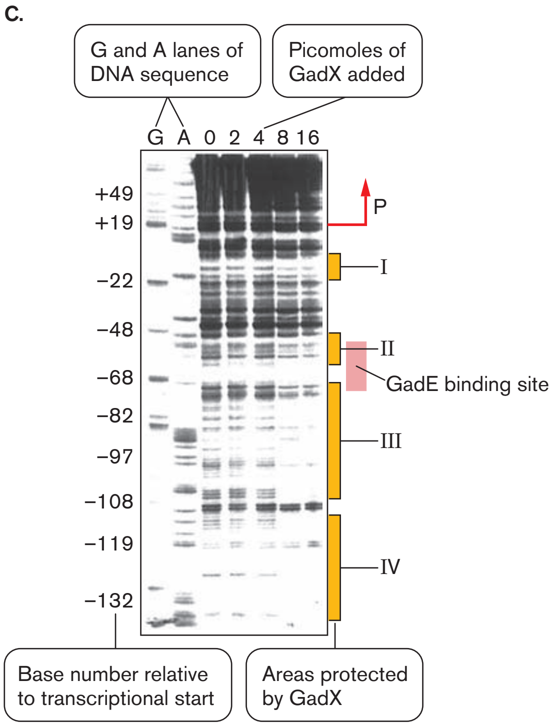
Figure 12.9 DNA protection assay using DNase I. Protein-DNA interactions can be revealed by an ability of the protein to protect DNA from nuclease digestion. **A.** DNase I will randomly nick unprotected double-stranded DNA. Conditions are designed so that there will be only one nick per molecule of DNA. To facilitate tracking, only one end of one strand is labeled (asterisk). *Left:* Random cleavage of unprotected DNA. *Right:* DNA-binding proteins block DNase I activity. **B.** The protein is removed, and the strands are separated by heat denaturation and run on polyacrylamide gels. By comparing the two lanes, one can see the "footprint" where the DNA-binding protein protected the fragment from nuclease digestion. **C.** Gel showing DNase I footprint where a regulator of *E. coli* acid resistance, GadX, binds to the *gadA* promoter region. The actual protein used was an MBP (maltose-binding protein)-GadX fusion protein. Numbers to the left indicate the number of bases relative to the transcriptional start (+1). The first two lanes represent the fragment's DNA sequence (G and A lanes only). Numbers above the gel indicate increasing amounts (picomoles) of GadX regulatory protein added. Orange boxes marked with roman numerals on the right indicate areas protected by GadX. The red box marks the sequence bound by the other regulator, GadE. The bent arrow denotes the transcriptional start site. *Source*: Angela Tramonti, et al. 2002. *Journal of Bacteriology* 184:2603.



specific DNA-binding domain. The DNA-binding domain binds to the yeast GAL1 gene promoter region, positioning the GAL4 activation domain to bind RNA polymerase and stimulate GAL1 transcription. If the domains are separated into two different peptides, GAL1 is not activated. However, when separated, both domains can still work together if each domain is fused to one member of a pair of other proteins that interact.

This strategy is exploited in the yeast two-hybrid system. The target gene is a chromosomal *GAL1-lacZ* fusion gene, although other reporter genes can be used. The *lacZ* gene encodes beta-galactosidase, whose enzymatic activity is easily measured. When the two resulting hybrid proteins interact via the two target protein domains, the GAL4 DNA-binding and activation domains are brought together. Thus assembled, the two-hybrid GAL4 complex will bind and activate transcription of *GAL1-lacZ*. Expression of *GAL1-lacZ* is then visualized on agar plates containing a substrate of beta-galactosidase, X-Gal. X-Gal is a colorless substrate that, when cleaved, produces a blue product.

The power of this technique is that it can also be used to find unknown proteins that interact with a known protein. A known protein is fused to one of the GAL4 domains and used as "bait" to find the "prey" proteins expressed by randomly cloned "prey" genes fused to the other GAL4 domain. Plasmids containing the bait and prey fusions are transformed into yeast cells and the transformants plated onto a medium containing an indicator of beta-galactosidase activity. After plating, colonies that express beta-galactosidase are the result of protein-protein interactions occurring between the bait and prey fusion proteins. Sequencing the DNA insertion can then identify the gene encoding the "prey" protein. An example of two-hybrid analysis is shown in **Figure 12.10B**. The two-hybrid approach could be used in our acid resistance research example to learn if any of the proteins involved interact with any other proteins in the cell.

THOUGHT QUESTION 12.5 How could you use two-hybrid analysis to determine if *three* proteins can interact? You suspect that proteins A and C can simultaneously bind to protein B and that this interaction then allows A to interact with C in the complex.

TO SUMMARIZE:

- **Northern blot technology** uses labeled DNA from a specific gene to probe the levels and sizes of RNA made from that gene.
- **Southern blot technology** uses labeled DNA from a specific gene to probe other genomes for the presence of that gene.
- **Western blot technology** uses antibodies to specific proteins to detect the quantity and size of those proteins in cell extracts.
- **Electrophoretic mobility shift assays** (EMSA) examine protein interactions with DNA.
- **Fusion proteins** are made to easily purify proteins for biotechnology purposes.
- **Primer extension analysis** uses labeled DNA probes and reverse transcriptase to identify the 5′ end of a transcript and thus the transcriptional start site of a gene.
- **DNase protection assays** reveal the bases in a DNA sequence protected by a DNA-binding protein.
- **Two-hybrid analysis** uses hybrid proteins to detect protein-protein interactions.

12.4 "Global" Questions of Cell Physiology

In addition to answering specific questions of cell physiology, biotechnology can be used to look into broad—even global—questions of whole-cell physiology and evolution. When a cell encounters a change in its environment, it is rare that only one gene or protein becomes affected. Rather, the impact on the cell radiates along and between pathways affecting many different genes and proteins. Tracking these global regulatory influences can show how a species adjusts its entire physiology to better tolerate, or even flourish in, a new environment.

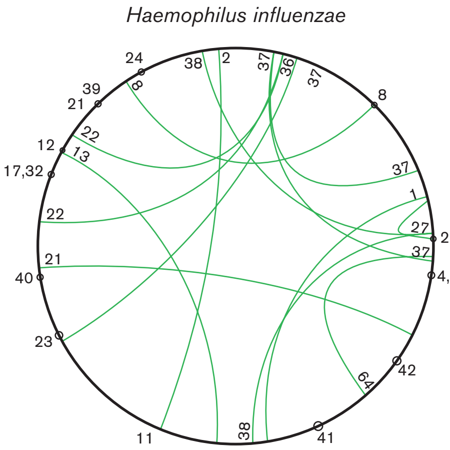
This section describes a number of these incredible tools. For example, how can we map protein-protein interactions throughout an entire cell? At the other extreme, how can we follow the intracellular movement of a single protein as it does its job? We will also describe ingenious PCR strategies that allow the unequivocal identification of individual species in a complex microbial community.

Mapping Protein-Protein Interactions

One example of global analysis of cell physiology involves a previously described tool that examines protein-protein interactions—the yeast two-hybrid system. Micheline Fromont-Racine and colleagues at the Pasteur Institute in Paris developed a high-throughput, genome-wide version of the yeast two-hybrid system to create protein interaction maps for whole cells (**Fig. 12.11**). The automated version of the procedure is rapidly becoming the method of choice for mapping whole proteomes. With a yeast cell mating procedure that increases screening efficiency, Fromont-Racine and colleagues used their complex yeast genomic library of 5×10^6 clones to test 7×10^8 interactions against 15 proteins.

The method identified and classified 170 potential interactors, including approximately 70 proteins of previously unknown function. More than 25% of the interactors are probably biologically relevant, although one cannot be sure without additional in vivo testing. The other 75% may be spurious interactions due to the unnatural overexpression of the two proteins in the test cells. Overexpression of two proteins could magnify low-affinity interactions that would not take place when those proteins are present at lower, more physiological concentrations.

The achievements of this group have opened the way to the systematic analysis of the protein interaction networks of the 6,000 open reading frames of the yeast proteome. Another European team (Hybrigenics, in Paris) has adapted the Fromont-Racine procedure to analyze a bacterial genome and has linked half of the 1,600 proteins of the ulcer-provoking bacterium *Helicobacter pylori* into partial protein interaction maps.



Haemophilus influenzae

Figure 12.11 Protein-protein interaction maps. Representation of a protein interaction map for the most likely interactions in *H. influenzae.* The large black circle represents the genome. 0° corresponds to the first base pair and 360° to the last base pair of the genome. Predicted protein interactions are indicated by linking the circular map positions of the genes (each gene named by an arbitrary number) involved. In cases of neighboring genes (<5°), a small circle indicates the predicted interaction between two genes at that region; otherwise, an arc links the two genes in question.

Tracking Cells and Cell Constituents with Light

The use of the green fluorescent protein GFP to track the location of DNA polymerase in living cells of *B. subtilis* is described in Section 7.3. The original technology was limited, however, by the single color of fluorescence, green, emitted by GFP. More recently, mutations in the *gfp* gene have been introduced to make derivative proteins that fluoresce at different wavelengths (that is, emit different colors). For example, YFP and CFP fluoresce yellow and blue (cyan), respectively. **Figure 12.12** illustrates how different-colored GFP proteins were used to show that type IV pili responsible for twitching motility are also required for biofilm development. Type IV pili contribute to biofilm formation because the pili can attach to many solid surfaces.

GFP technology can also be used to target how microbial proteins move through eukaryotic cells. For instance, the potato virus X (or potexvirus) is a positive-strand RNA virus (a positive-strand RNA is equivalent to mRNA). One viral protein called TBGp3 is required for the virus to move between plant cells. Investigators fused GFP to the TBGp3 protein and asked where the protein ended up in the plant leaves. They delivered the genes to plant cells by bombarding leaves with the fusion plasmids. As shown in **Figure 12.13**, GFP alone was diffusely located throughout the leaf. The GFP-TBGp3 fusion protein, however, inserted only into the reticulated network of veins. Altering specific residues within the protein via mutation prevented this localization and allowed the fusion protein to remain diffused throughout the plant

Figure 12.12 The use of fluorescently tagged cells to demonstrate that twitching motility is important for biofilm formation. Different strains of *Pseudomonas aeruginosa* were tagged with two different versions of green fluorescent protein, one that fluoresces yellow-green (YFP) and one that emits blue, or cyan (CFP). The two cell types were mixed, and their ability to form biofilms was determined by observing the spreading out and merging of microcolonies. Top panel shows microcolonies after one day of growth, while bottom panels are after four days of growth. Wild type and mutants lacking flagella merged well by day four, but mutants lacking type IV pili, which are responsible for twitching motility, do not merge.

cells. These results suggest that this protein helps move the virus through the plant's reticulated network.

Multiplex and Real-Time PCR

Food safety is a major concern for human health. Screening a food product for multiple pathogens one pathogen at a time can be laborious and costly. A technique that can screen for several organisms simultaneously would save time and money and thereby help keep food costs down. One such technique is PCR. Different species of microbes are distinguished by specific genes that define them. Pairs of oligonucleotide probes (that is, DNA primers) that amplify species-specific genes can be combined in a single PCR reaction called **multiplex PCR** (**Fig. 12.14**). For multiplex PCR to be successful, the oligonucleotide pairs cannot bind

Brasher, et al. 1998. *Current Microbiology* 37:101

Figure 12.14 Multiplex analysis of pathogenic *E. coli*, *Salmonella*, and *Vibrio* species. PCR products are shown in this agarose gel. Lane 1 shows the 123-bp DNA ladder used to estimate sizes of the amplified fragments. Each of the other lanes represents a multiplex PCR reaction that can detect segments of five different genes representing different bacterial pathogens. Lanes 2 through 6 used the multiplex oligonucleotide primers to detect single strains. Lane 2 detects the *uidA* (beta-glucuronidase) gene from *E. coli* (144 bp amplicon); lane 3, the *cth* (cytolysin hemolysin) gene from *V. vulnificus* (205 bp); lane 4, the *invA* invasion gene from *S. typhimurium* (273 bp); lane 5, the *ctx* (cholera toxin) gene from *V. cholerae* (302 bp); and lane 6 the *tl* hemolysin gene from *V. parahaemolyticus* (450 bp). Lanes 7 through 10 are replicates in which the multiplex reaction was tested on mixture of all five species.

to each other or inadvertently amplify some other chromosomal gene. In addition, the **amplicon** (amplified product) sizes for each pair must be clearly different so that they can be separated on a gel. If these conditions are met, finding a given fragment will unambiguously demonstrate that the corresponding organism was present in the material tested.

Another revolutionary modification of the PCR technique is called **real-time PCR**. Real-time PCR is a fluorescence assay with the ability to monitor the progress of PCR as it occurs (that is, in real time). Data are collected throughout the entire PCR process rather than just at the end of the reaction. A major advantage of real-time PCR is that it can be used to quantitate the level of DNA or RNA in a sample.

Real-time PCR changes how we approach PCR-based quantitation of DNA and RNA. In real-time PCR, DNA is quantified based on how long it takes to *first* detect an amplified product while the polymerase chain reaction is still running rather than how much product is formed after a fixed number of cycles, the endpoint technique typically used in the past. The higher the starting copy number of the nucleic acid target, the sooner a significant increase in fluorescence is observed; thus, the time at which fluorescence increases will indicate the amount of nucleic acid in the original sample. In contrast, the endpoint assay only measures the amount of accumulated PCR product at the end of the whole PCR cycle.

How does real-time PCR work? The procedure relies on an oligonucleotide probe that contains a reporter fluorescent dye on the 5′ end and a quencher dye on the 3′ end. As long as the probe remains intact, the quencher dye reduces the fluorescence emitted by the reporter dye by a process called **fluorescence resonance energy transfer (FRET)**. In other words, the quencher absorbs the energy emitted by the fluorescent dye. The reporter probe's function is not to act as a primer for DNA synthesis, but to act as an indicator (or reporter) of whether Taq polymerase has synthesized DNA from an upstream primer (**Fig. 12.15**). Thus, the reporter probe is designed to anneal in a target DNA sequence downstream of where the DNA synthesis primer anneals.

If the DNA sequence to be amplified is present in the sample, the reporter probe will anneal downstream from where the primer probe anneals. Taq polymerase will begin to synthesize DNA from the upstream primer. However, Taq polymerase also has 5′-to-3′ exonuclease activity. So, as Taq approaches the reporter probe, it will cleave the probe while the polymerase continues to synthesize DNA. Cleavage of the reporter probe separates the reporter dye from the quencher dye, increasing the fluorescence emitted from the reporter dye. The reporter probe is destroyed and thus removed from the template during this process. Meanwhile, primer extension by Taq polymerase continues to the end of the template. The template is amplified. After each annealing cycle, more reporter probe binds to the newly made templates and becomes cleaved with Taq polymerase during each round of polymerization. As a result, fluorescence continues to increase as the amount of template increases.

THOUGHT QUESTION 12.6 How would you have to modify real-time PCR to quantitate the level of a specific mRNA?

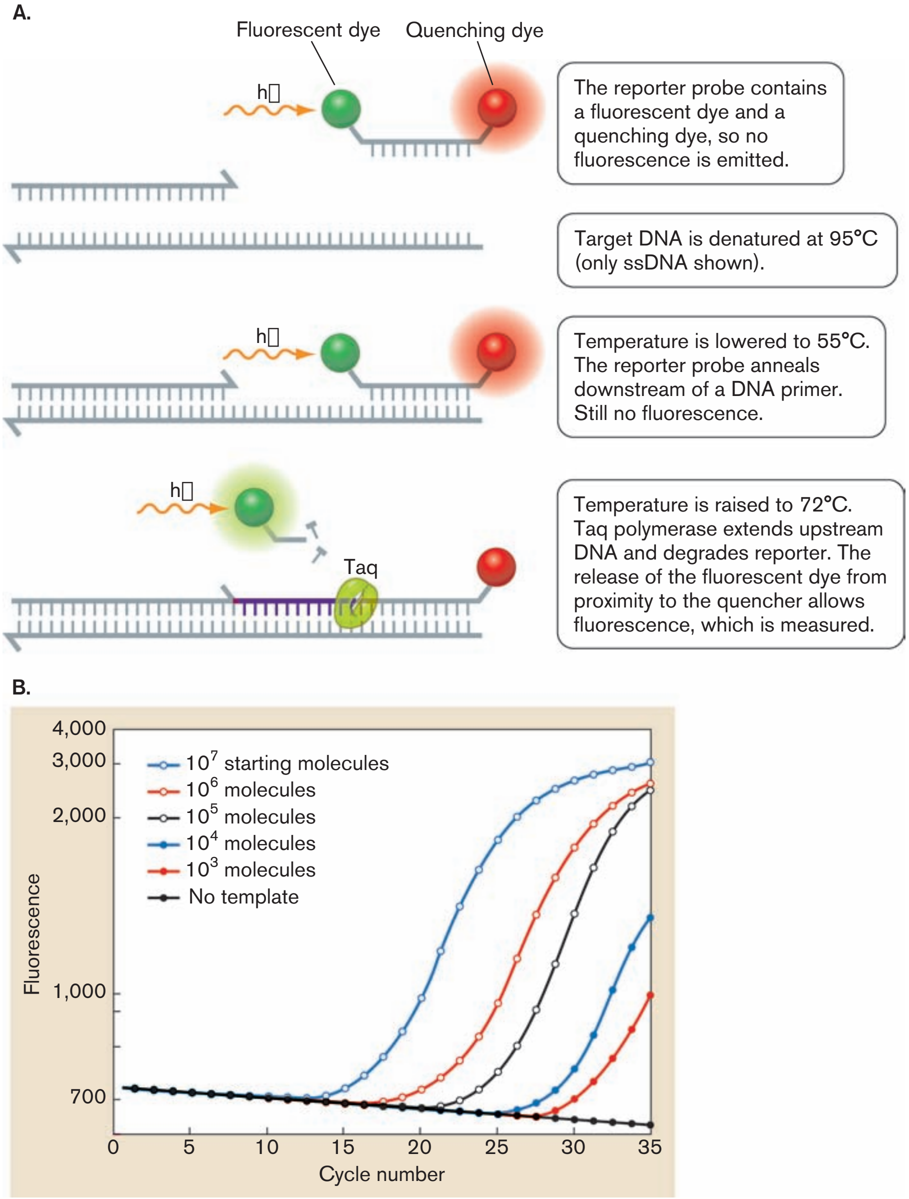
TO SUMMARIZE:

- **Automated yeast two-hybrid systems** expose interactions between many proteins in the cell, which can be used to build protein interaction maps.
- **Green fluorescent protein (GFP)** fused to a cell protein allows tracking of that protein's location or movement in a cell.
- **Multiplex PCR** is used to detect multiple organisms in complex environmental or food samples.
- **Real-time PCR** is used to quantitate specific DNA or RNA molecules present in cell extracts.

12.5 Biotechniques of Artificial Evolution

Previous chapters have discussed the principles that drive evolution of genomes in nature. But with all we know about manipulating DNA, can we speed the pro-

Figure 12.15 Real-time PCR. **A.** The Taq DNA polymerase extends an upstream primer and reaches the downstream reporter probe where a 5′-to-3′ exonuclease activity degrades the probe, releasing the fluorescent dye from the vicinity of the quencher so it can now fluoresce. **B.** Amplification plot of *Rhodococcus* with primer BPH4. Different numbers of DNA copies were used as follows: 10^7, 10^6, 10^5, 10^4, 10^3 copies per reaction mixture, and no-template control. The more DNA copies present in the initial reaction, the sooner (represented in numbers of cycles) fluorescence becomes detectable above background.



The reporter probe contains a fluorescent dye and a quenching dye, so no fluorescence is emitted.

Target DNA is denatured at 95°C (only ssDNA shown).

Temperature is lowered to 55°C. The reporter probe anneals downstream of a DNA primer. Still no fluorescence.

Temperature is raised to 72°C. Taq polymerase extends upstream DNA and degrades reporter. The release of the fluorescent dye from proximity to the quencher allows fluorescence, which is measured.

cess artificially in the laboratory to create a better enzyme? This section will describe how DNA sequences can be "shuffled" in vitro to evolve new genes not present in nature and how permutations of proteins can be expressed on phage surfaces so that the best proteins for a given purpose may be selected.

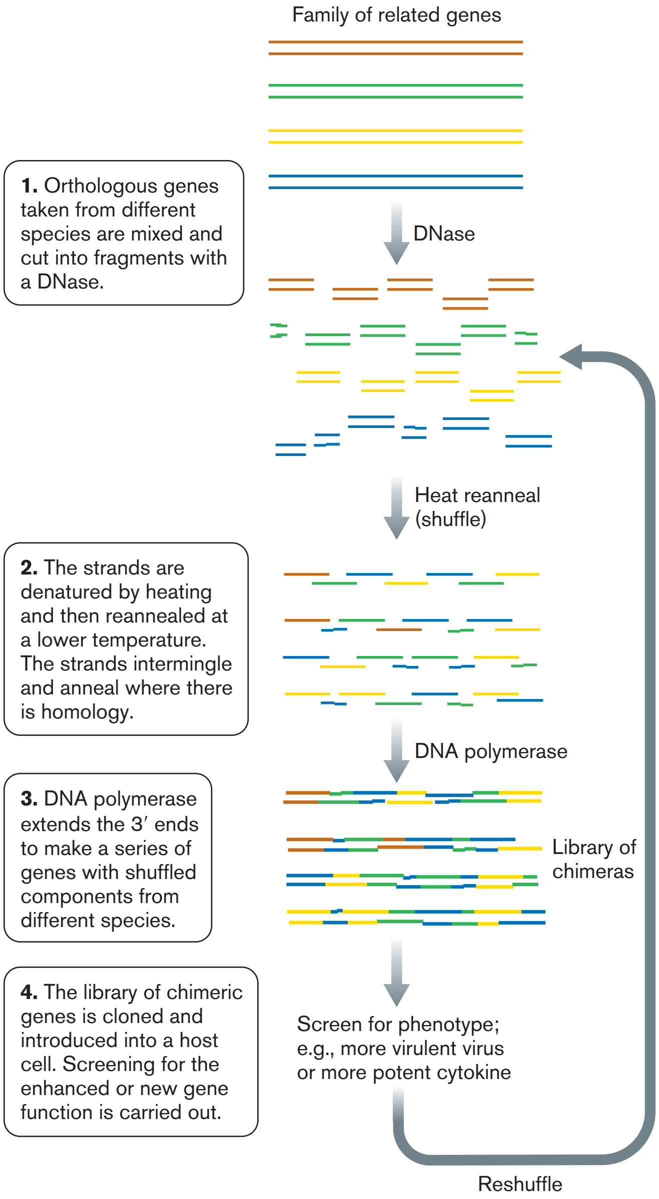
DNA Shuffling Creates In Vitro Evolution

Natural evolution takes centuries if not millennia to produce a new gene. We can now artificially evolve new genes in hours by a process called **DNA shuffling**. The basis of DNA shuffling is to mix and match fragments of different examples (or orthologs) of a given gene to make a new functional gene.

The DNA of each gene is digested with the enzyme DNase I into random fragments 10–50 bp in length. These fragments are then mixed and heated to separate the strands, then made to reanneal by lowering the temperature. This is done in the presence of a DNA polymerase. The separated strands of DNA pair up according to complementary base sequences in homologous DNA. The 3′ ends of overlapped fragments will "prime" the synthesis of DNA, for which the unpaired, opposite strand is used as a template, until the complete double-stranded DNA is restored. The fragments produced from the orthologs will reanneal randomly, but their order is ultimately based on overlapping homology. The DNA polymerase enzymes essentially fill in the gaps in the two strands. A simplified diagram of what is achieved in a typical experiment is shown in **Figure 12.16**.

DNA shuffling, therefore, is a method for quickly evolving new genes, operons, and even whole viruses for the acquisition of any desired properties. This has been used, for example, to generate new retroviruses that have altered tissue specificities. The process has also been used to create new cytokines. Cytokines are small immunomodulary peptides, produced by mammalian cells, that activate or inhibit functions of cells of the immune system (discussed in Chapters 23 and 24).

DNA shuffling of a family of more than 20 interferon-alpha genes (IFN-alpha, or IFN-α, is one type of cytokine) was used to derive variants that have increased antiviral and antiproliferative (inhibiting cell division) activities in mouse cells. Normally, the effects of a particular IFN are species specific, so there is minimal cross-species reactivity. For example, human IFN works on human cells, and mouse



1. Orthologous genes taken from different species are mixed and cut into fragments with a DNase.

2. The strands are denatured by heating and then reannealed at a lower temperature. The strands intermingle and anneal where there is homology.

3. DNA polymerase extends the 3′ ends to make a series of genes with shuffled components from different species.

4. The library of chimeric genes is cloned and introduced into a host cell. Screening for the enhanced or new gene function is carried out.

Figure 12.16 DNA shuffling: In vitro evolution. Starting with four genes from different sources, DNA shuffling can create a new gene with enhanced functions.

IFN works on mouse cells. In the shuffling experiment, the most active human IFN clone that was generated also worked on mouse cells 285,000-fold better than the original IFN. The resulting IFN is a chimeric protein derived from shuffling DNA fragments encoding parts of two or more natural IFNs. Sequence analysis of the human-mouse IFN chimeras showed that the sequence of the carboxyl-terminal residues at positions 121–125 is responsible for the unusually high activity in mouse cells. On the basis of functional experiments and modeling, the residues in this region are proposed to interact with the mouse IFN-alpha receptor.

The implications of this approach are profound. It will be of great interest to determine why the shuffled IFNs are so much more potent. Is it only due to enhanced receptor interactions or are there other reasons? DNA microarray analysis of cells that have been treated with these highly evolved cytokines may even reveal previously unrecognized target genes activated by cytokines.

In an experiment that shuffled retroviral genomes, six mouse leukemia viruses (MLVs) were recombined in a single round, giving a library of 5 million replicating recombinant viruses. Among them were completely new viruses capable of infecting Chinese hamster ovary cells, a feat none of the original MLVs could achieve. There is no doubt, however, that the shuffling procedure itself is potentially dangerous. Some of the recombinant viruses could well be lethal. Consequently, the potential misuse of this technology should not be dismissed. Nevertheless, many products developed from DNA-shuffling techniques will be beneficial for human life. These may include new cancer treatments, new vaccines, and new enzymes used in food making.

Directed Evolution through Phage Display Technology

Phage display, briefly described in Section 11.2, is a technique in which DNA sequences that encode peptides are cloned into a phage capsid gene. These peptides are then synthesized as part of the capsid protein and, upon phage assembly, are "displayed" on the surface of the phage (**Fig. 12.17**). The DNA sequences cloned can code for random peptides, antibodies cloned from natural sources, or libraries (collections) of mutant enzymes that one wishes to study.

The phage vectors used most often are the filamentous bacteriophages fd or M13 (discussed in Section 11.2). These phages infect *E. coli* strains containing the F plasmid (the phages attach to the sex pili) and replicate without killing the host cell. The phage particle consists of a single-stranded DNA molecule encapsulated in a long cylindrical capsid made up of five proteins. The major protein—the product of gene 8 (gp8)—is a small 5.2-kDa protein that forms the cylinder of the capsid. The other coat proteins (gp3, gp6, gp7, and gp9) cap the ends of the cylinder. The product of gene 3—present in three to five copies—is responsible for phage infectivity. Most phage display libraries have been created by cloning into gene 3.

Peptides displayed on filamentous phages have been used extensively to select peptide ligands or antibodies with high affinities for specific receptors or antigenic structures known as haptens (see Section 24.2). Recombinant phages that display high-affinity binding peptides are isolated from libraries in a process called biopanning (**Fig. 12.17B**). In biopanning, the target ligand—for example, a human virus attachment protein—is attached to a plastic plate or other support, and phages displaying random peptides are added. The phages that do not stick to the human virus protein are washed away. Those that do bind are subsequently released by adding free ligand (for example, human

2. The foreign gene is inserted between the sequences encoding the signal peptide and the mature coat protein g3p of the phage.

3. When the phage is assembled, the fusion protein is displayed on the phage surface.

1. A library of M13 coliphage, each displaying a different peptide sequence, is exposed to a plate coated with the target.

2. Unbound phage is washed away.

3. Specifically bound phage is eluted with an excess of a known ligand for the target or by lowering pH.

4. Eluted pool of phage is amplified, and the process is repeated for a total of 3–4 rounds.

Figure 12.17 Phage display technology. Phage display is a tool for the directed evolution of peptides. Discovering peptides that bind to specific target proteins is simplified by phage display techniques. **A.** Construction of phage display protein. **B.** Biopanning a library of M13 display phage for a peptide that specifically binds to a target molecule.

virus protein). This process is analogous to the way miners would pan rivers for gold. Several rounds of biopanning are required to obtain high-affinity clones. Following each round, the selected phages are enriched by repropagation in *E. coli*. Phage display was successfully used to identify high-affinity peptides that bind to attachment proteins of some eukaryotic viruses. These virus-binding peptides effectively block viral infection.

Phage display can also help retool entire enzymes. Natural enzymes, because they were selected by evolution to sustain life, do not necessarily have the stability or catalytic activity that would make them suitable for more harsh biotechnological applications. Enzymes from extremophiles can often be used in these applications, but one can't always find an appropriate enzyme from an extremophile.

Enzymes more suited to biotechnological applications have recently been engineered using whole-enzyme phage display. Libraries of phage enzyme mutants are generated using error-prone PCR (PCR done under conditions that will introduce occasional mutations). The process of selecting phages that display enzymes with enhanced catalytic activity is more demanding than simply selecting for protein variants with increased target affinity. In selecting for increased enzyme activity, one must look for an enzyme with a higher affinity for substrate and also an increase in the ability to catalyze a chemical reaction.

An experiment to prove that this in vitro evolution technique would work involved making a more effective *Bacillus cereus* metallo-beta-lactamase (**Fig. 12.18**). Beta-lactamase (β-lactamase) is an enzyme that cleaves the antibiotic penicillin. The selection process combined affinity chromatography with what is called catalytic elution. The protocol had three basic steps: (1) Phage-displayed

Zn^{2+}
Product

Figure 12.18 **Example of phage enzyme display.** Phage display was used to obtain a more active Zn^{2+}-binding protein. Randomly altered versions of the metalloenzyme beta-lactamase are displayed on phage. The Zn^{2+} from the prosthetic group is removed and the phage library added to plates containing bound substrate (penicillin). Only phage displaying high-affinity versions of the enzyme will attach. Returning Zn^{2+} will restore activity to versions of the enzymes that retained their catalytic activity. Cleavage of the substrate releases phages that display an active enzyme with high affinity. Those few phages can be repropagated to high numbers and repanned for further purification. *Source:* A. Fernandez-Gacio, et al. 2003. *Trends in Biotechnology* 21:408–414.

mutant enzymes were inactivated by extracting the catalytic metal ion; (2) the demetalated phage enzymes were adsorbed onto a support coated with penicillin, which bound the enzyme at the active site (only a phage with high affinity enzymes will attach); and (3) phages that displayed active enzymes on their capsids were selectively eluted by adding back the metal ion. The selective elution method works because adding back the metal cofactor reactivates the enzymes, which then convert the immobilized penicillin to a product. Because the enzyme has a lower affinity for the *product,* the phage enzyme is released and can be collected. The process eliminates mutant proteins that don't bind at all or that bind but have lost catalytic activity. This protocol succeeded in extracting several beta-lactamase enzymes with higher enzyme activity from a library of 5×10^6 clones generated by error-prone PCR. The purpose of this exercise was not to make a more active beta-lactamase, but to offer proof that in vitro evolution of an enzyme using phage display was possible.

THOUGHT QUESTION 12.7 You have just employed phage display technology to select for a protein that tightly binds and blocks the eukaryotic cell receptor targeted by anthrax toxin. When this receptor is blocked, the toxin cannot get into the target cell. You suspect that the protein may be a useful treatment for anthrax. How would you recover the gene following phage display and then express and purify the protein product?

TO SUMMARIZE:

- **DNA shuffling**—shuffling of DNA fragments made from orthologous genes (genes encoding similar proteins from different species)—can be used in vitro to create new genes whose protein products have new properties.
- **Phage display** is another form of in vitro evolution, where DNA sequences encoding random peptides are cloned into phage capsid protein genes. Phage particles displaying peptides with a desired binding property are pulled from the general phage population by biopanning.

12.6 Applied Microbial Biotechnology

It is remarkable how many useful products can be imagined and are being developed using the tools of biotechnology. You will be surprised to learn that bananas, as one example, are being engineered as edible vaccine delivery systems. In another development, we are finding that vaccines can be delivered not only by injecting a protein but by simply injecting DNA, which expresses the antigenic protein. We even have technology whereby a genetically engineered virus can repair a human genetic defect. These are all remarkable additions to our scientific toolbox and are already helping improve human life.

A Simple Bacterial Gene Saves Crops from Insect Devastation

Protecting crops such as corn and cotton from hungry insects is an age-old problem faced by farmers. Insects such as moths or beetles can cause widespread damage to a crop in a short period of time. In the nineteenth and twentieth centuries, chemical pesticides were widely used to kill these pests. While generally effective, chemical pesticides can contaminate soil and groundwater and can impact human health. But in 1911, a microorganism was discovered that led to a new way of protecting crops. The organism was *Bacillus thuringiensis,* a close relative of *Bacillus anthracis.*

Bacillus thuringiensis sporulates on the surfaces of plants. However, in addition to the spore, the sporulat-

Figure 12.19 The insecticidal bacterium *Bacillus thuringiensis*. A. A cell of *B. thuringiensis* in the process of sporulation, during which insecticidal proteins are produced and crystallize. **B.** Parasporal crystals from *B. thuringiensis* subsp. Kurstaki. Four major crystal proteins are formed (Cry1aa, Cry1ab, Cry1ac, and Cry2aa). They are used to control caterpillar pests. **C.** The parasporal crystal of *B. thuringiensis* subsp. israelensis contains four insecticidal proteins and is used to control mosquito and blackfly larvae.

ing cell makes a separate parasporal body that cradles the spore (**Fig. 12.19**). The parasporal body contains crystallized proteins that are toxic to insects feeding on the plant. A single subspecies of *B. thuringiensis* can produce multiple insecticidal proteins. Different subspecies (there are 34 of them) can produce different combinations of these proteins. After the insect or insect larva ingests the insecticidal protein crystals, the alkaline environment in the insect midgut dissolves the crystals, and insect proteases inadvertently activate the proteins. Activated insecticidal proteins insert into the membrane of the midgut cells and form pores that lead to loss of membrane potential, cell lysis, and death of the insect through starvation. Farmers have taken to spreading *B. thuringiensis* directly on their crops, where even dead cells are effective.

B. thuringiensis is generally considered a highly beneficial pesticide with few downsides. Unlike most insecticides, *B. thuringiensis* insecticides do not have a broad spectrum of activity, so they do not kill animals or beneficial insects—including the natural enemies of harmful insects (predators and parasites) as well as beneficial pollinators, such as honeybees. Therefore, *B. thuringiensis* integrates well with other natural crop controls. Perhaps the major advantage is that *B. thuringiensis* is essentially nontoxic to people, pets, and wildlife, so it is safe to use on food crops or in other sensitive sites where chemical pesticides can cause adverse effects.

While spreading *B. thuringiensis* on crops is helpful, an even more effective means of delivering the toxin has been developed. The genes encoding insecticidal proteins have been spliced right into the genomes of certain plants, such as cotton and corn. The gene is placed under the control of a plant promoter, so that the transgenic plant makes its own insecticide. **Table 12.1** presents the timeline of events leading up to this technological advance. As of 2003, 72% of the cotton, and 40% of the corn planted in the United States contain *B. thuringiensis* genes.

Although there have been no reports of adverse effects on humans, these proteins could cause allergic reactions in some people if they were ingested (much like peanuts, citrus, or shellfish). As a result of this concern, the use of transgenic corn expressing insecticidal proteins has been limited to cattle feed. In the bovine digestive tract, the protein is thoroughly digested to individual amino acids; thus, the protein does not show up in meat products produced from cattle and cannot cause an allergic reaction.

THOUGHT QUESTION 12.8 Would insect resistance to an insecticidal protein be a concern when developing a transgenic plant? Why? How would you design a transgenic plant to limit the possibility of insects developing resistance?

Table 12.1 Timeline in the development of *B. thuringiensis* as an insecticide.

Over a century after its discovery, *B. thuringiensis* is a widely used natural insecticide.

1901	Ishiwata Shigetane discovers a disease of silkworms caused by a previously undescribed bacterium.
1911	E. Berliner names the organism causing the silkworm disease *Bacillus thuringiensis (Bt)*.
1938	The first commercial products that contain *Bt* are marketed in France.
1954	T. Angus shows that crystalline proteins are responsible for the insecticidal action of *Bt*.
1983	Scientists demonstrate that plants can be genetically engineered.
1987	Plants engineered to contain the *Bt* gene are demonstrated to be pest resistant.
1996	*Bt* cotton reaches the U.S. market.
2001	69% of the cotton and 26% of the corn planted in the United States contain *Bt* genes.
2003	72% of cotton and 40% of corn contain *Bt* genes.

Special Topic 12.1 DNA Vaccines

Since the time of Edward Jenner, vaccines used to prevent microbial diseases have consisted of incapacitated microbes or inactivated microbial proteins (for example, inactivated toxins). These cellular or protein vaccines stimulate the immune system to make antibodies and immune cells that destroy the invader (see Chapters 23 and 24). Now, a new type of vaccine is being tested. It involves injecting DNA encoding bacterial proteins into humans.

To make the vaccine, DNA encoding a protein is isolated from an infectious organism such as a virus or bacterium and is altered to place eukaryotic promoters in front of the gene or genes. The modified DNA is then integrated into a plasmid vector. Quite amazingly, if this plasmid DNA is injected into a human cell, the injected DNA's genes will be expressed inside that cell and produce the microbial protein. At present, the muscle cell is the most common target for injection. The presence of these foreign proteins inside human cells causes the immune system to launch a powerful protective immune response against the microbial protein. This immune response will also protect against the live infectious organism.

But why make a DNA vaccine when other, traditional vaccines already work? One problem is that live, attenuated bacteria, even with minimal disease-producing potential, can still cause illness and in some cases serious disease. Selecting and expressing only one or two proteins from an infecting organism (provided those proteins are not toxins) enables us to avoid the risk of disease altogether. So why not just administer the protein directly? While this does work for many vaccines, the best way to generate a potent immune response is if the protein is actively synthesized within a host cell. The reason for this is that a small amount of any foreign protein synthesized in a host cell will be degraded and the pieces presented on the surface of that cell. Specialized immune cells surveying the body see these proteins, recognize that they are foreign, and initiate an immune reaction. This process is akin to what occurs during natural infection (discussed in Chapter 24). In contrast, proteins simply injected into a person are not processed the same way and may not generate a response as complete or long-lasting. **Figure 1** illustrates how a DNA vaccine will protect against infection with herpes simplex virus 2 (HSV-2). **Figure 1A** shows a newborn with an HSV-2 infection. The graph in **Figure 1B** shows the results of a mouse model examining HSV-2 infection and the protective effect of a DNA vaccine.

How is the DNA vaccine delivered? A modified air pistol called a gene gun can blast DNA-coated beads into muscle. A more intriguing delivery system places the recombinant DNA vaccine vector into attenuated strains of intracellular bacteria like *Salmonella* and lets the microorganism deliver the plasmid into cells (**Fig. 1C**). For *Salmonella*, this system will specifically deliver vaccine to the intestinal mucosa, where the salmonellae invade. Production of vaccine proteins in these host cells yields a powerful immune response.

We should stress that DNA vaccines are still experimental, although their future looks promising. For example, one report has used the herpes simplex virus type 2 glycoprotein D gene to immunize mice against genital herpes. Future application of this type of vaccine to numerous human diseases would eliminate considerable pain and suffering, both physical and emotional.

Vaccine Delivery Can Be Accomplished with Fruits and Vegetables

Starting with the war against smallpox in the late 1700s, vaccines have been used to inoculate humans against many terrible diseases (see Chapters 25 and 27). However, the cost of producing them is enormous, and the price, of course, is passed on to those who are vaccinated or to governments that conduct vaccination programs. This becomes problematic for the world's impoverished nations, and as a result, 20% of the world's infants do not receive proper vaccination, resulting in over 2 million preventable deaths annually.

An amazing solution to this problem is the invention of edible vaccines. In these vaccines, the gene encoding the vaccine protein is inserted into the genome of a fruit or vegetable native to the country where vaccination is desired. As in the case of transgenic plants encoding *Bt* toxins, the vaccine gene must be placed under the control of a well-expressed plant promoter. Their presence in var-

Figure 1 **DNA vaccines.** Directly injecting DNA that encodes a virulence protein into an animal can protect against infection. **A.** View of a newborn infected with HSV-2. **B.** Survival data for mice vaccinated with DNA encoding HSV-2 glycoprotein D show that vaccinated mice are protected from a lethal dose of HSV-2. Control mice ($n = 30$) were vaccinated with plasmid vector (no HSV gene). Test mice ($n = 40$) were vaccinated with plasmid containing the gene for HSV-2 glycoprotein D. Three weeks later, the mice were infected with a lethal dose of HSV-2. Survival was followed over 14 days. **C.** Example of bacterial vaccine delivery.

ious poor countries makes bananas, rice, corn, wheat, and soy the best choices for edible vaccine development. The agricultural vaccine machines can be grown and simply distributed to the population, without the need to handle needles or subject young patients to the pain of injection. Examples of edible vaccines under study include potatoes with hepatitis B surface antigen, *E. coli* labile toxin, and even human papillomavirus.

Actually, transgenic plants expressing bacterial or viral virulence proteins can be used in two ways: They can be direct vaccine delivery systems, as through edible fruits and vegetables (such as potatoes, tomatoes, and corn); or, as with transgenic tobacco crops, they can be a cheap way to grow large amounts of the vaccine protein that can be extracted later and used in more conventional ways. Other plants used to make vaccines are cited in **Table 12.2**.

Although this technology seems an ideal solution to vaccination, concerns persist. A key issue is that any release of genetically engineered microbes into the envi-

Table 12.2 Potential vaccine antigens expressed in plants.

Transgenic plants expressing bacterial or viral virulence proteins can be used as direct vaccine delivery systems (e.g., potatoes, tomatoes, corn) or as an inexpensive way to grow large amounts of the vaccine protein (tobacco crops).

Source of the protein	Vaccine protein or peptide	Plant
Enterotoxigenic *E. coli*	Heat-labile enterotoxin B subunit (LT-B)	Tobacco, Potato, Tobacco chloroplast, Maize kernels
Vibrio cholerae	Cholera toxin B subunit (CT-B)	Potato, Tobacco chloroplast
Hepatitis B virus	Hepatitis B surface antigen	Tobacco, Potato

Clostridium tetani	TetC	Tobacco chloroplast

ronment introduces the transgene into the gene pool. This irreversible introduction into the environment distinguishes the release of genetically modified organisms (GMOs) from many other technologies that can be reversed.

Viruses Can Be Used for Gene Therapy

A long-standing challenge for molecular biologists is to find a way to correct genetic mutations in humans. Many diseases, such as cystic fibrosis or Tay-Sachs disease, are the result of mutations in single genes. Implanting a copy of the correct gene in an embryo or, in some cases, a fully developed human would repair the defect and prevent development of disease. Cystic fibrosis, for example, is the result of a defect in a chloride channel gene (Cystic Fibrosis Transmembrane Regulator, CFTR) in the lungs. Introducing a normal copy of the gene into lung cells would prevent the disease. This type of treatment is called gene therapy.

But how do you get good genes into cells? One way is by cloning a copy of the gene into a viral vector. When that virus infects the cell, the good gene goes with it. Of course, not just any virus can serve as a vector. The virus DNA chosen must be one that enters the cell nucleus. For this reason, retroviruses are often used, since they efficiently enter the nucleus. The ideal vector would also integrate into the DNA of the nucleus, making the replacement permanent. However, the insertion process, which appears random, could mutate other genes. Another obvious requirement is that the virus be stripped of its disease potential.

Adenovirus and adeno-associated virus are vectors that have been employed in several gene therapy trials (**Fig. 12.20**). Although they don't have all the ideal properties just mentioned, they do have several others that make them attractive:

- Adenoviruses are double-stranded genomes, so cloning is easy.
- Adeno-associated viruses having a linear, single strand genome, can infect many different cell types and enter the nucleus.
- They don't cause severe disease.
- They can insert into nondividing cells.

These viruses have drawbacks, however, some of which may be corrected by modifying the adenovirus genome. One problem is that many adenovirus vectors are mutated in genes that, after infection, might make cells cancerous or lead to cell death. Another major problem is that an adenovirus does not permanently integrate its DNA into cells. As a result, the therapeutic gene could be lost when it disintegrates because the genetically altered virus will not replicate. To circumvent these difficulties, Mark Kay and his colleagues at Stanford University used two modified adenoviruses to deliver the gene for factor

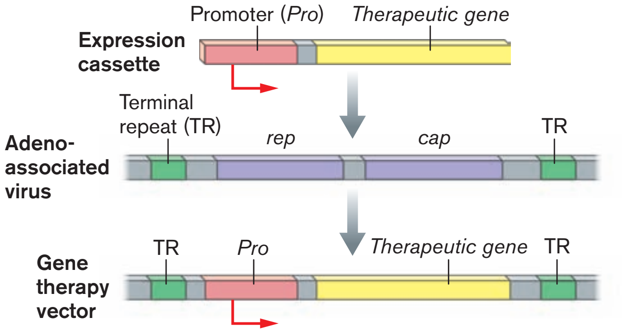

Figure 12.20 Basic construction of a gene therapy vector. The adeno-associated virus is a small linear single-stranded virus consisting of two genomic regions: *rep*, encoding proteins involved in replication and integration; and *cap*, encoding viral structural proteins. These regions are flanked on either side by a terminal repeat (TR). Reconstruction of the virus requires replacement of the *rep-cap* sequence with an expression cassette carrying a promoter (Pro) and the therapeutic gene. Because the genes required for replication were removed, replication of the vector virus requires cotransfection of the host cell with a helper adenovirus. The helper virus supplies the missing functions.

IX into mouse liver cells. People with a defective factor IX gene suffer from type B hemophilia. The gene delivery system resulted in permanent integration of the gene into the mouse cell genome while avoiding the integration of potentially cancerous adenovirus genes.

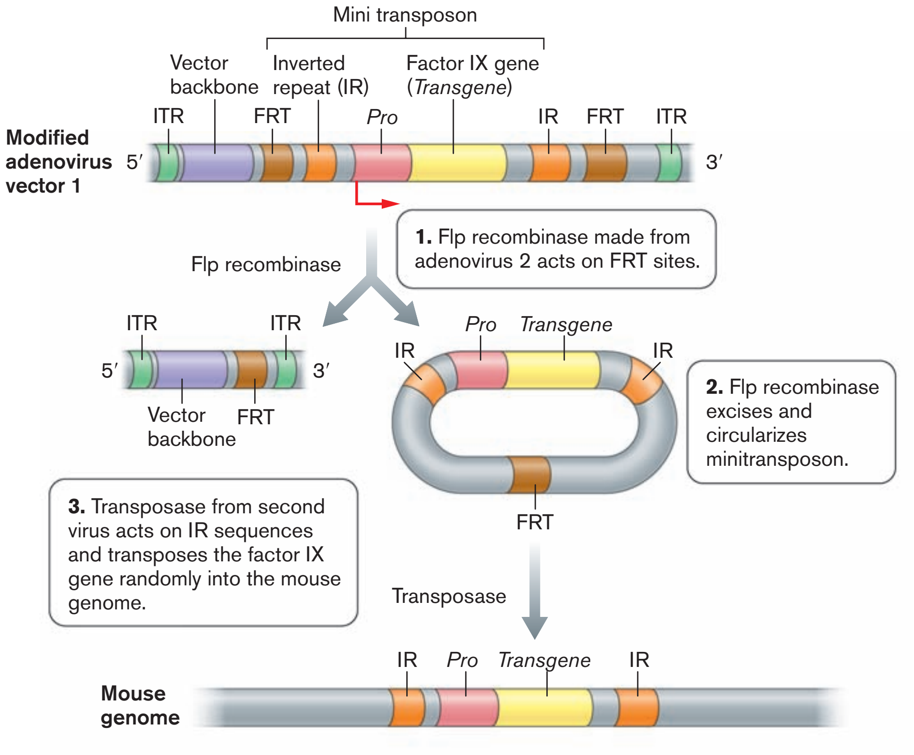
The strategy they used is illustrated in **Figure 12.21**. One adenovirus was genetically engineered to contain the normal factor IX gene. The integrated cassette was flanked first by inverted repeat DNA sequences that are targets for a specific transposase and second by sequences (called FRT) recognized by a recombinase called Flp (vector 1). They essentially constructed a minitransposon cassette that contained the therapeutic gene (factor IX). The second adenovirus was a helper virus that contained the transposase gene and the yeast gene for Flp recombinase (vector 2, not shown in figure). Neither adenovirus vector could, by itself, integrate into the genome. The goal was to have both viruses infect the same cell. The Flp recombinase made from vector 2 would excise the factor IX cassette from Vector 1 and circularize it to make a DNA molecule devoid of adenovirus genes (steps 1 and 2). The transposase made from vector 2, which acts only on circular molecules, would then catalyze transposition of the factor IX cassette from the circular molecule into the mouse genome (step 3). (See Chapter 9 for mechanisms of transposition and recombination.) When the scientists injected the two adenovirus vectors into mouse livers, they wound up with liver cells containing the factor IX gene integrated into the mammalian genome, exactly as planned.

Many other ideas to deliver genes have been developed and are being tested. For example, DNA sequences that target DNA to specific cellular locations in the cell (for example, nucleus and mitochondria) are attached to the gene payload. DNA is administered either by gene gun or by electroporation (see Section 9.2) to specific organs. The presence of the targeting DNA sequence ensures that the payload gene goes to the correct location.

Another amazing development is the use of modified human immunodeficiency viruses (HIV), a lentivirus, as gene delivery systems. The vector does not carry genes it needs to replicate, but will reverse transcribe its RNA engineered to encode therapeutic products, and integrate the cDNA into the genome of the host cell. The power of these vectors is that they can integrate into the genome of dividing or non-dividing cells. They are being developed as gene therapies for metabolic diseases, viral infections (HIV itself), hemophilia, cancer, and a host of other conditions.

TO SUMMARIZE:

- **Genes encoding insecticidal proteins** from *Bacillus thuringienesis* have been engineered into plant genomes to protect crops from insect devastation.
- **Proteins from pathogenic bacteria and viruses** cloned into fruits and vegetables may provide a cost-effective means to vaccinate large populations.
- **Genetically engineered viruses** are being tested as gene therapy vehicles to deliver DNA to correct inherited diseases in humans.



1. Flp recombinase made from adenovirus 2 acts on FRT sites.

2. Flp recombinase excises and circularizes minitransposon.

3. Transposase from second virus acts on IR sequences and transposes the factor IX gene randomly into the mouse genome.

Figure 12.21 Use of an adenovirus gene delivery system. Overview of a strategy to transpose the factor IX gene into the genome of mouse liver cells. The adenovirus used in this case is a double-stranded DNA virus. *Source*: From Yant, et al. 2002. *Nature Biotechnology* 20:999–1004.

Concluding Thoughts

This chapter has discussed only some of the available molecular techniques and developing technologies used to probe biological processes and manipulate them to our benefit. Keep them in mind as we progress deeper into the physiology of microbial growth and the mechanisms of microbial pathogenesis. Many of the approaches described here were used to generate the knowledge presented in later chapters.

CHAPTER REVIEW

Review Questions

1. What are important considerations when designing a mutant selection strategy?
2. Once the DNA sequence of a gene is known, how does one gain clues as to possible function of the gene product?
3. What are the key features of reporter genes used to measure transcriptional control? Translational control?
4. What is the difference between a Northern blot and a Southern blot?
5. Explain the principle of a Western blot.
6. What techniques are used to determine if a protein binds to a DNA sequence?
7. Explain the important points for constructing a plasmid that makes His_6-tagged protein.
8. Explain how one can determine the start site of a transcript.
9. How can protein-protein interactions be determined in vitro?
10. Describe two-hybrid analysis. What are bait and prey proteins?
11. How can the cellular location of a protein be tracked in vivo?
12. Explain how PCR can be used in a single reaction to identify which of two species of pathogenic bacteria are present in a food sample.
13. Discuss how gene shuffling or phage display might be used to create a more toxic toxin. What are the ramifications of these technologies?
14. Discuss some ways biotechnology has helped the agricultural industry. How has the field impacted vaccine delivery or our approaches to the treatment of metabolic diseases in humans?

Part 3

Metabolism and Biochemistry

AN INTERVIEW WITH

CAROLINE HARWOOD: BACTERIAL METABOLISM DEGRADES POLLUTANTS AND PRODUCES HYDROGEN

Caroline Harwood taught microbiology from 1988 to 2004 as a professor at the University of Iowa and since 2005 at the University of Washington. Harwood showed how soil bacteria catabolize some of nature's toughest compounds, such as lignin components, as well as related compounds that pollute our environment. She led the project to sequence the genome of *Rhodopseudomonas palustris*, a gram-negative purple bacterium capable of photosynthesis, heterotrophy, and hydrogen production. The diverse metabolism of *R. palustris* may be manipulated for bioremediation and production of hydrogen fuel. Harwood serves as editor for the journal *Applied and Environmental Microbiology*.

Why did you decide to make a career in microbiology?

I was interested in science since I was very young, but there were very few examples of women scientists at that time. I was fortunate to have been given excellent educational opportunities by my family. After college I had a chance to participate in an intensive summer course called "Microbial Diversity," given at the Marine Biological Laboratory at Woods Hole, Massachusetts. This was my first real exposure to bacteria and to microbiology, and I became captivated by the metabolic diversity of bacteria. Years later I took a turn as the director of this same course at Woods Hole.

Why did you study aromatic metabolism? What is significant about this process in microbes?

Aromatic compounds first caught my attention when I took organic chemistry. It was then that I became interested in the unique chemical properties of the benzene ring. I was also aware that a huge proportion of plant biomass—specifically the lignin component of wood—is a polymer of aromatic compounds and that these compounds must be degraded by living organisms in order for Earth's carbon cycle to operate. And of course, many environmental pollutants have benzene rings as part of their structure.

In graduate school, I found that biochemistry and microbiology textbooks included very little mention of aromatic compound degradation. Some might have concluded from this that the topic of aromatic compound degradation was not important, but I realized that bacteria and fungi can't read and so they didn't know this. In fact, aromatic compounds serve as the principal source of carbon and energy for many kinds of soil microbes. I could see an opportunity for discovery, so I went to do postdoctoral research with L. Nicholas Ornston at Yale, a world expert on bacterial degradation of aromatic compounds.

Courtesy of Caroline Harwood

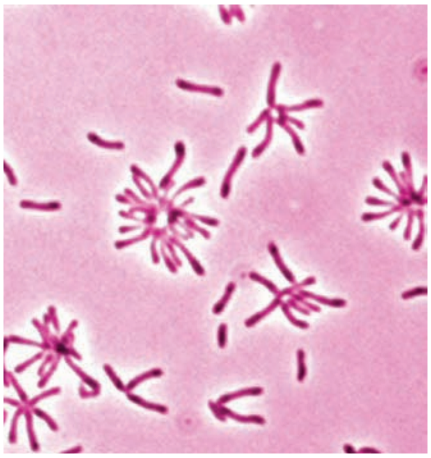
Caroline Harwood, professor of microbiology at the University of Washington.

Why do you study the soil bacterium *Rhodopseudomonas palustris*?

At the time I was a postdoctoral fellow, it was generally believed that only aerobic microbes could degrade aromatic compounds because one of the principal degradative enzymes inserts oxygen into the aromatic ring. But most soil microbes grow anaerobically, without oxygen. One day at lunch I wondered if aromatic compounds might also be degraded under anaerobic conditions. My postdoctoral advisor said yes, they could, but that not much was known. After lunch I went to the library and found that a few papers had been written on anaerobic aromatic degradation by a photosynthetic bacterium named *Rhodopseudomonas palustris*. At about that time, I moved to Cornell University and found a biochemistry professor, Jane Gibson, who showed me how to grow *R. palustris*. We collaborated on studies to work out the metabolic pathway for anaerobic benzoate degradation.

What did you find was unusual about *R. palustris* metabolism?

At first, we worked with *R. palustris* because it served as an excellent model organism to study anaerobic degradation of aromatic compounds. But when we saw its genome sequence, we realized that *R. palustris* was even more metabolically versatile than we had thought. It has genes for four dif-



Courtesy of Caroline Harwood

***Rhodopseudomonas palustris* bacteria.** The bacteria grow in rosette-shaped clusters (cell length, 2–4 μm; LM).

ferent aerobic benzene ring cleavage pathways in addition to the anaerobic pathway that we had been studying. It has five different sets of "light-harvesting" genes, enabling photosynthesis at low levels of light. Finally, from the genome sequence, we realized that *R. palustris* encodes three different nitrogenase enzymes for converting nitrogen gas to ammonia and hydrogen. *Rhodopseudomonas palustris* is a remarkable microbe that can grow using all the major modes of energy metabolism that exist on Earth.

Why does *R. palustris* produce hydrogen gas? What are the potential applications of biogenic hydrogen for energy?

R. palustris produces hydrogen as an unintended product of nitrogen fixation. For humans, hydrogen is a clean-burning form of energy that can be easily converted to electricity in hydrogen fuel cells. It can be used as automobile fuel and as fuel for any electricity-driven process. At present, the major commercial routes for hydrogen production depend on fossil fuels and petroleum products. Biogenic hydrogen, derived from microbes, does not depend on these dwindling resources, but instead depends on light from the sun and biomass, a renewable resource.

Would you describe your experience working with graduate students?

I would be nothing without the graduate students that I've had the privilege of working with. The best graduate students make one see things in new and different ways and will drag you into new areas of inquiry. Through the process of mentoring graduate students and helping them to become more critical thinkers and careful experimenters, I have become a better scientist myself. Working with graduate students is one of the greatest joys of my job.

As an educator, how has your research impacted your teaching?

I try to communicate the thrill of the hunt in research and to make students realize that research is a creative process and a social process that depends on teamwork among laboratory workers. The arena that I favor for teaching undergraduate students is the teaching laboratory. It has a more relaxed pace, and teaching laboratories give me a chance to get to know students on an individual basis, to see their personalities and how they interact with each other.

What have you learned through editing a research journal?

As a journal editor I have learned that people react to constructive criticisms from peer reviewers in surprisingly varied ways. Most people are gracious and respond by trying to improve their papers and their work; these investigators have been good role models for me. But others have taught me what not to do. I also have a better appreciation for what it takes to make an original and significant contribution to the scientific literature.

What do you think are the most exciting areas for students entering microbiology today?

Advances in genome sequencing and in imaging make possible sophisticated studies of interactions between bacteria and viruses and their human or animal hosts. In the near future, it will be possible to study the activities of single bacterial cells and of complex bacterial communities.

How does your family relate to your career in microbiology?

I grew up as one of six children and part of a large extended family, and I learned the value of family support networks. My experiences and attitudes about large families apply to my interactions with the members of my laboratory. The line between family and work is sometimes a bit blurred in my case because my husband is also a microbiology professor. It has been a help to have a spouse who completely understands my job and my passion.

What advice do you have for today's students?

Pursue what interests you. Follow your passions. This is the most certain pathway to success and happiness.

Chapter 13

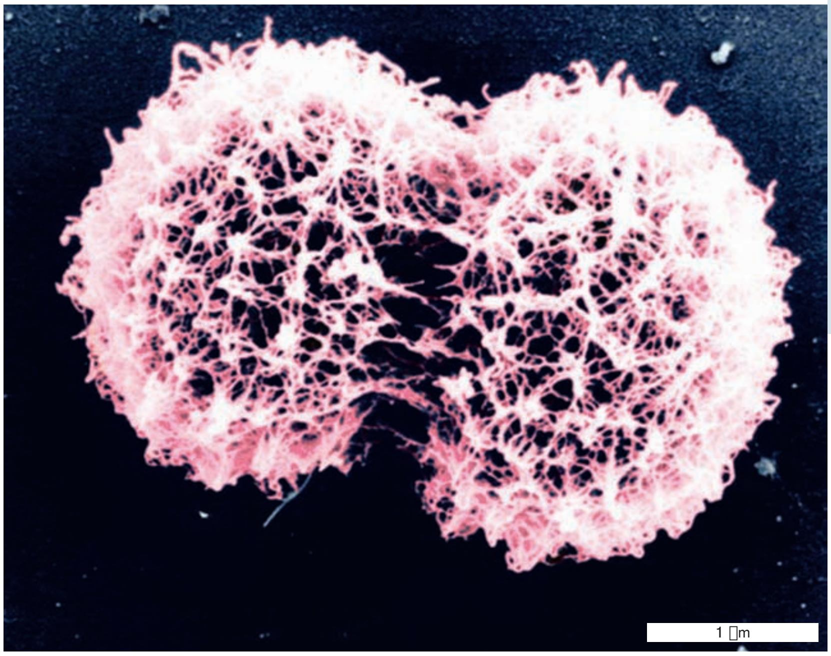
Energetics and Catabolism

13.1 Energy and Entropy: Building the Cell
13.2 Energy and Entropy in Biochemical Reactions
13.3 Energy Carriers and Electron Transfer
13.4 Catabolism: The Microbial Buffet
13.5 Glucose Breakdown and Fermentation
13.6 The Tricarboxylic Acid (TCA) Cycle
13.7 Aromatic Catabolism

To grow, all cells need energy. Energy comes from chemical reactions that transfer electrons within a molecule or between two molecules. For microbes, the variety of such reactions is limitless; virtually any kind of molecule in our biosphere can yield energy for some kind of microbe, from hydrogen gas to chlorinated pollutants.

To capture and use energy, microbes must regulate their energy-yielding reactions and couple them to biosynthesis, using enzymes. Enzymes direct the transfer of energy onto carriers such as ATP. ATP acts as an energy currency that is generated by energy-yielding reactions and spent by reactions that build the cell.

A major class of energy-yielding reactions used by microbes involves the breakdown of complex molecules into smaller ones, a process called catabolism. Microbes catabolize chemicals within our own digestive tracts and all around us, in the soil and water. Collectively, microbes show astonishing potential to catabolize nearly any organic substance, including petroleum, hard woods, and synthetic polymers. The products of their catabolism range from ethanol to the generation of electricity in fuel cells.



A new species of bacteria was discovered to catabolize naphthalene, a complex aromatic molecule that is a common environmental pollutant from creosote-treated wood. The bacterium, called strain CJ2, is a beta-proteobacterium closely related to *Polaromonas vacuolata*. Its rough surface texture consists of extracellular polysaccharides.
Source: Che O. Jeon, et al. 2003. *Proceedings of the National Academy of Sciences USA* 100:13591.

All growing microbes gain energy from their surroundings. One place to see microbial energetics at work is in composting, a process by which we dispose of food and yard waste. Composting is done by individuals or at community composting centers (**Fig. 13.1**). The U.S. Army uses microbial composting to remediate sediments containing explosives such as trinitrotoluene (TNT). In composting, nitrogen-rich manure or food waste is mixed with cellulose-rich yard waste or newspaper. The mixed compost materials are aerated to provide oxygen for the oxidative breakdown of food by bacteria and fungi. The breakdown of complex molecules, such as cellulose, to smaller molecules, such as carbon dioxide, is called **catabolism**. Catabolism provides energy for **anabolism**, the reactions that build microbial cells. But some of the energy is always released as heat. In a compost pile, heat is produced faster than it dissipates, and the temperature typically rises to 60°C. As temperature rises, thermophilic species of *Bacillus* and *Thermus* take over. The thermophiles metabolize even faster, and the heat they release maintains the compost at a high temperature that favors their growth. The heat of compost can actually be used by other organisms, such as certain nesting birds that use compost to warm their eggs.

In Part III of this book we explore microbial metabolism and biochemistry. **Chapter 13** explains how microbes gain energy from chemical reactions, based on the transfer of electrons between molecules. This chapter emphasizes catabolism, the breakdown of complex organic molecules with transfer of their electrons to an electron acceptor. Inorganic reactions such as metal oxidation can also yield energy for microbes, as shown in Chapter 14. Chapter 14 explores electron transport in greater depth, through pathways of organic respiration (oxidation of organic nutrients), lithotrophy (oxidation of *in*organic nutrients), and photosynthesis. The energy from all these pathways is used to build cells by pathways of anabolism (biosynthesis), the focus of Chapter 15. Finally, Chapter 16 explores commercial applications of microbial metabolism to produce food and beverages as well as industrial products and pharmaceuticals.

The major kinds of energy-yielding reactions discussed in Chapters 13 and 14 are summarized in **Table 13.1**. Chapter 13 emphasizes reactions of organic compounds donating electrons to yield energy, known as **organotrophy**. For each class of metabolism, Table 13.1 shows only a few examples. Microbes use many energy-yielding reactions unavailable to animals or plants. For example, *Pseudomonas* and related species of soil bacteria can gain energy by catabolizing camphor, benzene, or chlorinated aromatic pollutants. On the other hand, the archaeon *Pyrodictium occultum* gains energy by oxidizing hydrogen gas with sulfur, an inorganic reaction.

NOTE: **Organotrophs** use preformed organic compounds to yield energy. Most organotrophs are also **heterotrophs**, organisms that use preformed organic compounds for biosynthesis. Introductory texts often equate heterotrophy with organotrophy, although in rare cases an organism shows one but not the other.

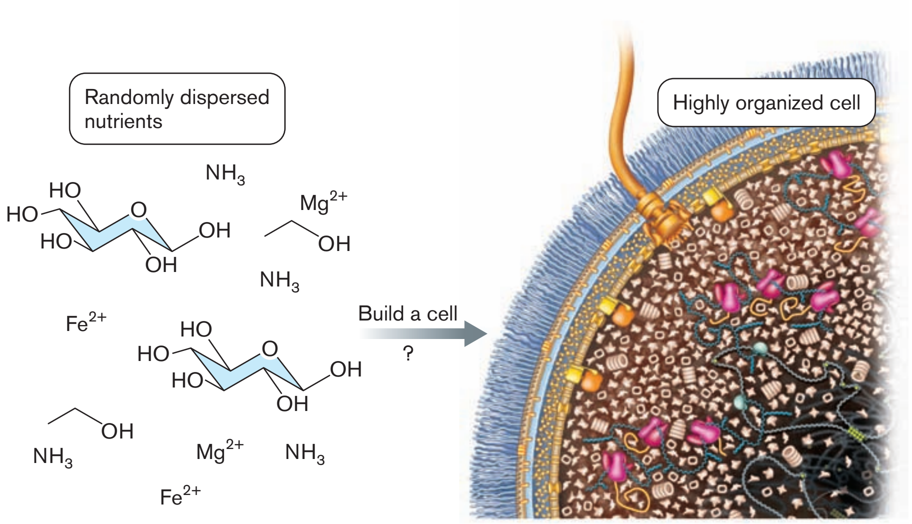
Figure 13.2 **Living organisms acquire energy to build cells.** Early twentieth-century biologists wondered how the "spontaneous" growth of cells could obey the laws of conservation of energy and increase of entropy.



13.1 Energy and Entropy: Building a Cell

Every form of life, from a composting microbe to a human body, uses energy. **Energy** is the ability to do work, such as flagellar propulsion or the growth of a cell. Energy is used to organize proteins and to maintain ion gradients across the cell membrane. Yet the laws of thermodynamics tell us that systems tend to become less ordered and that **entropy**, the disorder, or randomness, of the universe, always increases. So how do cells assemble simple, disordered molecules into complex, ordered forms (**Fig. 13.2**)? How does life build order out of disorder?

Microbes Use Energy to Build Order

To explain how microbes build order requires a closer look at the thermodynamic relationship between energy and entropy. Gaining energy enables organisms to grow, thus increasing their structural order. As order increases, the cell is said to decrease in entropy, or disorder. But the decrease in entropy is local to the cell, and temporary. Ultimately, the cell's energy must be spent as heat, which radiates away, causing entropy to increase. In other words, the local, temporary gain of energy enables a cell to grow. Continued growth requires continual gain of energy and continual radiation of heat.

What is true of the cell holds as well for the entire biosphere. In Earth's biosphere, the total metabolism of all life must ultimately dissipate most energy as heat. Biological heat production is not always obvious because soil and water provide a tremendous heat sink. But overall, Earth's biosphere behaves as a giant thermal reactor (**Fig. 13.3**). As solar radiation reaches Earth, a small fraction is captured by photosynthetic microbes and plants. The fraction captured is largely in the range of visible light (**Fig. 13.4**), the range of wavelengths in which the photon energies are appropriate for the controlled formation and dissociation of molecular bonds. Microbial and plant photosynthesis generates biomass, which is consumed by heterotrophs and decomposers. The consumers store a small fraction of their energy in biomass. At each successive level, the majority of energy is lost, radiated from Earth as heat. Despite growth of living organisms on Earth, the universe as a whole becomes more disordered.

THOUGHT QUESTION 13.1 Why can't photosynthesis be driven by solar microwaves or by X-rays?

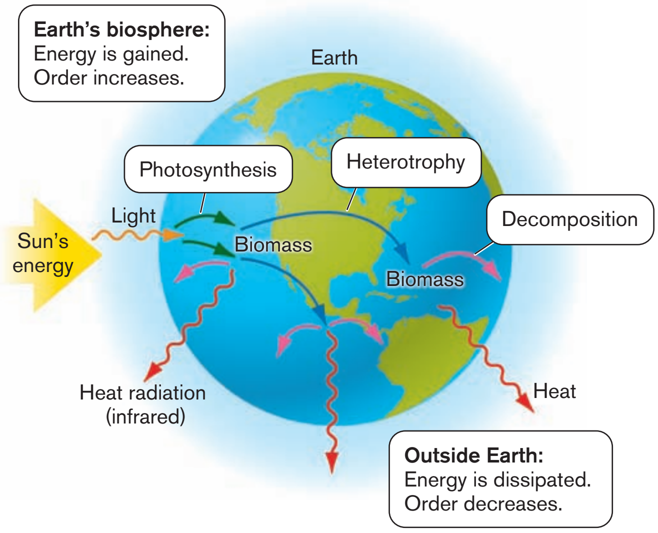


Figure 13.3 Solar energy. Solar radiation reaches Earth, where a small fraction is captured by photosynthetic microbes and plants. The microbial and plant biomass enters heterotrophs and decomposers, which convert a small fraction to biomass at each successive level. At each level, the majority of energy is lost, radiated from Earth as heat.

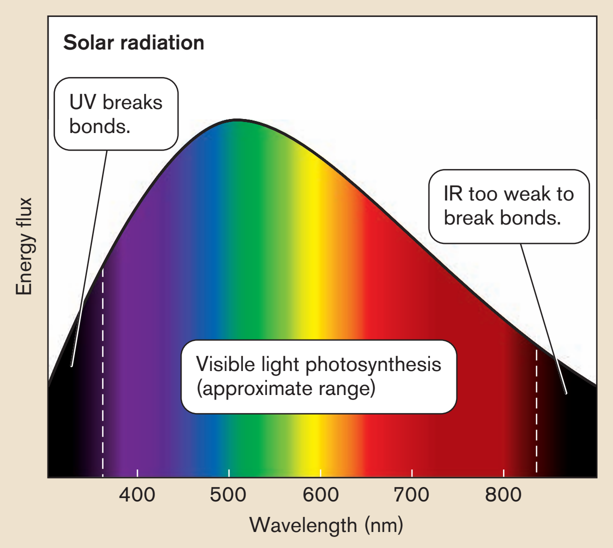

Figure 13.4 The solar spectrum. The sun radiates across the spectrum, but the intensity of solar radiation reaching Earth peaks in the range of visible light.

Gibbs Free Energy Change Includes Heat and Entropy

To provide energy to a cell, a biochemical reaction must go forward from reactants to products. The direction of a reaction can be predicted by a thermodynamic quantity known as the **Gibbs free energy change**, ΔG, also known as free energy change or Gibbs energy change. The ΔG value of a reaction determines how much energy is potentially available to do work, such as to drive rotary flagella, to build a cell wall, or to store accurate information in DNA.

ΔG includes enthalpy and entropy. The free energy change ΔG has two components:

- ΔH = change in **enthalpy**, the heat energy absorbed or released as reactants become products at constant pressure. When reactants absorb heat from their surroundings as they convert to products, ΔH is positive. When, instead, heat energy is released, then ΔH is negative. Release of heat (negative value of ΔH) can yield energy for the cell to use.
- ΔS = change in **entropy**, or disorder. Entropy is based on the number of states of a system, such as the number of possible conformations of a molecule. If a cellular reaction splits one molecule into two, all else being equal, entropy increases; the system is more

disordered, and ΔS is positive. If, however, two molecules become one, then order is increased overall, and ΔS is negative.

The relationship between ΔH and ΔS is given by the Gibbs-Helmholtz equation:

$$\Delta G = \Delta H - T\Delta S$$

The value of free energy, ΔG, determines whether a process may go forward spontaneously. Negative values of ΔG mean that heat is released and/or order is decreased. If ΔG is negative, the process may go forward, whereas positive values mean that the reaction will go in reverse.

The overall sign of ΔG depends on its two components: ΔH, the absorption or release of heat energy, and $-T\Delta S$, the product of entropy change (ΔS) and temperature (T). In living organisms, a sufficiently negative ΔH (energy lost as heat) often overrides $-T\Delta S$, the term for increase in order (negative value of ΔS, positive value of $-T\Delta S$). Thus, a living organism, whose development entails increasing order and decreasing ΔS, can grow so long as the sum of its metabolism has a sufficiently negative value of ΔH. The negative ΔH includes energy gained by the cell as well as energy lost to the surroundings as heat. The heat loss associated with ΔH is obvious in a compost pile, and it occurs as well for all living organisms and communities.

Negative ΔG Drives a Reaction Forward

An example of a thermodynamically favored reaction is the oxidation of hydrogen gas to form water. Hydrogen gas is oxidized for energy by many kinds of bacteria in soil and water. For example, hydrogenotrophic bacteria of the genus *Ralstonia* have been isolated from ultrapure water used for nuclear fuel storage, where radioactive ionization generates H_2. The chemical reaction of hydrogen oxidation is:

$$2H_2 + O_2 \rightarrow 2H_2O$$

In this reaction, two molecules of hydrogen gas donate four electrons to oxygen, forming water. For this reaction, at standard temperature (298 K) and pressure (sea level), $\Delta H = -484$ kJ/mol (kilojoules per mole). The ΔH is strongly negative (much heat is released) because the bonds of the product H_2O are much more stable than those of the substrates H_2 and O_2. However, entropy decreases because the three molecules are replaced by two, a more ordered state. Thus, ΔS is negative ($\Delta S = -0.0886$ kJ/mol·K); and in the Gibbs equation, the negative sign on the entropy term $-T\Delta S$ makes its contribution to ΔG positive, unfavorable for reaction. So which term wins, ΔH or $-T\Delta S$?

$$\begin{aligned}\Delta G &= \Delta H - T\Delta S\\ &= -484 \text{ kJ/mol} - (298 \text{ K})(-0.0886 \text{ kJ/mol}\cdot\text{K})\\ &= -484 \text{ kJ/mol} + 27 \text{ kJ/mol}\\ &= -457 \text{ kJ/mol}\end{aligned}$$

Overall, ΔG is negative, and so bacteria with the appropriate enzyme pathways can use the reaction of hydrogen gas with oxygen to provide energy.

NOTE: Joules (J) are the standard SI unit to denote energy. 1 kilojoule (kJ) = 1,000 joules. Another unit commonly used is kilocalories (kcal). The conversion factor is: 1 kJ = 0.239 kcal.

TO SUMMARIZE:

- **Energy** enables cells to build ordered structures out of simple molecules from their environment.
- **The free energy change (ΔG)** includes enthalpy (ΔH), the heat energy absorbed or released, and $-T\Delta S$, the product of temperature and entropy change (ΔS).
- **Negative values of ΔG** show that a reaction may drive the cell's metabolism. The sign of ΔG depends on the relative magnitude of ΔH and $-T\Delta S$.

13.2 Energy and Entropy in Biochemical Reactions

The energy required for all growth processes is supplied by biochemical reactions. But which direction will a biochemical reaction go? The values of ΔH and $-T\Delta S$ determine which reactions will proceed and whether they can provide energy under actual conditions of the cell. The overall free energy change ΔG determines which "foods" a microbe can eat or, more precisely, which reactions between available molecules can be harnessed for microbial growth.

Enthalpy and Entropy in Microbial Metabolism

The relative contributions of ΔH and $-T\Delta S$ indicate the roles of chemistry and temperature in microbial metabolism.

- **ΔH-driven reactions release heat.** The ΔH term dominates bioenergetic reactions involving strong oxidants such as O_2 (reactions such as glucose respiration and photosynthesis). ΔH-driven reactions release a lot of heat, causing, for example, the rise in temperature of an aerated compost pile.
- **ΔS-driven reactions depend on temperature.** The entropy-driven component of Gibbs energy, $-T\Delta S$, grows larger as temperature increases. This term dominates reactions that generate a larger number of products than reactants but have a relatively small change in oxidation state. An example is glucose fermentation to ethanol and CO_2 during production of alcoholic beverages. Fermentation reactions produce less heat than oxidative catabolism, and their energy yield increases with environmental temperature.

An extreme case of entropy-driven metabolism is that of acetate conversion to methane and CO_2, conducted by soil archaea such as *Methanosarcina barkeri*. This methanogen actually cools its environment, absorbing heat to form products of higher chemical energy. Its growth is driven by the increase in entropy.

Measuring ΔH and ΔS. The actual ΔH and $-T\Delta S$ of biochemical reactions can be determined by calorimetry, measuring the heat released or absorbed during a reaction. One type of calorimetry is isothermal titration calorimetry, in which heat release is measured as the amount of energy needed to cool the system while keeping the temperature constant. Observing the reaction at different fixed temperatures reveals the temperature dependence of the reaction and hence the relative contribution of the entropic term $-T\Delta S$. A common application of isothermal titration calorimetry is to study the ΔH and $-T\Delta S$ of a reaction in which a drug binds to its target receptor protein, such as an inhibitor binding to the protease of HIV (human immunodeficiency virus). The ΔH and $-T\Delta S$ of the inhibitor-binding reaction indicate its binding strength, an important factor in predicting its efficacy in treating patients.

Factors That Determine the Direction of a Reaction

The ΔG for a given reaction is determined by several factors:

- **Molecular stability.** When reactants combine to form products with more stable bonds, the reaction has a negative ΔH. For example, the reaction of a sugar with oxygen has a negative ΔH because the relatively unstable oxygen molecules are reduced to H_2O.
- **Entropy increase.** Reactions in which a complex molecule is broken down to a greater number of smaller molecules increase entropy (positive ΔS, negative $-T\Delta S$). Entropy also increases with formation of gaseous products, such as CO_2, or of carboxylic acids, such as lactic acid, in which H^+ dissociates from a carboxylate ion ($RCOO^-$).
- **Concentrations and environmental factors.** The direction of reaction depends not only on the intrinsic properties of the reactants, but on environmental factors such as temperature, pressure, and reactant concentration. A large excess of reactants over products makes ΔG more negative (favoring the forward reaction). An excess of product makes ΔG more positive (favoring the reverse reaction).

Standard reaction conditions. The thermodynamic values reported in data tables hold only for isolated reactions under specified conditions that differ greatly from those of living cells. These conditions include temperature, ionic strength, and gas pressure (in the case of gaseous components, such as CO_2), as well as the concentrations of reactants and products. To enable comparison, thermodynamic values are commonly presented under standard conditions for temperature, pressure, and concentration. The standard conditions define a **standard Gibbs free energy change, $\Delta G°$**. The standard conditions for **$\Delta G°$** are as follows:

- The temperature is 298 K (25°C).
- The pressure is 1 atm (standard atmospheric pressure).
- All concentrations of substrates and products are 1 molar.

These standard conditions also apply to changes in enthalpy ($\Delta H°$) and entropy ($\Delta S°$), which contribute to $\Delta G°$. In biochemistry, an additional standard condition is that of pH 7, as living cells commonly maintain their cytoplasm within a unit of neutral pH. The thermodynamic terms in biochemistry are thus designated $\Delta G°'$, $\Delta H°'$, and $-T\Delta S°'$.

NOTE: Remember to distinguish these forms of the Gibbs free energy term:

ΔG = Change in Gibbs free energy for a reaction under defined conditions.

$\Delta G°$ = ΔG at standard conditions of temperature (298 K) and pressure (sea level), with all reactants and products at a concentration of 1 M.

$\Delta G°'$ = ΔG at standard temperature, pressure, and concentrations for $\Delta G°$, plus the additional condition of pH 7 (H^+ concentration of 10^{-7} M) commonly specified by biochemists.

Concentrations affect ΔG. In living cells, the concentrations of reactants and products usually differ from 1 molar; thus, the actual ΔG differs from $\Delta G°$ or $\Delta G°'$. Consider a reaction in which reactants A and B are converted to products C and D, as well as conversion in reverse

$$A + B \rightleftharpoons C + D$$

Higher concentration of reactants (A or B) drives the reaction forward, whereas higher concentration of products drives it in reverse. So, ΔG includes the ratio of products to reactants:

$$\Delta G = \Delta G° + RT \ln \frac{[C]\ [D]}{[A]\ [B]}$$

$$= \Delta G° + 2.303\ RT \log \frac{[C]\ [D]}{[A]\ [B]}$$

Table 13.2 Effect of the concentration ratio on ΔG.

Ratio of products to reactants: $\frac{[C][D]}{[A][B]}$	Change in ΔG (kJ/mol) at standard temperature (298 K) and atmospheric pressure	Result of change from standard concentrations
10^{-4}	−23	Products increase
10^{-2}	−11	Products increase
1	0	$\Delta G = \Delta G°$
10^{2}	+11	Reactants increase
10^{4}	+23	Reactants increase

where R is the gas constant ($R = 8.315$ J/mol) and T is the absolute temperature in Kelvins (298 K for 25°C). The factor 2.303 converts the logarithm of the ratio of products to reactants from base e to base 10.

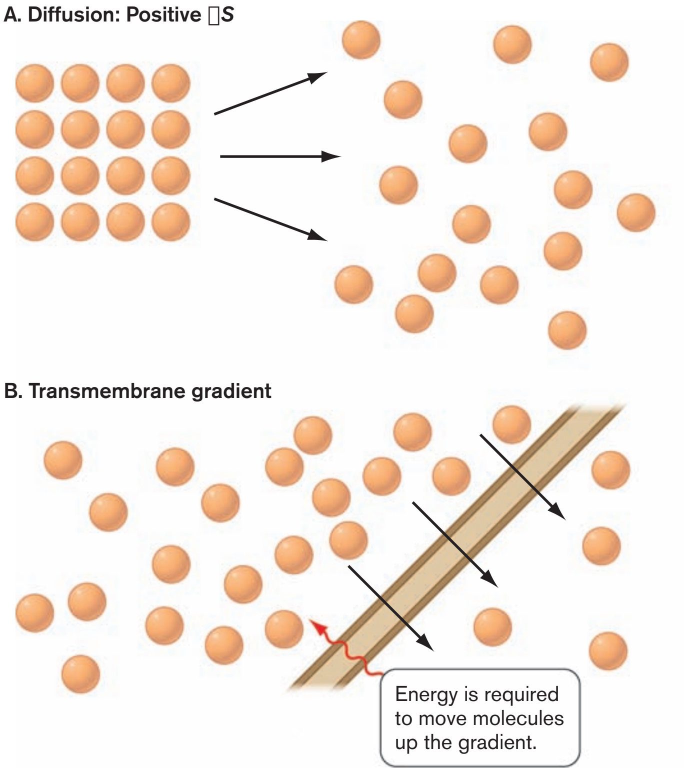
The effect of the concentration ratio on ΔG is shown in **Table 13.2**. In reactions at medium temperature (25–40°C), a hundredfold increase in the ratio of products to reactants adds about 11 kJ/mol to ΔG. ΔG is then less negative and the reaction less favorable. On the other hand, a hundredfold decrease in the concentration ratio makes ΔG more negative by –11 kJ/mol.

In some environments, a highly negative concentration term can override a positive $\Delta G°$, resulting in a reaction with negative ΔG that microbes can use for energy. For example, in an iron mine the high concentration of reduced iron favors iron-oxidizing microbes. Alternatively, a high temperature may increase the magnitude of the term 2.303 RT log [products]/[reactants] when it is negative, until it overrides a positive $\Delta G°$. This occurs in thermophiles such as *Sulfolobus*, which metabolize sulfur at 90°C by reactions unfavorable at lower temperatures.

Another way the direction of reaction may change is for a second metabolic process to remove one of the reaction's products (C or D) as fast as it is produced. The total ΔG for both reactions could then be negative, even if the first reaction had a positive ΔG. In **glycolysis**, the pathway of glucose breakdown to pyruvate, many of the individual reactions have $\Delta G^{\circ\prime}$ values smaller than 5 kJ/mol. Their actual direction of reaction in the cell depends on concentrations of products and reactants. Glycolytic reactions with near-zero $\Delta G^{\circ\prime}$ are reversible and can in fact participate in the biosynthetic pathway of gluconeogenesis (glucose biosynthesis).

Energy and Entropy in Concentration Gradients

A growing cell needs to obtain essential molecules from outside, such as sugars and amino acids, and inorganic ions. The difference in concentration of a nutrient inside a cell versus outside generates a concentration gradient that stores energy.



A. Diffusion: Positive ΔS
B. Transmembrane gradient
Energy is required to move molecules up the gradient.

Figure 13.5 Diffusion and transport. A. Water-soluble molecules diffuse to uniform concentration throughout the solution: ΔS is positive, $-T\Delta S$ negative; the entropy term favors the process. **B.** If a membrane separating two compartments is permeable, molecules move from a compartment with high concentration to one with low concentration. Energy is required to move molecules up their concentration gradient.

In water solution, a dissolved substance diffuses by random movements until its distribution has the same concentration throughout (**Fig. 13.5A**). The random distribution of molecules at uniform concentration represents the state of greatest entropy. Diffusion in the environment ultimately brings nutrients into contact with microbial cells, even cells that lack chemotactic motility to hunt for food. For example, sugars in the food we eat diffuse through our saliva to reach the bacteria growing in biofilms on our teeth.

The cell membrane contains transporters for useful molecules, allowing the nutrient molecules to cross. Entropy favors their movement from higher to lower concentration (**Fig. 13.5B**). In most environments, however, the nutrients are at lower concentrations than inside the cell. To obtain these molecules from outside, the bacterial cell must transport them against their gradient—that is, from lower to higher concentration—increasing the concentration difference and thus decreasing entropy. Uptake against a gradient requires an energy source to power transport proteins embedded in the membrane. The transporters must spend energy to compensate for the decrease in entropy when a cell transports the nutrient against its concentration gradient.

To form a chemical gradient requires expenditure of energy, so establishing a gradient stores energy. The energy stored in a gradient across a cell membrane can be interconverted with the energy of biochemical reactions such as sugar catabolism. For example, respiration generates a proton gradient (chemical gradient of H^+), which then drives the ATP synthase to synthesize ATP. The interconversion of gradient energy with chemical reaction energy was first known as the "chemiosmotic hypothesis," earning the 1978 Nobel Prize in Chemistry for Peter Mitchell (discussed in Chapter 14).

Microbial Thermodynamics Includes Other Factors

Within living cells, numerous other factors influence the Gibbs energy values of microbial growth. The Gibbs equation as presented assumes constant concentrations of reactants and products. In living cells, however, the reactant concentrations are continually changing. To account for changing concentrations requires a level of analysis more complex than we can present here.

An important source of concentration change is the coupling of energy-generating reactions to the energy-spending reactions of biosynthesis. The energy-spending reactions subtract from the observed free energy release of a growing microbe. A model proposed by Urs von Stockar and colleagues predicts that microbes optimize their coupling of catabolism with biosynthesis to maintain a net Gibbs energy of growth within a range of 300–450 kJ/mol per carbon of substrate catabolized. Different forms of catabolism, however, offer very different yields of biomass (cell mass synthesized per unit substrate). For example, the oxidative respiration of glucose yields five times the biomass produced by glucose fermentation, although respiring and fermenting cells show similar net Gibbs energy of growth.

A surprising discovery has been that many bacteria and archaea in natural environments grow extremely slowly, at values of ΔG approaching zero (that is, thermodynamic equilibrium). When the actual ΔG (under actual reaction conditions) equals zero, a reaction proceeds equally forward and reverse, and there is no net change in energy. At equilibrium, the ratio of product and reactant concentrations exactly cancels $\Delta G°$ or $\Delta G°'$:

$$\Delta G = 0 = \Delta G° + 2.303\,RT \log \frac{[C]\,[D]}{[A]\,[B]}$$

$$\Delta G° = -2.303\,RT \log \frac{[C]\,[D]}{[A]\,[B]}$$

Living cells can never grow exactly at equilibrium ($\Delta G = 0$), but some gain energy from reaction pathways whose Gibbs free energy just exceeds equilibrium. Michael McInerney, Derek Lovley, and colleagues have identified soil bacteria and archaea that gain energy from metabolic pathways with ΔG values as small as –20 kJ/mol, less than one ATP's worth of energy per cycle. An example of an energy-yielding pathway with near-zero ΔG is CO_2 reduction to methane (a form of methanogenesis). How such pathways are coupled to biosynthesis is poorly understood. The discovery of low-ΔG energetics has opened new possibilities for industrial microbiology previously thought impossible, such as the anaerobic digestion of complex organic pollutants in contaminated soil.

THOUGHT QUESTION 13.2 Methanogens are a small proportion of the microbial community in soil, and the ΔG of methanogenesis is small. Yet methanogens produce large volumes of methane, large enough to contribute significantly as a greenhouse gas to global warming. Why would methanogens produce a relatively large quantity of waste product?

THOUGHT QUESTION 13.3 The soil bacterium *Geobacter* can metabolize acetic acid by the following reaction:

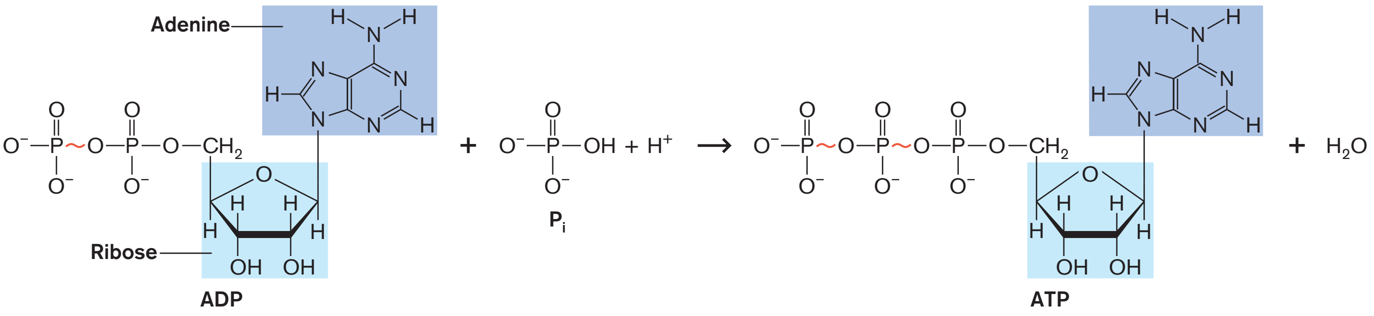
$$CH_3COOH + 2H_2O \rightarrow 2CO_2 + 4H_2$$

Yet the $\Delta G°'$ is +95 kJ/mol. What could happen in the soil enabling *Geobacter* to grow?

TO SUMMARIZE:

- **The direction of reaction** is determined by the molecular stability of reactants and products and by entropy change associated with number of products, gaseous products, or products with multiple forms.
- **Concentrations of reactants and products affect ΔG.** The lower the concentration ratio of products to reactants, the more negative the value of ΔG.
- **A concentration gradient stores energy.** Solutes run down their concentration gradient unless energy is applied to reverse the flow.

A. ADP phosphorylation to ATP



B. Mg^{2+}-ATP

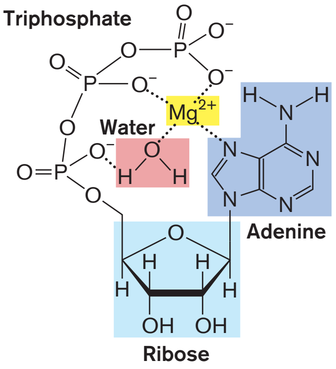


Figure 13.6 ADP plus inorganic phosphate makes ATP. The reaction requires energy input (positive ΔG) because the negatively charged oxygens of the phosphates are forced into proximity. **A.** The chemical reaction phosphorylating ADP to ATP. **B.** Model of Mg^{2+}-ATP. The multiple negative charges of ATP are stabilized by complexing with magnesium ion plus a water molecule.

- **Cellular thermodynamics involves** changing reactant and product concentrations and coupling of energy-yielding reactions with energy-spending reactions.
- **Reaction pathways with ΔG near zero** can drive microbial growth.

13.3 Energy Carriers and Electron Transfer

Our ΔG equations show only the total energy of a reaction such as glucose oxidation. If all the energy were released at once, however, it would dissipate as heat without building biomass. In living cells, glucose oxidation never occurs in one step. Instead, the energy yield is divided among a large number of stepwise reactions with smaller energy changes. In this way, the cell can be thought of as "making change" by converting a large energy source to numerous smaller sources that can be "spent" conveniently for cell function and biosynthesis. The "spending" of energy is controlled by enzymes that couple all energy-providing reactions to specific energy-spending reactions.

Energy Carriers Gain and Release Energy

Many of the cell's energy transfer reactions involve **energy carriers**. Examples of energy carriers are ATP (adenosine triphosphate) and NADH (nicotinamide adenine dinucleotide). Energy carriers are molecules that gain and release small amounts of energy in reversible reactions. Energy carriers are used to transfer energy in a wide range of biochemical reactions.

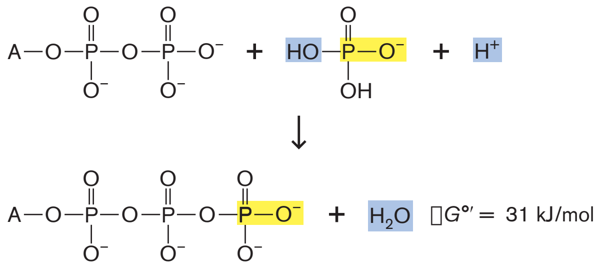
Some energy carriers, such as NADH, transfer energy associated with electrons received from a food molecule. A molecule that transfers, or "donates," electrons to another molecule is called an **electron donor** or a reducing agent; a molecule that receives, or "accepts," electrons is called an **electron acceptor**. For example, during glucose catabolism, a molecule of glyceraldehyde 3-phosphate transfers a pair of electrons ($2e^-$) with a hydrogen ion to NAD^+, forming NADH. NAD^+ is an electron acceptor that receives the electrons; it then becomes the electron donor, NADH. Electron donors such as NADH mediate electron transfer from reduced food molecules to a terminal electron acceptor such as oxygen. Energy carriers that transfer electrons are needed for all energy-yielding pathways and for biosynthesis of cell components such as amino acids and lipids.

ATP Carries Energy through Phosphorylation

Adenosine triphosphate ATP (**Fig. 13.6A**) is composed of a base (adenine), a sugar (ribose), and three phosphates. Note that adenine-ribose-phosphate is equivalent to a nucleotide "link" of RNA. The base adenine is a fundamental molecule of life, one that forms spontaneously from methane and ammonia in experiments simulating the origin of life on early Earth. Like the sugar ribose, ATP is an ancient component of cells, found in all living organisms.

Note that under physiological conditions, ATP always complexes with Mg^{2+} (**Fig. 13.6B**). The magnesium cation partly neutralizes the negative charges of the ATP phosphates, stabilizing the structure in solution. Most enzyme-binding sites for ATP actually bind Mg^{2+}-ATP. This is one reason magnesium is an essential nutrient for all living cells.

ADP phosphorylation to ATP. During cell metabolism, ATP is generated by **phosphorylation**, the condensation of inorganic phosphate with **adenosine diphosphate (ADP)**:



The phosphorylation of ADP to form ATP requires energy input (positive Δ*G*).

Why does ATP formation require energy? The inorganic phosphate has four oxygen atoms that share a negative charge. When phosphate reacts with another phosphate to form a bond, the charged oxygens of adjacent phosphates are forced into proximity despite charge repulsion. The two phosphoanhydride bonds in ATP show charge repulsion, associated with a large negative ΔG of hydrolysis. Hydrolysis of each bond yields energy; thus, they are referred to as high-energy bonds. The formation and hydrolysis of ATP are shown as

$$\text{A-P}{\sim}\text{P} + \text{H}^+ + \text{P}_\text{i} \rightleftharpoons \text{A-P}{\sim}\text{P}{\sim}\text{P} + \text{H}_2\text{O}$$

where ~ designates each "high-energy" bond and P_i designates inorganic phosphate; or in more concise shorthand,

$$\text{ADP} + \text{P}_\text{i} \rightleftharpoons \text{ATP} + \text{H}_2\text{O}$$

ATP transfers energy. ATP can transfer energy to cell processes in three different ways: hydrolysis releasing phosphate; hydrolysis releasing pyrophosphate (diphosphate); and phosphorylation of an organic molecule. Each process serves different functions in the cell.

- **Hydrolysis releasing phosphate.** The **hydrolysis** of ATP at the terminal phosphate consumes H_2O to produce ADP and P_i. Hydrolysis of the phosphodiester bond releases energy. The energy released by ATP hydrolysis can be transferred to a coupled reaction of biosynthesis, such as building an amino acid. The two reactions are coupled by an enzyme with binding sites specific for ATP and the substrate.
- **Hydrolysis releasing pyrophosphate.** ATP can hydrolyze at the middle phosphate, releasing pyrophosphate (PP_i). The pyrophosphate usually hydrolyzes shortly afterward to make 2 P_i; thus, approximately twice as much energy is spent as in release of 1 P_i from ATP. The advantage of pyrophosphate release is that it drives a reaction strongly forward. Pyrophosphate release occurs in reactions that must avoid reversal—for example, the incorporation of nucleotides into growing chains of RNA.
- **Phosphorylation of an organic molecule.** ATP can transfer its phosphate to the hydroxyl group of a molecule such as glucose to activate the substrate for a subsequent rapid reaction. No inorganic phosphate appears, and no water molecule is consumed:

  $$\text{ATP} + \text{glucose} \rightarrow \text{ADP} + \text{glucose 6-phosphate}$$

  Some enzymes catalyze ATP transfer of phosphate to activate sugar molecules for catabolism. Other enzymes couple the phosphorylation of a sugar to its transport across the cell membrane; consequently, these enzymes are known as the **phosphotransferase (PTS)** family. The PTS enzymes play a critical role in determining which nutrients from the environment a microbe can acquire and catabolize (discussed in Chapter 4).

Note that besides ATP, other nucleotides carry energy. Guanidine triphosphate (GTP) provides energy for ribosome elongation of proteins. And the phosphodiester bonds of all four nucleotide triphosphates, as well as their corresponding deoxyribonucleotide triphosphates, carry energy for their own incorporation into RNA and DNA, respectively.

ATP produced by glucose catabolism. A large number of ATPs can be formed by coupling ATP synthesis to the step-by-step breakdown and oxidation of a food molecule such as glucose. In theory, complete oxidation of glucose through respiration can produce as many as 38 ATP molecules. The overall Δ*G*°′ of the coupled reactions is

$$\begin{array}{ll} \text{C}_6\text{H}_{12}\text{O}_6 + 6\text{H}_2\text{O} + 6\text{O}_2 \rightarrow & \\ \qquad 12\text{H}_2\text{O} + 6\text{CO}_2 & \Delta G^{\circ\prime} = -2{,}878 \text{ kJ/mol} \\ 38\,[\text{ADP} + \text{P}_\text{i} \rightarrow \text{ATP} + \text{H}_2\text{O}] & \Delta G^{\circ\prime} = 38 \times (31 \text{ kJ/mol}) \\ \hline & \text{Net } \Delta G^{\circ\prime} = -1{,}700 \text{ kJ/mol} \end{array}$$

The difference in Δ*G*°′ for the coupled reactions is the energy lost as heat and entropy, in this case –1,700 kJ/mol (–2,978 kJ/mol + 1,178 kJ/mol). Thus, the maximal efficiency of energy capture by ATP is about 40%, a level that may be approached by highly efficient systems such as mitochondria. When ΔG values are corrected for cellular concentrations of reactants and products, the actual efficiency appears to be greater than 50%. For comparison, the efficiency of a typical machine such as an internal combustion engine is about 20%.

Under conditions such as low oxygen concentration, much smaller amounts of ATP are made per molecule of glucose. On the other hand, the vast majority of microbial catabolism in soil and water involves nonsugar substrates consumed by reactions at near-zero values of ΔG, which require multiple cycles to make a single molecule of ATP. These near-equilibrium reactions remain poorly understood, but their efficiency may approach 100%.

THOUGHT QUESTION 13.4 After ATP has been dephosphorylated to ADP, how else might ADP provide energy for the cell?

THOUGHT QUESTION 13.5 Linking an amino acid to its cognate tRNA is driven by ATP hydrolysis to AMP plus pyrophosphate. Why release PP_i instead of P_i?

THOUGHT QUESTION 13.6 In the microbial community of the bovine rumen, the actual ΔG value has been calculated for glucose fermentation to acetate:

$$C_6H_{12}O_6 + 2H_2O \rightarrow 2C_2H_3O_2^- + 2H^+ + 4H_2 + 2CO_2$$
$$\Delta G = -318 \text{ kJ/mol}$$

If the actual ΔG for ATP formation is 44 kJ/mol and each glucose fermentation yields four molecules of ATP, what is the thermodynamic efficiency of energy gain? Where does the lost energy go?

NADH Carries Energy and Electrons

A major energy carrier that donates and accepts electrons is **nicotinamide adenine dinucleotide** (**NADH**, reduced; **NAD^+**, oxidized). NADH carries two or three times as much energy as ATP, depending on cell conditions. It is used to carry electrons from breakdown products of glucose. The oxidized form NAD^+ receives two electrons ($2e^-$) plus a proton (H^+) from a food molecule; a second H^+ from the food molecule enters water solution. Overall, reduction of NAD^+ consumes two hydrogen atoms to make NADH:

$$NAD^+ + 2H^+ + 2e^- \rightarrow NADH + H^+ \qquad \Delta G^{\circ\prime} = 62 \text{ kJ/mol}$$

For this reaction, $\Delta G^{\circ\prime}$ is positive; therefore, it requires input of energy from the food molecule. The reduced energy carrier NADH can then reverse the above reaction by donating two electrons ($2e^-$) to another molecule, regenerating NAD^+.

NOTE: In this book, our discussion of metabolism makes the following assumptions:

- A proton is equivalent to a hydrogen ion (H^+). In water solution, H^+ combines with H_2O to form hydronium (H_3O^+), but for clarity we use H^+.
- An atom of hydrogen removed from a C–H bond consists of a proton (H^+) plus an electron (e^-). In a reaction, the proton and electron may be transferred to one molecule or to different molecules.

NADH structure and function. NAD^+ consists of an ADP molecule attached to a nicotinamide group instead of a third phosphate. The nicotinamide group, like a ribonucleotide, contains a nitrogenous base attached to a sugar phosphate. In NAD^+, the dehydrogenated (oxidized) nicotinamide has a ring structure (shaded pink in **Fig. 13.7A**) that forms a stable cation.

NAD^+ is a relatively stable structure because the ring electrons are **aromatic**; that is, the bonding electrons delocalize equally around the ring, as in benzene. Aromatic rings that contain noncarbon atoms are said to be **heteroaromatic**. Many biologically active molecules are heteroaromatic, including adenine and other nucleotide bases. A heteroaromatic ring is stable, but its disruption requires less energy than the disruption of benzene. Thus, it is possible to disrupt the ring by adding two electrons with a proton, eliminating one double bond. The donation of electrons eliminates the ring's aromaticity, generating NADH, which carries energy in an amount useful for cell reactions.

The electrons transferred to NADH eventually must be put somewhere else, onto the next electron acceptor. NADH cannot build up in the cell; it must always be recycled to NAD^+, to continue oxidizing food molecules. One way the energy stored by NADH can be spent is to transfer $2H^+ + 2e^-$ onto a product of catabolism. For example, in ethanolic fermentation to make wine or beer, NADH reduces pyruvate to ethanol. In this case, however, the energy is lost to the cell. Alternatively, NADH can transfer its electrons to one of a series of electron carrier molecules known as the **electron transport system (ETS)**.

The Electron Transport System (ETS)

The electron transport system (also known as the electron transport chain) stores energy from electron transfer as ion gradients across the membrane of the cell or an organelle. The ETS enables production of ATP. The ETS includes a series of proteins and small organic molecules that can be reduced and cyclically reoxidized. At the end of the series of oxidation-reduction transfers, the pair of

Figure 13.7 Reduction of NAD$^+$ and FAD. **A.** In the reduction of NAD$^+$, the nicotinamide ring (shaded pink) loses a double bond as two electrons are gained from an electron donor. Two hydrogen atoms are consumed; one bonds to NADH, while the other ionizes. **B.** In FAD, the flavin isoalloxazine ring system gains two electrons associated with two hydrogens.

electrons are transferred to a **terminal electron acceptor** whose product leaves the cell. For example, molecular oxygen (O_2) as a terminal electron acceptor is reduced to H_2O.

The reaction of O_2 reduction to H_2O is coupled to oxidation of NADH or another reduced energy carrier:

$$\begin{aligned}
&\text{NADH} + \text{H}^+ \rightarrow \\
&\qquad \text{NAD}^+ + 2\text{H}^+ + 2e^- && \Delta G°' = -62 \text{ kJ/mol}\\
&\tfrac{1}{2}\text{O}_2 + 2\text{H}^+ + 2e^- \rightarrow \text{H}_2\text{O} && \Delta G°' = -158 \text{ kJ/mol}\\
\hline
&\text{NADH} + \text{H}^+ + \tfrac{1}{2}\text{O}_2 \rightarrow \\
&\qquad \text{NAD}^+ + \text{H}_2\text{O} && \Delta G°' = -220 \text{ kJ/mol}
\end{aligned}$$

The total energy spent by NADH oxidation through the ETS is –220 kJ/mol (–62 kJ/mol –158 kJ/mol). This energy is converted to transmembrane proton potential, which then drives nutrient transport, motility, and synthesis of ATP. The ETS and the proton potential are discussed in detail in Chapter 14.

Many microbes can reduce terminal electron acceptors other than O_2, such as nitrate (NO_3^-) or pyruvate. Humans, unlike most microbes, have no alternative electron acceptors; thus, we need to breathe oxygen. When no terminal electron acceptor is available to accept electrons, NADH builds up to unfavorably high levels, leaving no more NAD$^+$ available to be reduced. When muscle tissues run out of oxygen, they transfer electrons from NADH back to the products of glucose catabolism, producing lactic acid. The buildup of lactic acid drives down pH, causing the muscle to cramp.

Other energy carriers that transfer electrons. Different steps of metabolism utilize different but related energy carriers. For example, NADPH differs from NADH only in its extra phosphate attached to the 2′ carbon of adenine. Some enzymes can utilize both NADPH and NADH, whereas other enzymes use only one or the other. In many bacteria, NADPH is used for biosynthesis, whereas NADH feeds the ETS to yield energy. Other species, particularly phototrophs, use NADH and NADPH interchangeably.

Another related coenzyme is **flavin adenine dinucleotide (FADH$_2$)**, in which flavin substitutes for nicotinamide. The flavin nucleotide includes a ring structure whose aromaticity is eliminated by receiving two electrons (**Fig. 13.7B**). The redox function of the flavin isoalloxazine ring system is similar to that of NADH:

$$\text{FAD}^+ + 2\text{H}^+ + 2e^- \rightarrow \text{FADH}_2$$

Like NADH, FADH$_2$ donates $2e^-$ to an electron acceptor. FADH$_2$ is a weaker electron donor than NADH, but when combined with a strong electron acceptor such as O_2, electron transfer occurs and significant energy is released ($\Delta G°'$ = –158 kJ/mol).

For several reasons, different kinds of reactions use different energy carriers:

- **Different amounts of energy.** Biochemical reactions yield different amounts of energy—that is, different values of ΔG. Suppose that a reaction can provide more than enough energy to generate ATP from ADP (31 kJ), but not quite enough to generate NADH from NAD^+ (62 kJ). An example is the conversion of succinate to fumarate in the TCA cycle (see Section 13.6). This reaction provides the energy to reduce FAD to $FADH_2$, whose oxidation by O_2 can yield two molecules of ATP. Thus, the use of $FADH_2$ enables the cell to make more efficient use of its food than if generation of ATP or NADH were the only choices.
- **Different redox levels.** Food molecules may have more or fewer electrons (level of reduction/oxidation) than those associated with the cell structure. For example, lipids are more highly reduced than glucose. Thus, lipid catabolism requires a greater proportion of electron-accepting energy carriers (such as NAD^+ or $NADP^+$) than glucose catabolism and makes relatively few ATP molecules directly. A combination of energy carriers that do or do not change redox state enables cells to balance their electrons while acquiring energy.
- **Regulation and specificity.** Specific energy carriers can direct metabolites into different pathways serving different functions. For example, in many bacteria, NADH is directed into the ETS, whereas NADPH, the 2′-phosphorylated form of NADH, is directed into biosynthesis of cell components such as amino acids and lipids.

The concentrations and reduction level of energy carriers provide much information on the state of a cell, such as the effects of environmental stress on cell metabolism. Energy carriers can be observed in living cells by the technique of nuclear magnetic resonance (NMR) spectroscopy (see **Special Topic 13.1**). The use of NMR to observe living cells led to the development of magnetic resonance imaging (MRI) to observe the entire human body.

Enzymes Catalyze Metabolic Reactions

In living cells, each reaction must occur only as needed, in the right amount at the right time. The rate of reaction is determined by the **activation energy** (E_a), the input energy needed to generate the high-energy transition state on the way to products (**Fig. 13.8**). Most biochemical reactions have an activation energy that exceeds the kinetic energy of the reactant molecules colliding. Thus, no matter how negative the ΔG, the reaction will proceed only when the activation energy is lowered by interaction with a catalyst, an agent that participates in a reaction without being consumed.

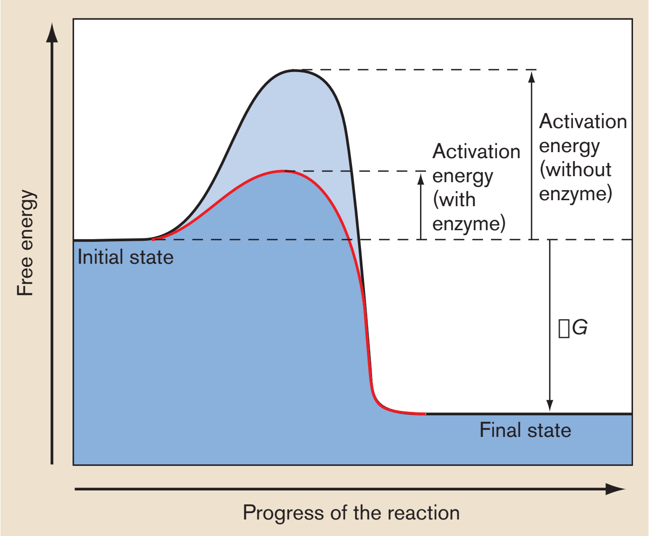

Figure 13.8 Enzyme lowers the activation energy of the transition state. In the presence of an enzyme, the activation energy of the reactants is decreased, allowing rapid conversion of reactants to products.

Biological reactions are catalyzed by **enzymes**, structures composed of protein (or, in some cases, RNA) that bind substrates of a specific reaction. The enzyme lowers the activation energy by bringing the substrates in proximity to one another and by correctly orienting them to react. In some cases, enzymes provide a reactive amino acid residue to participate in a transition state between reactants and products. Microbial enzymes have growing importance in industry; they are used for food production, fabric treatment, and drug therapies (discussed in Chapter 16).

Enzymes couple specific energy-yielding reactions (such as those of glucose breakdown) with the cell's reactions requiring energy, such as making ATP. An example of coupled reactions is shown in **Figure 13.9**. The substrate **phosphoenolpyruvate (PEP)**, a phosphorylated breakdown product of glucose, is converted to pyruvic acid while the phosphate is added to ADP to generate ATP:

Figure 13.9 The enzyme pyruvate kinase. Pyruvate kinase catalyzes the transfer of a phosphoryl group from PEP to ADP, generating pyruvate and ATP. The enzyme possesses separate binding sites for substrates and allosteric effectors.

The $\Delta G^{\circ\prime}$ of phosphate cleavage from PEP is –62 kJ/mol, whereas the $\Delta G^{\circ\prime}$ of ATP formation is only 31 kJ/mol. Thus, the net $\Delta G^{\circ\prime}$ is negative (–31 kJ/mol), and the reaction goes forward to pyruvate. But a high activation energy makes the reaction extremely slow; it essentially never occurs on the timescale of life. The reaction occurs only when the two reacting substrates (PEP and ADP) are coupled by the enzyme **pyruvate kinase** (**Fig. 13.10**). Pyruvate kinase has specific binding sites for each of its substrates, PEP and ADP. The ADP and PEP are brought together by the enzyme and positioned so as to lower the activation energy of phosphate transfer.

In addition to the catalytic site, the enzyme has an **allosteric site** (a regulatory site distinct from the substrate-binding site) for its activator fructose 1,6-bisphosphate. The difference between a substrate-binding site and an allosteric site can be seen in the molecular model, based on X-ray crystallography (**Fig. 13.10**). The allosteric site is found at a distance from the substrate-binding site, but its interaction with the regulator, fructose 1,6-bisphosphate, alters the conformation of the entire enzyme, increasing the rate of reaction. As we shall see, fructose 1,6-bisphosphate is a central intermediate of glycolysis; thus, it makes sense that as this molecule builds up, it activates pyruvate kinase to remove products farther down the chain of catabolic reactions, maintaining the steady flow of metabolites.

Special Topic 13.1 Observing Energy Carriers in Living Cells

Energy carriers lead a dynamic existence, often with rapid turnover. How are energy carriers measured in living cells? One way is to use nuclear magnetic resonance (NMR) spectroscopy (**Fig. 1**). The use of NMR for real-time observation of live organisms was pioneered in the 1970s by Robert Shulman and colleagues at Yale University. Further advances led to magnetic resonance imaging (MRI), a technique in which the human body is scanned for NMR signals to build a three-dimensional image. MRI is now the method of choice for noninvasive imaging of patients with tumors, stroke, or other internal defects.

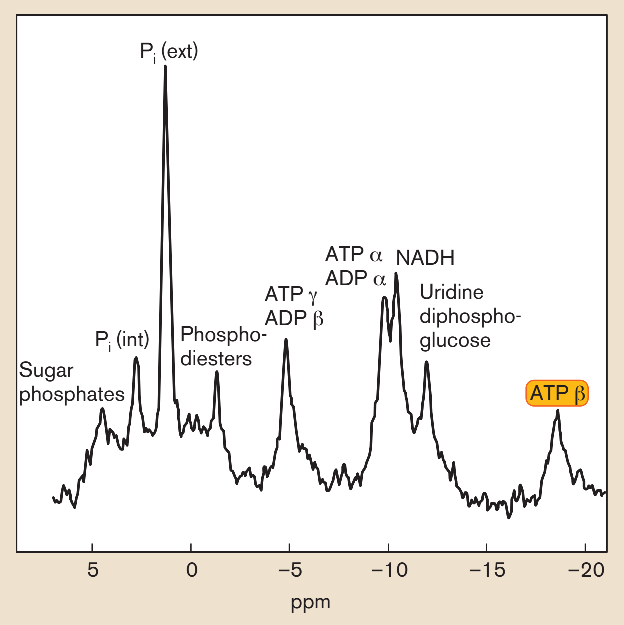

Figure 1 Phosphorylated energy carriers observed by ^{31}P NMR. The ^{31}P NMR spectrum reveals peaks corresponding to cytoplasmic levels of nucleotide triphosphates (primarily ATP) and NADH. The alpha-phosphate links directly to the nucleotide; the beta-phosphate lies between two phosphates; and the gamma-phosphate is terminal. The beta-phosphate of ATP (ATP β) generates a well-isolated peak indicating ATP concentration. *Source:* Elke M. Lohmeier-Vogel, et al. 2004. *Applied and Environmental Microbiology* 70:7342.

NMR spectroscopy gives detailed information about molecules containing nuclei of odd atomic number or mass number, which possess nuclear magnetic moment. Nuclei particularly useful in biochemistry include ^{1}H, ^{13}C, and ^{31}P. NMR detects nuclear spin transitions associated with the nuclear magnetic moment of nuclei suspended within the intense magnetic field of a superconducting magnet. The spin transition occurs as the nuclear magnetic moment of each atom interacts with electromagnetic radiation, producing a signal.

Within live cells, NMR can be used to observe concentrations of molecules with extremely high turnover, such as ATP and NADH (**Fig. 1**). These energy carriers are detected based on NMR signals from their phosphate groups. The naturally occurring phosphorus isotope ^{31}P has a nuclear spin, which generates the nuclear magnetic moment required for an NMR signal. The ^{31}P NMR spectrum of live *E. coli* cells reveals several peaks corresponding to cytoplasmic levels of nucleotide triphosphates (primarily ATP) and NADH. Each phosphorus signal position is "shifted" by shielding from electrons in molecular orbitals. The shift differs for each phosphorus in the molecule.

In **Figure 1**, the levels of phosphorylated energy carriers were used to assess the overall energy levels of *E. coli* cells exposed to tellurite, a toxic chemical. The ^{31}P NMR spectrum reveals three shift peaks corresponding to the three phosphates of ATP and the two of ADP. The middle phosphate of ATP (ATP β) generates a well-isolated peak indicating ATP concentration. As the overall energy level of the cell rises upon addition of glucose, the ATP β peak increases. Thus, the concentration of phosphorylated energy carriers serves as a measure of energy flux within the cell. Similar measurements for human tissues are used to study the biochemistry of athletic performance.

THOUGHT QUESTION 13.7 What would happen to the cell if pyruvate kinase catalyzed PEP conversion to pyruvate but failed to couple this reaction to ATP production?

Note that pyruvate kinase is actually named for its reverse reaction, the use of ATP to phosphorylate pyruvate to PEP. This may be because the activity of the purified enzyme was originally observed in the reverse direction. Enzymes can catalyze both forward and reverse reactions; the predominating direction depends on the concentrations of substrate and products, which determine ΔG, and on allosteric regulators.

TO SUMMARIZE:

- **Catabolic pathways organize the breakdown of large molecules** in a series of sequential steps coupled to reactions that store energy in small carriers such as ATP and NADH.
- **ATP and other nucleotide triphosphates store energy** in the form of phosphodiester bonds.
- **NADH, NADPH, and FADH each store energy** associated with an electron pair that carries reducing power.
- **Enzymes catalyze reactions by lowering the ΔG** required to reach the transition state. They couple energy transfer reactions to specific reactions of biosynthesis and cell function.

Figure 13.11 Carbon sources for catabolism. **A.** Polysaccharides such as starch, cellulose, and pectin are broken down by microbes to glucose, which undergoes glycolysis. **B.** Lipids and complex aromatic structures are broken down to acetate, which enters the TCA cycle. Halogenated aromatic pollutants are broken down by white rot fungi, a promising agent of bioremediation.

13.4 Catabolism: The Microbial Buffet

In the early twentieth century, it was thought that microbes could catabolize a limited subset of naturally occurring organic molecules, such as sugars. Molecules not known to be catabolized were termed "xenobiotics," especially if they were "synthetic" products of human industry. We have since found that virtually any organic molecule can be catabolized by a microbe that has evolved the appropriate enzymes. Catabolism also plays key roles in microbial disease; for example, the causative agent of acne, *Propionibacterium acnes*, degrades skin cell components such as sialic acids, matrix molecules, lipids, and pore-forming factors.

Note that besides releasing energy, the breakdown of organic food molecules provides substrates for biosynthesis. Biosynthesis is covered in Chapter 15.

Classes of Catabolism

Microbial pathways of catabolism are summarized in **Table 13.1**. Most catabolic pathways fall into one of three classes:

- **Fermentation.** First identified by Louis Pasteur as "la vie sans air," or "life without air," fermentation is the partial breakdown of organic food without net transfer of electrons to an inorganic terminal electron acceptor; thus, it can take place in the absence of oxygen. Fermentation has a favorable ΔG owing to breakdown of a large molecule to several smaller products, which are usually more stable as well. Types of fermentation pathways include ethanolic fermentation, producing alcoholic beverages, and lactic acid fermentation by lactic acid bacteria, producing cheese and yogurt.
- **Respiration.** Respiration combines catabolic breakdown of organic molecules with electron transfer to a terminal electron acceptor such as oxygen. Respiration yields far more energy from catabolism than does fermentation. For humans, respiration is synonymous with breathing; but in the absence of O_2, many microbes use alternative electron acceptors, such as nitrate or sulfate. Thus, microbes—unlike humans and other animals—have the capacity for anaerobic respiration.

- **Photoheterotrophy.** Some microbes conduct catabolism with a “boost” from light absorption. In photolytic catabolism, or photoheterotrophy, light absorption by chlorophyll drives the photolysis of an organic molecule such as succinate. Photoheterotrophy is common in marine and freshwater bacteria (discussed in Chapter 14).

Diverse Substrates for Catabolism

Microbes catabolize many different kinds of substrates, or catabolites (**Fig. 13.11**). While in principle virtually any organic constituent may be catabolized, certain kinds of substrates are widely used. Many of these substrates are of economic and environmental significance and generate products important to our nutrition and technology.

Carbohydrate catabolism. Historically, the catabolism of carbohydrates (sugars and sugar polymers) has been important because of its relevance to human digestion and to the microbial production of food and drink (presented in Chapter 16). Glucose as such is rarely available to microbes, except to those pathogens growing within a host. But the pathways of glucose catabolism provide entry points for a diverse range of food molecules found in the environment, such as sugar chains, known as **polysaccharides**. For example, the cellulose of plant cell walls, the starch of potatoes, the pectin of fruit—all contain sugar chains that are broken down by microbial enzymes, first to short chains (oligosaccharides), then to two-sugar units (disaccharides), and then to monosaccharides such as glucose or fructose.

Even tiny differences between sugars can mean the difference between growth or starvation for a microbe. **Figure 13.12B** shows ^{13}C NMR spectra of two monosaccharides, glucose and galactose, that differ in the position of the hydroxyl group on a single carbon, C-4. This small difference is important because different microbial

Figure 13.12 **Different sugars distinguished by NMR.** **A.** Mo Hunsen (left), chemist at Kenyon College, demonstrates the use of the Bruker 300-MHz NMR. A sample is inserted into a superconducting magnet. NMR spectroscopy gives detailed information about molecules containing nuclei of odd atomic number or mass number, which possess nuclear magnetic moment. The nuclear magnetic moment of each atom interacts with electromagnetic radiation, producing a signal. **B.** ^{13}C NMR spectra distinguish two highly similar sugars, glucose and galactose, which are carbon sources for microbial catabolism. Within each sugar, the signal of each ^{13}C nucleus has a “shift” in position based on its shielding by electrons in the molecule. Because glucose and galactose each exist as an equilibrium mixture of two different isomers, each carbon is associated with two peaks with different shift positions.

Figure 13.13 Many carbon sources enter central pathways of catabolism. Carbohydrates are broken down by specific enzymes to disaccharides, then to monosaccharides such as glucose. Glucose and sugar acids are converted to pyruvate, which yields acetyl groups. Acetyl groups or acetate are also the breakdown products of fatty acids, amino acids, and complex aromatic plant materials such as lignin.

enzymes (encoded by different genes) have evolved specifically to catabolize different sugars.

Polysaccharides are hydrolyzed to products that enter central catabolic pathways such as glycolysis (**Fig. 13.13**). In some sugars, the aldehyde is replaced by a hydroxyl (sorbitol, mannitol) or a carboxylate (gluconate, glucuronate). These sugar derivatives may be taken up by specific transporters and converted to glucose by specific enzymes. Alternatively, the sugar acids (carboxylate sugars) can be broken down by the Entner-Doudoroff pathway, an important variant of glycolysis. Pyruvate is commonly reduced to fermentation products such as lactate or ethanol. In the presence of a terminal electron acceptor such as oxygen, pyruvate yields an acetyl group to the tricarboxylic acid cycle (TCA), also known as the Krebs cycle or citric acid cycle. The TCA cycle transfers electrons to the electron transport system, and ultimately the terminal electron acceptor. Glycolysis and the TCA cycle are presented in Sections 13.5 and 13.6.

Different species differ profoundly in their abilities to digest particular polysaccharides. The starches (glucans) and pectins (pectic acids) are the most widely digested. Cellulose forms particularly stable fibers that are digestible by some bacteria and fungi, but not by animals. For this reason, some animals, such as cattle and termites, require bacteria such as *Ruminococcus* and *Succinomonas* living within their digestive tracts to ferment cellulose from grasses or wood. Even humans derive about a tenth of our caloric intake from catabolism of plant fibers by bacteria such as *Bacteroides thetaomicron*. Microbiologists consider the human gut flora a functional part of the human body, and their genomes are functionally part of the human "metagenome." Medical conditions such as obesity may depend in part on the catabolic activities of gut flora.

In a complex environment such as the intestinal lumen, with numerous potential substrates for catabolism, organisms select preferred substrates based on availability and energy efficiency. Selection occurs by regulating gene expression, as discussed in Chapter 10. For example, in *E. coli*, the sugar lactose induces transcription of genes that encode beta-galactosidase (*lacZ*) and lactose permease (*lacY*). In the presence of glucose, however, a preferred carbon source, *lac* transcription is halted. Halting *lac* transcription enables preferential catabolism of glucose. The process of prioritized consumption of substrates is known as **catabolite repression**.

Catabolism of lipids and amino acids. Many bacteria respire lipids from sources such as milk, animal fats, and nuts; this causes the rancid odor of partly oxidized lipids in meat or butter. Lipids are catabolized by hydrolysis to glycerol and fatty acids (see **Fig. 13.13**). Glycerol, a three-carbon triol, can enter catabolism either as a three-carbon intermediate of glycolysis or through breakdown to acetate, entering the TCA cycle. Fatty acids undergo oxidative breakdown to acetyl groups.

Amino acids are the building blocks of proteins, but when present in excess of the cell's needs, they are catabolized to provide energy. Specific enzymes catalyze the early steps in the degradation of each amino acid until products are formed that can enter common pathways of carbohydrate catabolism or the TCA cycle. The initial step of amino acid degradation is one of two kinds: decarboxylation (removal of CO_2) to produce an amine (**Fig. 13.14**); or deamination (removal of NH_3) to produce a carboxylic acid. Carboxylic acids are degraded through the TCA cycle. Amine products, such as cadaverine and putrescine, are often excreted, causing the noxious odor of decomposing flesh. In general, microbes favor decarboxylation during growth at low pH, because the amine products buffer the cell against acidity. Growth at higher pH favors deamination, because the acidic products buffer the cell against alkalinization.

The initial steps of amino acid catabolism are regulated genetically by multiple factors, including substrate availability and environmental conditions such as pH. In *E. coli*, low pH induces expression of several amino acid decarboxylases that release amines raising pH. An example is the *cadBA* operon encoding lysine permease and lysine decarboxylase (see **Fig. 13.14**). Expression of *cadBA* is induced by lysine binding to the membrane-bound regulator LysP; by acid, which changes the conformation of regulator CadC; and by low oxygen, which increases transcription by unknown means.

Other reactions of amino acids generate small amounts of products with intense odors and flavors. Products of amino acid catabolism confer some of the distinctive flavors of fermented foods and beverages. For example, catabolites of aspartate and methionine generate the flavors of cheese (**Special Topic 13.2**). Microbial food production is discussed in Chapter 16.

Aromatic catabolism. Aromatic compounds are more difficult to digest than sugars because of the exceptional stability of aromatic ring structures. Yet many bacteria metabolize benzene derivatives, and even polycyclic aromatic molecules, either partly or all the way to CO_2. A particularly important aromatic substance found in nature is **lignin** (see **Fig. 13.11B**), which forms the key structural support of trees and woody stems. A discouragingly complex molecule, lignin is made from sugars oxidized to benzene rings, with ether connections that are difficult for enzymes to break down. Certain fungi and soil bacteria have evolved to digest lignin, ultimately directing its carbon into the TCA cycle.

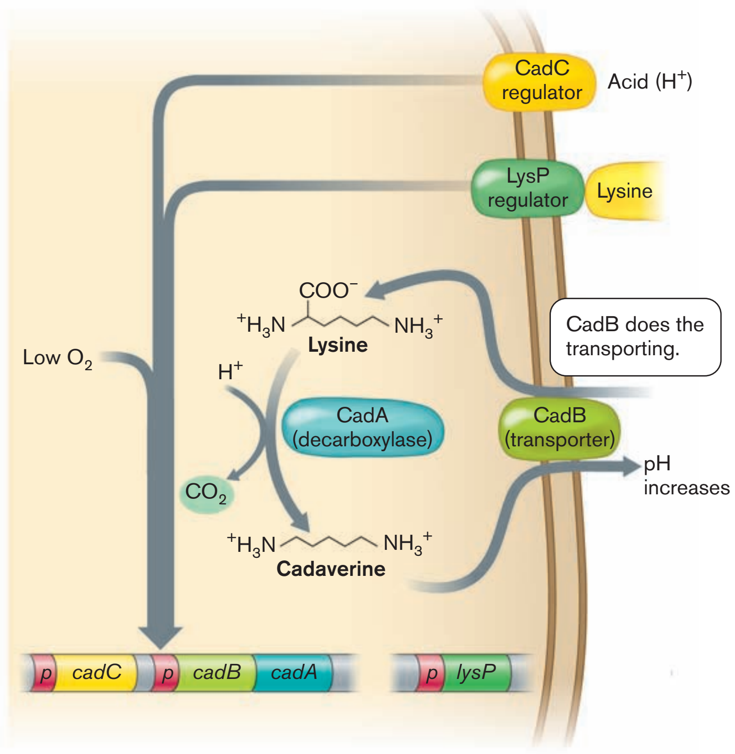

Figure 13.14 Lysine catabolism responds to the environment. Transcription of the operon encoding lysine transporter (CadB) and lysine decarboxylase (CadA) is induced by acid, lysine, and low oxygen concentration.

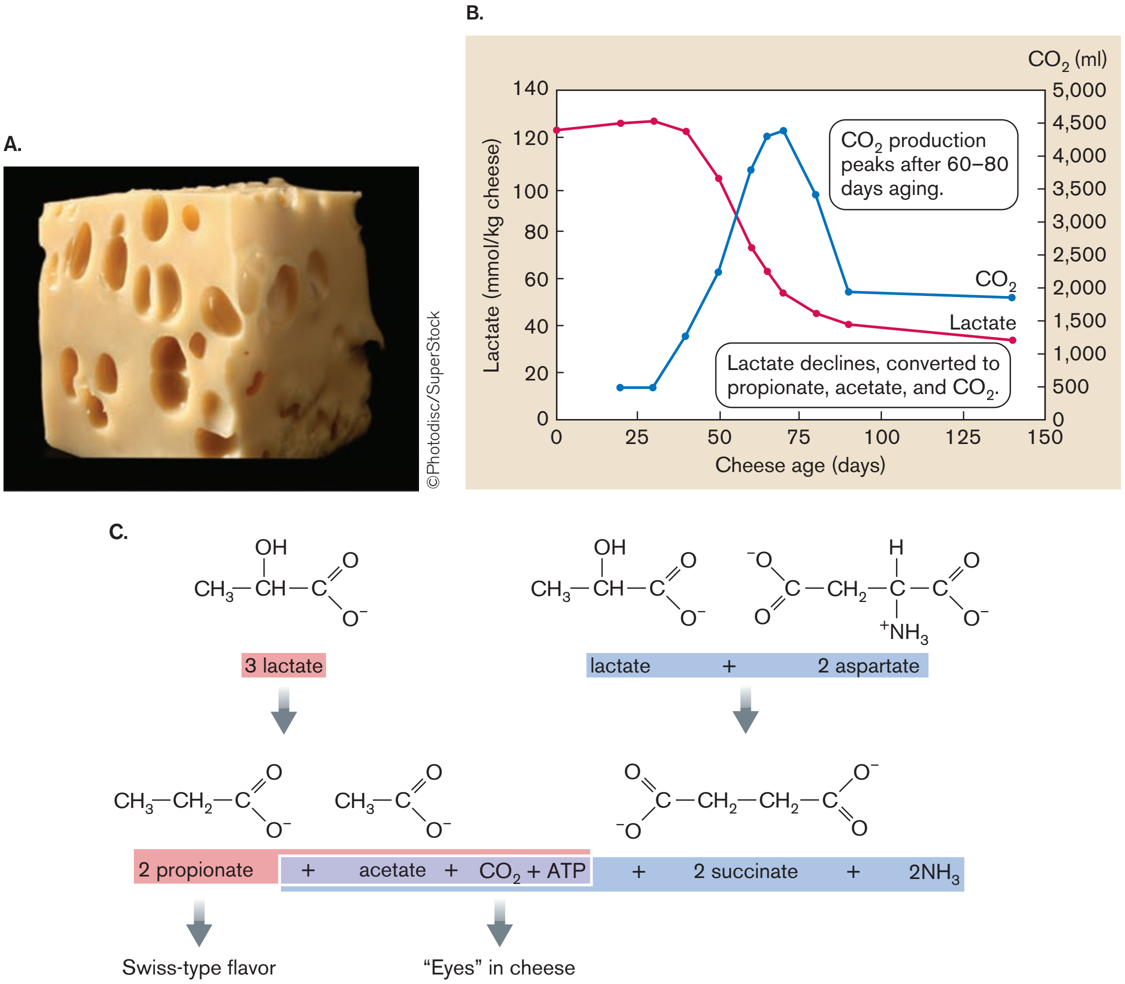
Special Topic 13.2 Swiss Cheese: A Product of Bacterial Catabolism

Swiss cheese is famous for its large, round holes, known as "eyes," as well as for its distinctive flavor (**Fig. 1A**). Both the eyes and the flavor derive from common pathways of bacterial fermentation that occur during cheese production. The original Swiss cheese, or Emmentaler, was made in the Emmen valley from cows pastured in the mountains. Today, related "Swiss-type" cheeses such as Jarlsburg are produced in large quantities throughout Europe and America.

Emmentaler cheese production involves two fermentation stages. The first stage, at high temperature, is dominated



©Photodisc/SuperStock

Figure 1 Swiss cheese (Emmentaler) involves fermentation of lactate to propionate. A. Swiss cheese (Emmentaler). **B.** As a Swiss cheese ages, lactate declines and CO$_2$ rises, gradually forming the "eyes" (holes). **C.** Lactate is fermented by *Propionibacterium freudenreichii* to propionate, acetate, and CO$_2$. Concurrent fermentation of lactate and aspartate generates additional CO$_2$, increasing the size and number of eyes.

Today, the environment contains increasing amounts of aromatics, including growing amounts of halogenated aromatics, such as polychlorinated biphenyls. These compounds, produced for herbicides and other industrial uses, are the source of highly toxic dioxins. These substances concentrate in the food chain, reaching levels potentially dangerous to human consumers. Halogenated aromatics turn out to be catabolized by a number of soil microbes, which offer promising candidates for bioremediation of polluted environments (described in Section 13.7).

by thermophilic lactic acid bacteria such as *Lactobacillus helveticus* and *Streptococcus salivarius*. Lactic acid bacteria ferment the milk sugar lactose, a disaccharide of glucose and galactose, generating mainly lactic acid. The high temperature ensures rapid buildup of acid and retards growth of harmful species from the unpasteurized milk.

The second fermentation stage is unique to Swiss-type cheeses. The fermented milk curd is cooled and inoculated with *Propionibacterium freudenreichii*, a species that converts lactate to propionate, acetate, and CO_2 (**Figs. 1B** and **C**). This propionic fermentation generates another ATP, in addition to the ATPs of glycolysis. Propionic fermentation proceeds at cool temperatures, very slowly, over many months. During this period as the cheese is "aged," lactate declines while CO_2 increases. The gradual CO_2 production forms the eyes, or holes, for which Swiss cheese is known. The propionate contributes to the distinctive flavor.

The optimal production of eyes and flavor depends on several side pathways of fermentation of amino acids. Fermentation of aspartate plus lactate generates additional CO_2, thus increasing the size of the eyes, and increases the overall efficiency of lactate fermentation. Thus, addition of aspartate as well as use of a strongly aspartate-fermenting bacterial strain can enhance the quality of the cheese.

The full flavor of a cheese results from a large number of minor fermentation pathways that produce trace amounts of aldehydes, esters, alcohols, and ketones. One substance that contributes to the Swiss-type flavor is methional, a derivative of methionine (**Fig. 2**). During the initial fermentation by lactic acid bacteria, small amounts of methionine are deaminated and decarboxylated to methional, a strong odorant. An alternative side reaction generates methanethiol, an odorant more characteristic of cheddar cheese. The basis for favoring one pathway or another remains unknown, but these side reactions are responsible for generating many distinctive varieties of cheeses. Microbial food production is discussed further in Chapter 16.

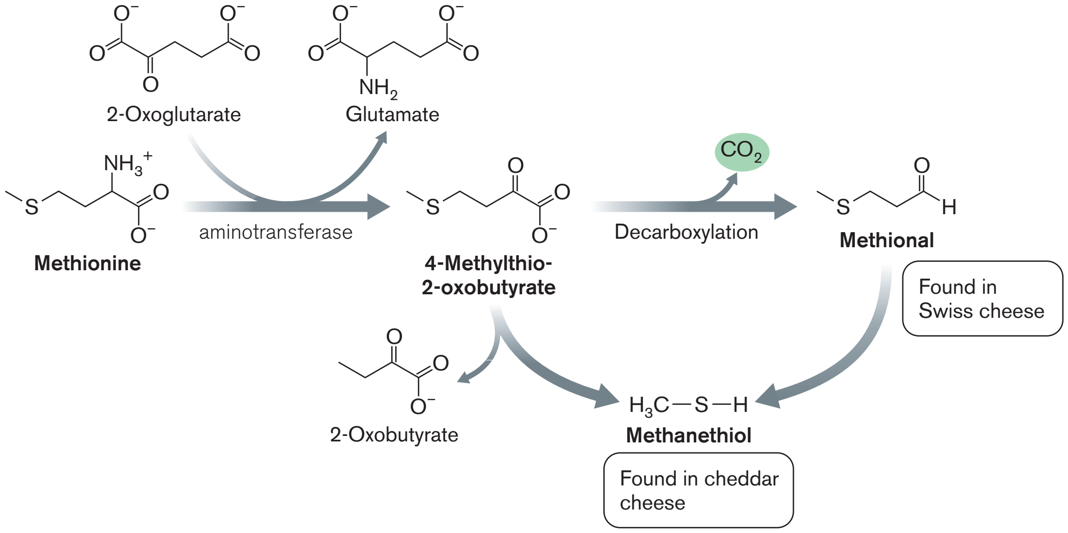


Figure 2 Methionine is fermented to flavor molecules. Methionine undergoes deamination and oxidation, followed by decarboxylation to methional, an aldehyde odorant characteristic of Swiss cheese. Alternative reactions generate methanethiol, more typical of cheddar.

A given species of bacteria or fungi may catabolize thousands of different carbon sources, each requiring specific transporters and enzymes for initial breakdown. In most cases, these products ultimately funnel into one of a few common pathways of metabolism. The remainder of this chapter presents key pathways in detail: glycolysis and other pathways of glucose catabolism; the TCA cycle; and the catechol pathway of benzoate catabolism. These pathways play key roles in medical microbiology and in industrial fields such as bioremediation.

TO SUMMARIZE:

- **Fermentation, respiration, and photoheterotrophy are forms of catabolism.** In fermentation, the catabolite is broken down to smaller molecules without an inorganic electron acceptor. Respiration requires an inorganic terminal electron acceptor such as O_2 or nitrate. In photoheterotrophy, catabolism is supplemented by light absorption.
- **Carbohydrates or polysaccharides are broken down to disaccharides, then to monosaccharides.** Sugars and sugar derivatives, such as amines and acids, are catabolized to pyruvate.
- **Pyruvate and other intermediary products of sugar catabolism are fermented, or they are further catabolized to CO_2 and H_2O through the TCA cycle** (in the presence of a terminal electron acceptor).
- **Lipids and amino acids are catabolized to glycerol and acetate** as well as other metabolic intermediates.
- **Aromatic compounds such as lignin and benzoate derivatives** are catabolized to acetate through different pathways, such as the catechol pathway.

13.5 Glucose Breakdown and Fermentation

Glucose catabolism is important not only as a widespread source of energy, but also as a source of key substrates for biosynthesis such as five-carbon sugars to build nucleic acids (discussed in Chapter 15). Glucose and related sugars are catabolized through a series of phosphorylated sugar derivatives. A common theme in sugar catabolism is the split of a six-carbon substrate into two three-carbon products. The three-carbon products may yield two molecules of pyruvate:

$$C_6H_{12}O_6 \;\square\; 2C_3H_4O_3 + 4H \text{ (on NADH)}$$

Under anaerobiosis—the prevailing condition of many microbial habitats—the pyruvate obtained from sugar breakdown must be converted to forms that receive electrons from NADH, in order to restore the electron-accepting form NAD^+. Different microbes reduce pyruvate to different end products of fermentation. Alternatively, through anaerobic respiration, NADH may reduce an electron acceptor such as oxygen or nitrate, allowing pyruvate to feed into the TCA cycle (discussed in Section 13.6).

NOTE: The carboxylic acid intermediates of metabolism exist in equilibrium with their dissociated, or ionized, form, identified by the suffix *-ate*. For example, lactic acid dissociates to lactate; acetic acid dissociates to acetate. We use the "-ate" terms for acids whose ionized form predominates under typical cell conditions (around pH 7).

To catabolize glucose, bacteria and archaea use three main routes to pyruvate (**Fig. 13.15**):

- **Glycolysis** or the **Embden-Meyerhof-Parnas (EMP) pathway**, in which glucose 6-phosphate isomerizes to fructose 6-phosphate, ultimately yielding two molecules of pyruvate. EMP is used by many bacteria, eukaryotes, and archaea. From each glucose, the pathway generates net 2ATP and 2NADH.
- **Entner-Doudoroff (ED) pathway**, in which glucose 6-phosphate is oxidized to 6-phosphogluconate, a phosphorylated sugar acid. Alternatively, sugar acids may be converted directly to 6-phosphogluconate. Sugar acids often derive from intestinal mucus, and the ED pathway is essential for enteric bacteria to colonize the intestinal epithelium. The ED pathway generates only one ATP, one NADH, and one NADPH.
- **Pentose phosphate shunt (PPS)**, in which glucose 6-phosphate is oxidized to 6-phosphogluconate, then decarboxylated to a five-carbon sugar (pentose), ribulose 5-phosphate. The PPS produces sugars of three to seven carbons, which serve as precursors for biosynthesis or convert to pyruvate as needed. The PPS generates one ATP plus 2NADPH, the reducing cofactor most commonly associated with biosynthesis.

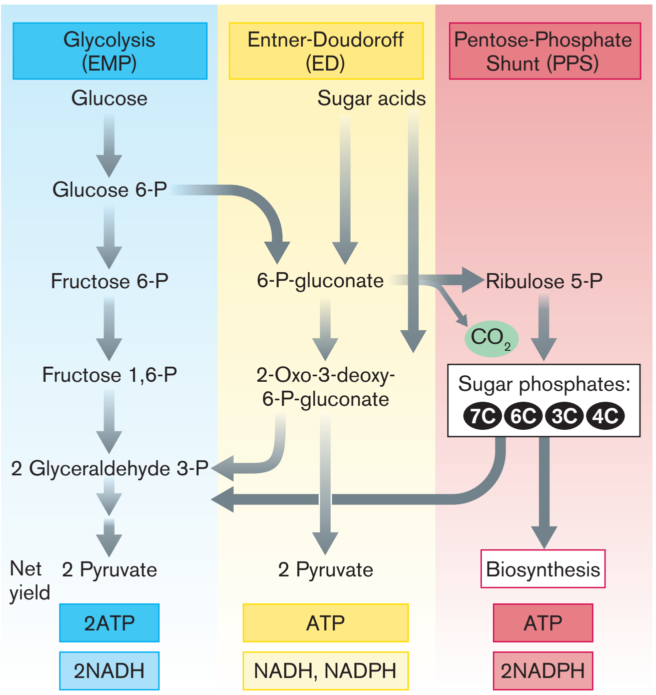

Figure 13.15 From glucose to pyruvate: three pathways. The Embden-Meyerhof-Parnas (EMP) pathway of glycolysis, the Entner-Doudoroff (ED) pathway, and the pentose-phosphate shunt (PPS) each catabolize carbohydrates by related but different routes.

The Embden-Meyerhof-Parnas Pathway Generates ATP and NADH

The Embden-Meyerhof-Parnas (EMP) pathway, or glycolysis, is the form of glucose catabolism most commonly studied in introductory biology; it is central for animals and plants as well as many bacteria. In the EMP pathway, one molecule of D-glucose undergoes stepwise breakdown to two molecules of pyruvic acid (or its anion, pyruvate) (**Fig. 13.16**). The breakdown of glucose takes place in two stages. In the first stage, the glucose molecule is primed for breakdown by two steps of sugar phosphorylation by ATP. Each ATP phosphotransfer step requires input of Gibbs energy. The phosphoryl groups tag two sides of the glucose for splitting into two three-carbon molecules of glyceraldehyde 3-phosphate (G3P). In the second stage, each glyceraldehyde 3-phosphate is oxidized by NAD^+ through steps leading to pyruvate. Each conversion of glyceraldehyde 3-phosphate to pyruvate forms two molecules of ATP, one from dephosphorylation of the substrate and one from the addition of inorganic phosphate. The net gain of energy carriers is two molecules of NADH plus two molecules of ATP.

Most of the conversion steps are associated with a small change in energy, so small that the sign of ΔG depends on the concentrations of substrates or products; thus, some individual steps are reversible. In the cytoplasm, however, as intermediate products form, they are quickly consumed by the next step, and so the pathway flows in one direction. The direction of flow is determined by the key irreversible reactions that consume ATP. These steps "prime" the pathway by spending energy.

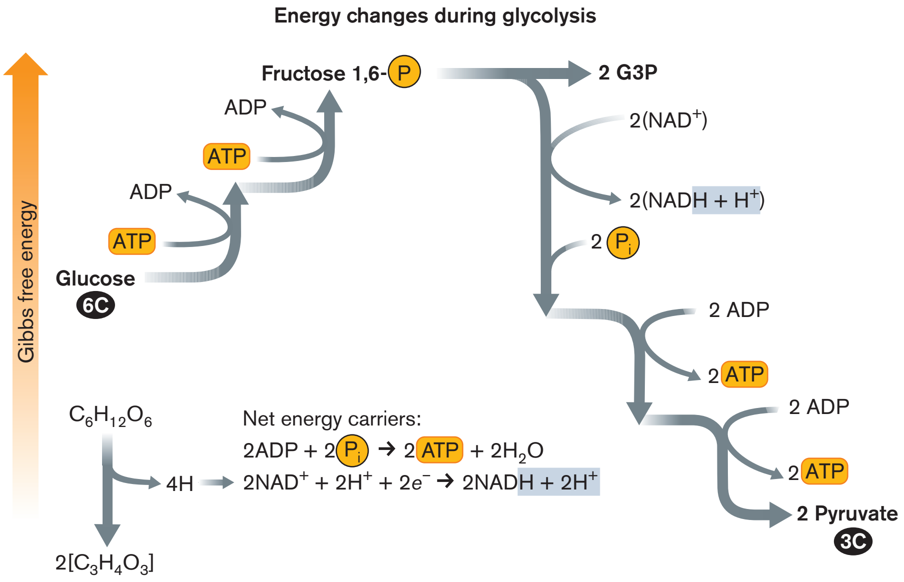
Phosphorylation and splitting of glucose. In the first stage of the EMP pathway, the six-carbon sugar is activated by two phosphorylation steps (**Fig. 13.17**). The first phosphoryl group (phosphate) is added at carbon 6 of glucose. (In some species of bacteria, the first phosphoryl group is added by phosphoenolpyruvate instead of ATP, but the net effect is the same.) The next enzyme-catalyzed step, rearrangement of glucose 6-phosphate to fructose 6-phosphate, involves no significant change in energy, but prepares the sugar to receive the second phosphoryl group, yielding fructose 1,6-bisphosphate.

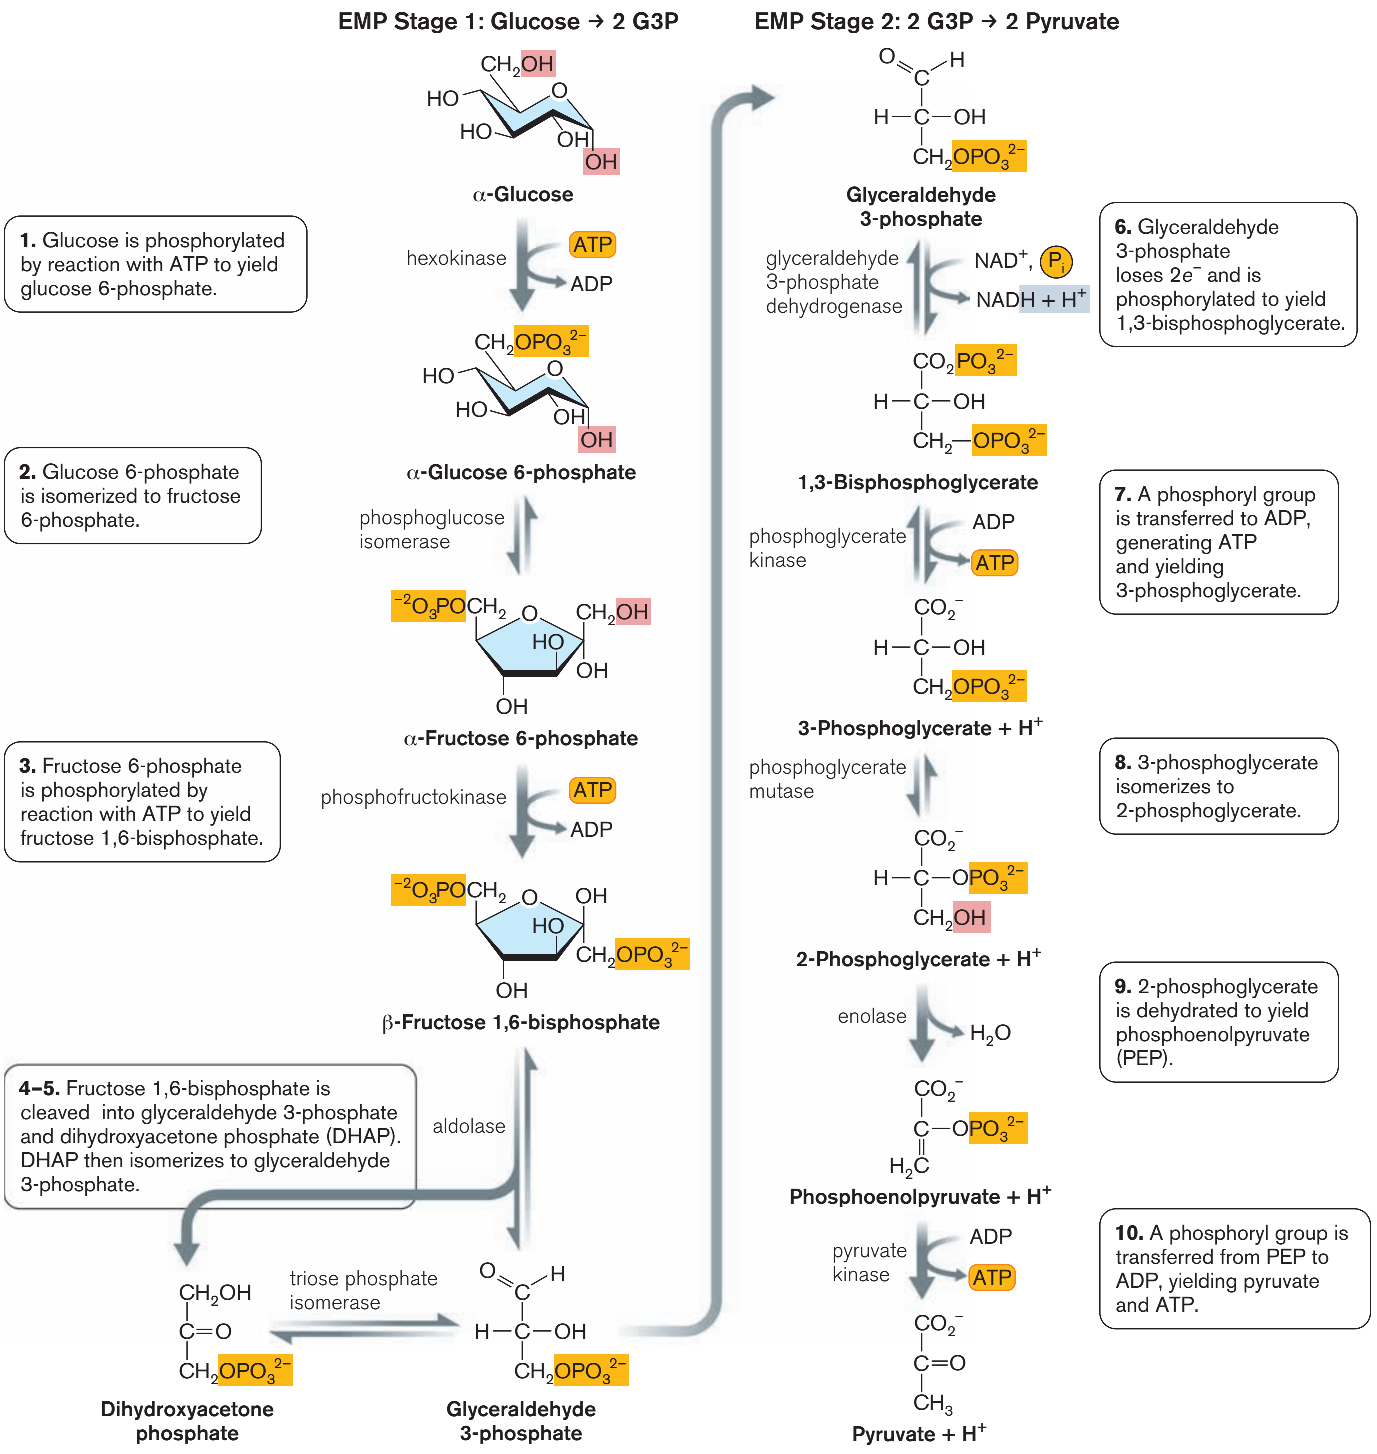
The sugar then splits into two three-carbon sugars (trioses), each tagged with one of the two phosphates. The splitting of this molecule has a favorable entropy change (ΔS), but its chemical change (ΔH) is unfavorable, largely canceling out the energy yield. The two triose phosphates, glyceraldehyde 3-phosphate and dihydroxyacetone phosphate, have nearly the same energy value, so an enzyme interconverts them reversibly. Interconversion is necessary because only glyceraldehyde 3-phosphate proceeds further in the pathway.

THOUGHT QUESTION 13.8 Some bacteria make an enzyme, dihydroxyacetone kinase, that phosphorylates dihydroxyacetone to dihydroxyacetone phosphate. Why would this enzyme be useful?

NOTE: In Chapters 13–16, every substrate conversion shown requires catalysis by an enzyme. For the EMP pathway, the enzymes are shown, but for other pathways, the enzyme names are omitted.

Figure 13.16 Energy changes during the Embden-Meyerhof-Parnas pathway of glycolysis. Glucose is activated through two substrate phosphorylations by ATP. The breakdown of glucose to two molecules of pyruvate is coupled to net production of two ATP and two NADH.





EMP Stage 1: Glucose → 2 G3P

EMP Stage 2: 2 G3P → 2 Pyruvate

1. Glucose is phosphorylated by reaction with ATP to yield glucose 6-phosphate.

2. Glucose 6-phosphate is isomerized to fructose 6-phosphate.

3. Fructose 6-phosphate is phosphorylated by reaction with ATP to yield fructose 1,6-bisphosphate.

4–5. Fructose 1,6-bisphosphate is cleaved into glyceraldehyde 3-phosphate and dihydroxyacetone phosphate (DHAP). DHAP then isomerizes to glyceraldehyde 3-phosphate.

6. Glyceraldehyde 3-phosphate loses 2e^- and is phosphorylated to yield 1,3-bisphosphoglycerate.

7. A phosphoryl group is transferred to ADP, generating ATP and yielding 3-phosphoglycerate.

8. 3-phosphoglycerate isomerizes to 2-phosphoglycerate.

9. 2-phosphoglycerate is dehydrated to yield phosphoenolpyruvate (PEP).

10. A phosphoryl group is transferred from PEP to ADP, yielding pyruvate and ATP.

Figure 13.17 Embden-Meyerhof-Parnas pathway (glycolysis).

ATP generation. In glycolysis, each three-carbon glyceraldehyde 3-phosphate is directed into an energy-yielding pathway to pyruvate. First, the aldehyde (R-CHO) is converted to the carboxylate (R-COO$^-$ + H$^+$). Conversion to a carboxylate releases a substantial amount of energy (negative ΔG). This oxidation of the aldehyde represents the major source of energy in glycolysis—the step at which the energy obtained is used to transfer a pair of electrons onto NAD$^+$, forming NADH with an ionized H$^+$. In addition, sufficient energy is released to add a phosphoryl group (from inorganic phosphate, P_i) to the carboxylate, generating 1,3-bisphosphoglycerate.

In subsequent steps, the added phosphoryl group will be transferred to ADP, yielding the one net ATP generated per pyruvate (two per glucose). The transfer of a phosphoryl group from an organic substrate to make ATP is called **substrate-level phosphorylation**. With subtraction of the initial two ATP molecules invested, the net energy carriers gained from each glucose are as follows:

$$2NAD^+ \rightarrow 2NADH + 2H^+$$

$$2ADP + P_i \rightarrow 2ATP + 2H_2O$$

THOUGHT QUESTION 13.9 In the EMP pathway, how are the two water molecules generated?

Regulation of glycolysis. Enzymes of catabolism are regulated at the level of transcription of the enzyme. In addition, the activities of certain enzymes in long pathways require allosteric regulation. Allosteric regulation by enzyme substrates and products ensures that excess intermediates do not build up and avoids releasing more energy than the cell can use at a given time. Glycolysis is regulated so that its reactions go forward only when the cell needs energy, not when the cell is trying to synthesize glucose. The regulation occurs at steps where the products are consumed so rapidly that their forward reaction is effectively irreversible. Irreversible steps are shown as unidirectional arrows in **Figure 13.17**.

Enzymes that catalyze irreversible steps are regulated so as to maintain consistent levels of intermediates in the pathway. The most important irreversible reaction in glycolysis is the phosphorylation of fructose 6-phosphate to fructose 1,6-bisphosphate, mediated by the enzyme phosphofructokinase. This enzyme is activated allosterically by ADP and inhibited by ATP or by the alternative phosphoryl donor, phosphoenolpyruvate.

What happens when the cell needs to reverse glycolysis in order to make glucose? Most of the intermediate reactions are reversible, and so the same enzymes can be used for biosynthesis. Pathways that participate in both catabolism (breakdown) and anabolism (biosynthesis) are called **amphibolic**.

An amphibolic pathway such as glycolysis includes enzymes such as phosphoglucose isomerase that can run in either direction, but also requires key enzymes that operate only in the catabolic direction or in the anabolic direction. For example, in glycolysis the ATP phosphorylation of fructose 6-phosphate is catalyzed by the enzyme phosphofructokinase, whereas in biosynthesis this step is reversed by a different enzyme, fructose bisphosphatase. Instead of regenerating ATP, fructose bisphosphatase removes the second phosphoryl group as inorganic phosphate—a step releasing energy and thus driving the whole pathway in reverse (toward biosynthesis of sugar). The two enzymes are regulated differently; the catabolic enzyme phosphofructokinase is activated by ADP, a signal of energy need, whereas the biosynthetic enzyme is inhibited by such signals.

The Entner-Doudoroff Pathway Catabolizes Sugar Acids

The Entner-Doudoroff (ED) pathway offers a slightly different route to catabolize sugars as well as sugar acids (sugars with acidic side chains). The ED pathway was originally studied for its role in production of the Mexican beverage *pulque*, or "cactus beer," by *Zymomonas* fermentation of the blue agave plant. More recently, Tyrrell Conway and colleagues have found genes encoding the Entner-Doudoroff enzymes in the genomes of numerous bacteria and archaea. In the human colon, the ED pathway enables *E. coli* and other enteric bacteria to feed on mucus secreted by the intestinal epithelium (**Fig. 13.18**). Some gut flora, such as *Bacteroides thetaiotaomicron*, actually induce colonic production of the mucus that they consume. These bacteria that "farm" intestinal mucus may enhance human health by preventing colonization by pathogens.

The ED pathway probably evolved earlier than the EMP pathway, as it involves fewer substrate phosphorylation steps and produces less ATP, and it is found in a wider range of prokaryotes. As in the EMP pathway, glucose is phosphorylated to glucose 6-phosphate (**Fig. 13.19**). The next step, however, involves oxidation by NAD^+ at carbon 1, with loss of two hydrogens to form 6-phosphogluconate. Gluconate is a sugar acid found in intestinal mucus; it can be phosphorylated to enter the ED pathway.

The hydrogens and electrons from glucose 6-phosphate are transferred to $NADP^+$, instead of the NAD^+ as in the EMP pathway. This step differs from the EMP pathway in two respects: The carrier used is $NADP^+$ instead of NAD^+, and the electron transfer occurs early,

Figure 13.18 Intestinal bacteria use the Entner-Doudoroff pathway. **A.** Intestinal *E. coli* (orange) primarily feed on gluconate from mucus secretions (fluorescence micrograph). **B.** Tyrrell Conway, at the University of Oklahoma, used genomics and genetic analysis to dissect the role of the Entner-Doudoroff pathway in the enteric bacterial catabolism of sugar acids from intestinal mucus.

without a second ATP-consuming phosphorylation step. When the six-carbon substrate is eventually split into two three-carbon products, one of the three-carbon products is glyceraldehyde 3-phosphate, which enters the second stage of glycolysis. NADH is made, and two ATP are made by substrate-level phosphorylation. The remaining three-carbon product, however, is pyruvate. This one-step production of pyruvate short-circuits the catabolic pathway, missing the formation of an ATP. The unused potential energy is released as waste heat.

The net ATP gain from the Entner-Doudoroff pathway is only one ATP per molecule of glucose, half that of the EMP pathway (see page 483 and **Fig. 13.15**). The electrons transferred, however, are equivalent: Instead of two molecules of NADH, the Entner-Doudoroff pathway generates one NADH and one NADPH.

THOUGHT QUESTION 13.10 Explain why the ED pathway generates only one ATP, whereas the EMP pathway generates two.

The Pentose Phosphate Shunt Yields NADPH and Substrates for Biosynthesis

A third pathway of glucose catabolism is the pentose phosphate shunt (PPS), which forms the key intermediate **ribulose 5-phosphate**, a five-carbon sugar. The pentose phosphate shunt generates one ATP with no NADH, but two NADPH for biosynthesis (**Fig. 13.20**). In addition, PPS generates a more complex series of intermediates than the EMP or ED pathway, which can be redirected as substrates for biosynthesis of diverse cell components such as amino acids and vitamins.

The pentose phosphate shunt starts like the Entner-Doudoroff pathway: Glucose 6-phosphate gives up two electrons to form NADPH and is oxidized to 6-phosphogluconate. Thus, only one net ATP is gained from breakdown to pyruvate. The next step involves a second oxidation to NADPH, with loss of a carbon as CO_2. The loss of CO_2 generates the five-carbon sugar ribulose 5-phosphate (hence the pathway name "pentose phosphate"). In succeeding steps, pairs of sugars, such as

sedoheptulose 7-phosphate and glyceraldehyde 3-phosphate, exchange short carbon chains, giving rise to sugar phosphates of various lengths—for example, ribose 5-phosphate and erythrose 4-phosphate, which are precursors of purines and aromatic amino acids, respectively. Alternatively, if these routes to biosynthesis are not taken, the intermediates convert to fructose 6-phosphate and reenter the EMP pathway, where ATP and NADH are produced.

Fermentation Completes Catabolism and Yields Useful Products

None of the pathways from glucose to pyruvate constitutes a completed pathway of catabolism, because NADH and NADPH remain to be recycled. In the absence of oxygen or other electron acceptors, heterotrophic cells must transfer the hydrogens from NADH + H^+ back onto the

products of pyruvate, forming partly oxidized fermentation products with the same redox level (balance of O and H) as the original glucose. For example, glucose may be fermented to two molecules of lactic acid (**lactate fermentation**) or two molecules of ethanol plus two CO_2 (**ethanolic fermentation**) or one lactic acid, one ethanol, and one CO_2 (**heterolactic fermentation**). These fermentation products are then excreted from the cell.

Most fermentation pathways do not generate ATP beyond that produced by substrate-level phosphorylation, the direct transfer of a phosphate group from an organic phosphate to ADP. An example is the final step of glycolysis, catalyzed by pyruvate kinase (**Fig. 13.17**). Much of the energy available from glucose remains unspent or is lost as heat. Nevertheless, fermentation is essential for microbes in environments such as anaerobic soil or animal digestive tracts. Even aerated cultures of bacteria start fermenting once their demand for oxygen exceeds the rate of oxygen dissolving in water. Microbes compensate for the low efficiency of fermentation by consuming large quantities of substrate.

Fermentation pathways. The large quantities of substrate consumed in fermentation generate large amounts of waste products to be excreted. Numerous different pathways have evolved to dispose of the waste in different forms (**Fig. 13.21**). *E. coli* ferments mainly by the mixed-acid pathway, yielding acetate, formate, lactate, and succinate, as well as ethanol, H_2, and CO_2. The mix of products varies with pH; low pH favors ethanol and lactate (which minimize acidification) in preference to formate and acetate. *Clostridium* species produce alcohols (butanol, isopropanol), whereas *Porphyromonas gingivalis*, a cause of periodontal disease, produces short-chain acids (propionate, butyrate).

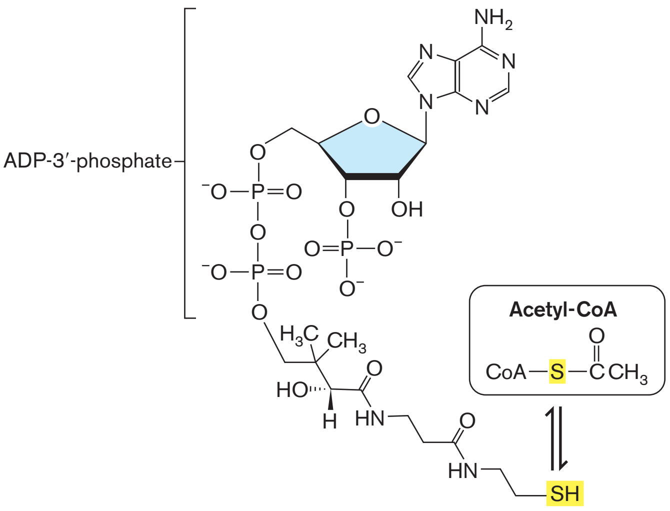

Figure 13.22 Structure of coenzyme A. The thiol (SH) forms an ester link with the COOH of acetic acid, generating acetyl-CoA.

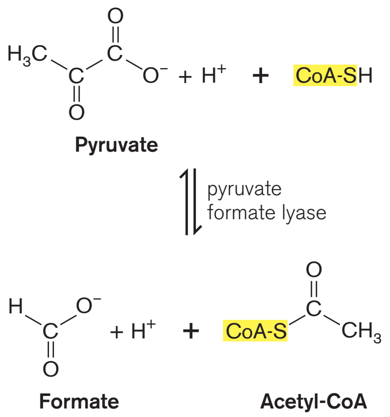
Many fermentation products share key intermediates, such as **acetyl-CoA**. Acetyl-CoA is a versatile two-carbon intermediate, the "Lego block" of metabolism. It consists of an acetyl group esterified to **coenzyme A** (**CoA**; **Fig. 13.22**), a famous coenzyme whose discovery won Fritz Lipmann the 1953 Nobel Prize in Medicine with Hans Krebs. CoA has a thiol (–SH) that exchanges its hydrogen for an acyl group, thus activating the molecule for transfer in various metabolic pathways.

THOUGHT QUESTION 13.11 How does the structure of coenzyme A resemble that of NADH? How does it differ?

In the mixed-acid fermentation pathway, typical of *E. coli* and *Salmonella*, the enzyme pyruvate formate lyase splits pyruvate to form acetyl-CoA plus formate:



The SH group of CoA is indicated to emphasize its role in accepting the acetyl group to form acetyl-CoA. The hydrogen ($H^+ + e^-$) of the SH group is transferred onto the carboxyl carbon of pyruvate, generating formate.

Acetyl-CoA can be converted to different fermentation products by several different pathways. The simplest is water exchange with CoA, yielding acetate:

$$CH_3CO{-}S{-}CoA + H_2O \rightleftharpoons CH_3COO^- + H^+ + HS{-}CoA$$

Incorporation of water restores the hydrogen to the thiol of CoA and the OH to acetate. The acetate thus formed may then be excreted by the cell.

Note that the excreted acids and alcohols are readily recovered by cells when an electron acceptor becomes available for oxidation or when these fermentation products are needed as building blocks for biosynthesis. Alternatively, the excreted "wastes" may be utilized by other species capable of fermenting them further.

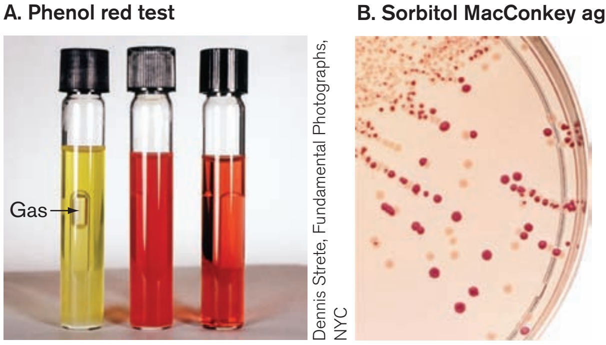
Food and industrial applications. The "waste products" of fermentation retain much of their organic structure and food value. Thus, fermentation products have proved extremely useful in human culture and technology. For thousands of years, ethanolic fermentation by yeast has been used to produce wine and beer, while lactate fermentation has been used to produce yogurt and cheese. The minor product butyric acid (butyrate) lends taste to butter. Similarly, propionic acid (propionate) provides the distinctive flavor of Swiss cheese, while CO_2 gas generates the holes, or "eyes" (see **Special Topic 13.2**).

In the chemical industry, microbial fermentation produces industrial solvents such as butanol and acetone. Acetone production had historic impact during the World War I, when Britain needed a source of acetone to manufacture gunpowder. Acetone and butanol were produced as fermentation products by *Clostridium acetobutylicum*, a bacterium identified by the biochemist Chaim Weitzmann. Weitzmann was a Russian-born Jew who sought a Jewish homeland in Palestine. At the end of the war, Weitzmann's process for acetone production helped earn him the British government's support for the national homeland of Israel, where the biochemist later became the country's first president.

Today, microbial fermentation produces many "commodity chemicals" such as ethanol, butanol, and glycerol. Compared to industrial alternatives, such as production from petroleum, microbial culture is environmentally desirable and energy efficient. Furthermore, microbes are "smart" producers of small but complex pharmaceuticals such as vitamins, amino acids, and antibiotics, molecules that would require many steps of organic synthesis. Applications of microbial biosynthesis are discussed further in Chapters 15 and 16.

Diagnostic applications. Another important application of fermentation lies in diagnostic microbiology. To quickly identify the microbe causing a disease and prescribe an effective antibiotic, hospitals use rapid and inexpensive biochemical tests. A general test for fermentation pathways is the **phenol red broth test** (**Fig. 13.23A**). Phenol red is a pH indicator, which is orange-red at neutral pH. It turns yellow in medium acidified by fermentation acids (below pH 6.8) and red at higher pH (above pH 7.4). A culture of *Escherichia coli*, which ferments quickly, turns phenol red to a medium yellow after 24 hours. *Alcaligenes faecalis*, meanwhile, ferments poorly on sugar but converts peptides in the broth to alkaline amines; this culture turns deep red.

More specific tests depend on the microbe's ability to ferment specific sugars. Different species possess different enzymes able to convert different sugars and sugar derivatives to glucose, which then enters the common fermentation pathway. A well-known example is the use of sorbitol MacConkey agar to test for *E. coli* O157:H7, a lethal pathogen contaminating ground beef and cider. The pathogen lacks the ability to ferment sorbitol, so failure to ferment sorbitol indicates a high probability that the strain is *E. coli* O157:H7. On sorbitol MacConkey agar, bacteria that ferment sorbitol during growth produce acids. The acidity causes a dye to turn red (the opposite of the phenol red test). Failure to ferment sorbitol (observed as pale colonies) indicates high probability of *E. coli* O157:H7 (**Fig. 13.23B**).



Dennis Strete, Fundamental Photographs, NYC

Troy Biological BD Worldwide

Figure 13.23 Clinical tests based on fermentation.
A. Phenol red broth test. Organisms are cultured in a tube of broth containing phenol red. The dye turns yellow when protonated at low pH. Phenol red is orange-red at neutral pH, yellow at lower pH (acid), and red at higher pH (base). A small inverted tube (Durham tube) collects gaseous fermentation products (CO_2 and H_2). Left to right: *Escherichia coli* gives acidic fermentation products (yellow) and gas in Durham tube; *Alcaligenes faecalis* does not ferment, tube turns red without gas; uninoculated control, red. **B.** Sorbitol fermentation test for pathogen *E. coli* O157:H7. White colonies (strain O157:H7) fail to ferment sorbitol, unlike red colonies (nonpathogenic *E. coli*).

TO SUMMARIZE:

- **Glucose catabolism** occurs by three related pathways of stepwise degradation of glucose to pyruvate. In the absence of oxygen, completion of catabolism requires generation of fermentation products.
- **In the Embden-Meyerhof-Parnas (EMP) pathway**, glucose is activated by two substrate phosphorylations, then cleaved to two three-carbon sugars. Both sugars eventually are converted to pyruvate. The pathway produces 2 ATPs and 2 NADHs.
- **In the Entner-Doudoroff (ED) pathway**, glucose is activated by one phosphorylation, then dehydrogenated to 6-phosphogluconate. 6-Phosphogluconate is cleaved to pyruvate and a three-carbon sugar, which enters the EMP pathway to form pyruvate. The ED pathway produces 1 ATP, 1 NADH, and 1 NADPH.
- **In the pentose phosphate shunt**, 6-phosphogluconate is converted to a series of sugars of carbon length 3 to 7, including fructose 6-phosphate, which reenters the EMP pathway.
- **Intermediates of sugar catabolism may serve as substrates for biosynthesis** of amino acids and other cell components.
- **Glucose catabolism is reversible**, enabling cells to build glucose from small molecules. Glucose biosyn-

thesis uses some enzymes of glycolysis in reverse, but also requires enzymes that bypass irreversible steps in the catabolic pathway.

- **Fermentation is the completion of catabolism** *without* the electron transport system and a terminal electron acceptor. The electrons from NADH are restored to pyruvate or its products in reactions that generate fermentation products, including alcohols and carboxylates as well as H_2 and CO_2. Fermentation has applications in food, industrial, and diagnostic microbiology.
- **Acetyl-CoA is a key intermediate** in several fermentation pathways.

13.6 The Tricarboxylic Acid (TCA) Cycle

In the presence of O_2 or another terminal electron acceptor, the products of sugar breakdown can be catabolized to CO_2 and H_2O through the **tricarboxylic acid (TCA) cycle**. The TCA cycle is also known as the Krebs cycle, named for Hans Krebs (1900–1981) who shared the 1953 Nobel Prize in Medicine with Fritz Lipmann. Krebs and his colleagues at Sheffield University, England, studied catabolism by observing the oxidizing activities of crude enzyme preparations from sources such as pigeon breast muscle, beef liver, and cucumber seeds. In all of these animal and plant tissues, the TCA cycle is conducted by mitochondria, using virtually the same process as their bacterial ancestors.

Glucose catabolism connects with the TCA cycle through pyruvate breakdown to acetyl-CoA and CO_2. Recall from Section 13.4 that acetyl-CoA is also generated from many other catabolic pathways, including those for breakdown of fatty acids, amino acids, and even benzoate derivatives. Regardless of its source, the acetyl-CoA enters the TCA cycle by condensing with the four-carbon intermediate oxaloacetate to form citrate (**Fig. 13.24**). Citrate undergoes two steps of oxidative decarboxylation, in which CO_2 is released and two hydrogens with electrons are transferred to produce $NADH + H^+$ or $FADH_2$. The TCA cycle, in whole or in part, is found in all microbial species except for degenerately evolved pathogens dependent on host metabolism.

We present first the connecting step between pyruvate and acetyl-CoA, followed by the details of the TCA cycle. Different species of bacteria and archaea use at least ten known variations on the TCA cycle, conducted by diverse species under various environmental conditions. You will be relieved to hear that we present only one, the Krebs TCA pathway best known in gram-negative and gram-positive bacteria. Variant pathways are detailed in online resources such as the KEGG Pathway Database.

WWW | KEGG

Pyruvate Dehydrogenase Connects Sugar Catabolism to the TCA Cycle

Pyruvate is converted to acetyl-CoA through removal of CO_2 and transfer of $2e^-$ onto NAD^+. The removal of CO_2 and transfer of two electrons is known as oxidative decarboxylation. The oxidative decarboxylation of pyruvate,

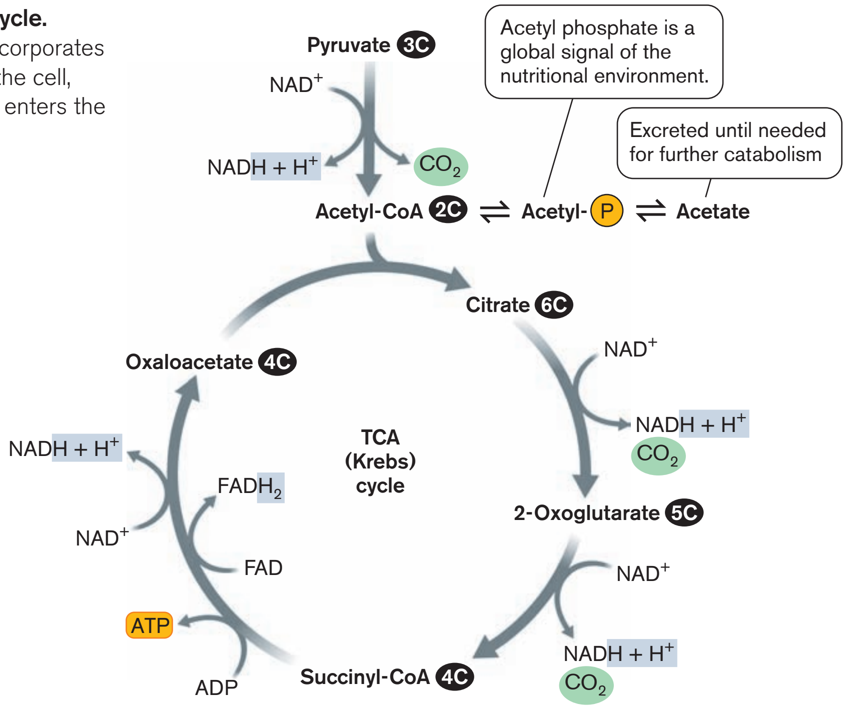


Figure 13.24 **Acetyl-CoA feeds into the TCA cycle.** Pyruvate undergoes oxidative decarboxylation and incorporates CoA to form acetyl-CoA. Depending on the state of the cell, acetyl-CoA is converted to acetate for excretion or it enters the TCA cycle.

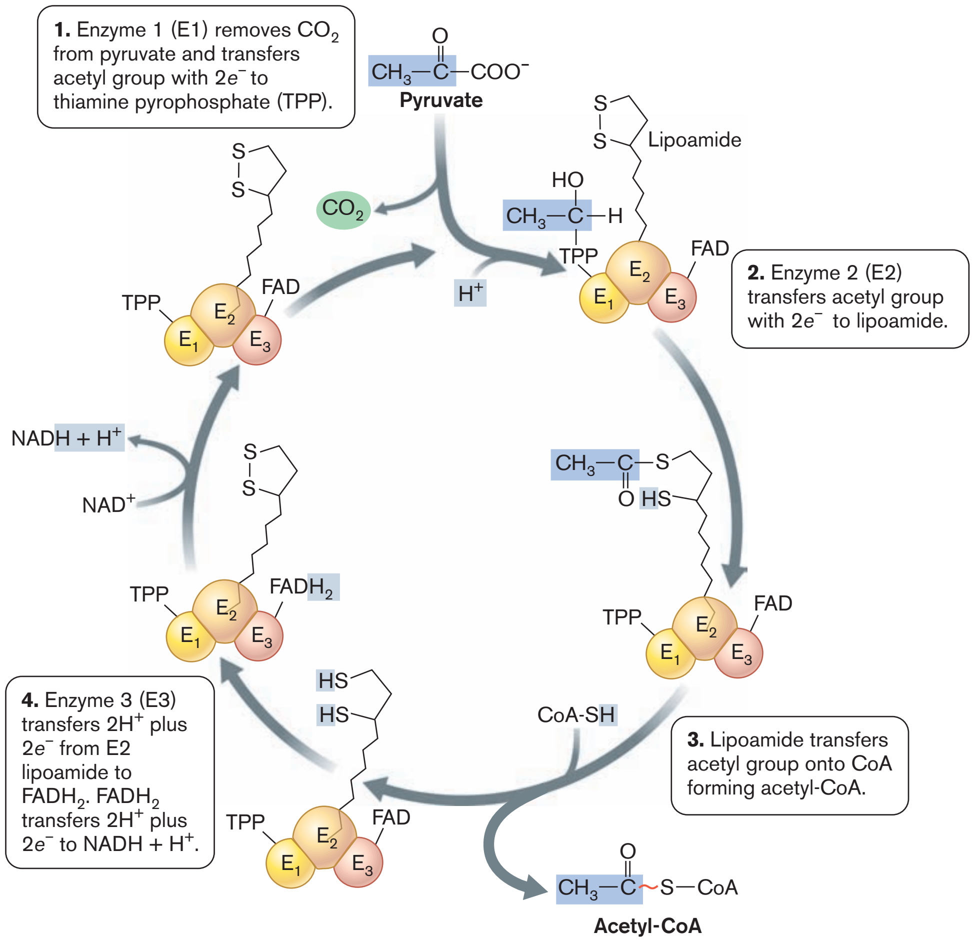
A. Pyruvate is converted to acetyl-CoA



1. Enzyme 1 (E1) removes CO_2 from pyruvate and transfers acetyl group with $2e^-$ to thiamine pyrophosphate (TPP).

2. Enzyme 2 (E2) transfers acetyl group with $2e^-$ to lipoamide.

3. Lipoamide transfers acetyl group onto CoA forming acetyl-CoA.

4. Enzyme 3 (E3) transfers $2H^+$ plus $2e^-$ from E2 lipoamide to $FADH_2$. $FADH_2$ transfers $2H^+$ plus $2e^-$ to NADH + H^+.

Figure 13.25 Pyruvate dehydrogenase complex. **A.** Reaction mechanism: (1) Enzyme 1 acquires the acetyl group of pyruvate, condensed to thiamine pyrophosphate (TPP). (2) The acetyl group with $2e^-$ is transferred to the lipoamide of enzyme 2. (3) The acetyl group is transferred to HS-CoA to form acetyl-CoA. (4) The two thiols are oxidized to disulfide, and their $2e^-$ + $2H^+$ reduce FAD to make $FADH_2$. $FADH_2$ reduces NAD^+ to NADH + H^+. **B.** The bacterial pyruvate dehydrogenase complex contains multiple copies of each component. (PDB codes: 1EAA, 1L8A)

coupled to CoA incorporation, is performed by an unusually large multisubunit enzyme called the **pyruvate dehydrogenase complex**, or **PDC** (**Fig. 13.25**). PDC is a key component of metabolism in bacteria and mitochondria, the first molecular player to direct sugar catabolism into respiration. In human mitochondria, defects in PDC are associated with myocardial malfunction and heart failure, maple syrup urine disease, and neurodegeneration.

Reaction mechanism of PDC. The overall reaction catalyzed by PDC is:

$$CH_3COCOO^- + H^+ + HS\text{-}CoA \rightarrow CH_3CO\text{-}S\text{-}CoA + CO_2 + 2H^+ + 2e^-$$

$$NAD^+ + 2H^+ + 2e^- \rightarrow NADH + H^+$$

The removal of stable CO_2 yields energy for the electron transfer to NADH. The protons dissociated from pyruvate and thiol (SH) of CoA ($2H^+$ in total) are balanced by the net gain of protons by NADH + H^+.

The coupling of all the molecular transfers actually requires three distinct enzyme components within the complex, designated E1, E2, and E3 (see **Fig. 13.25**). Each of these enzymes possesses a distinct coenzyme to mediate electron transfer.

The bacterial pyruvate decarboxylase complex contains multiple copies of all three enzymes (**Fig. 13.25B**). Central to the structure is a core containing 24 E2 proteins surrounded by 12 E1 dimers and 6 E3 dimers. Mitochondrial complexes are even larger and more intricate. The reason for this degree of complexity is unknown, but it is clear that organisms invest considerable energy and material in the construction and function of PDC.

Regulation of PDC. The activity of PDC is increased by high concentrations of its substrates, CoA and NAD^+, and inhibited by its products acetyl-CoA and NADH. The product, acetyl-CoA, may enter one of several pathways. In *E. coli*, when glucose is plentiful, acetyl-CoA is mostly converted to acetate via the intermediate acetyl phosphate (see **Fig. 13.24**). Acetyl phosphate is a global signal molecule that indicates to the cell the quantity and quality of carbon source available. As glucose decreases, the cell starts to take back acetate, converting it back to acetyl-CoA for entry into the TCA cycle.

At the level of gene expression, PDC responds to environmental conditions. As would be expected, PDC gene expression is repressed by carbon starvation and at low oxygen. More surprising, expression is strongly induced both at high pH and at low pH, compared to growth at pH 7. The basis for extreme-pH induction is unknown.

THOUGHT QUESTION 13.12 Compare the reactions catalyzed by pyruvate dehydrogenase and pyruvate formate lyase (see Section 13.4). What conditions favor each reaction, and why?

Acetyl-CoA Enters the TCA Cycle

Acetyl-CoA enters the TCA cycle by condensing the acetyl group with oxaloacetate, a four-carbon dicarboxylate (double acid). The condensation yields citrate, a six-carbon tricarboxylate (**Fig. 13.26**). An advantage of intermediates with two or more acidic groups is that the concentration of the fully protonated form is extremely low; thus, the molecule is unlikely to be lost from the cell by diffusion across the membrane, as are monocarboxylic acids, such as acetate. Through the rest of the cycle, citrate loses two carbons as CO_2 by a series of reactions that transfer increments of energy to 3NADH, $FADH_2$, and ATP. Each reaction step couples energy-yielding to energy-storing events.

Step 1. As the acetyl group condenses with oxaloacetate, the removal of CoA consumes a molecule of H_2O to restore HS-CoA. The removal of HS-CoA yields energy to incorporate acetate into oxaloacetate, forming citrate.

Step 2. Citrate undergoes two rearrangements with little energy change to form isocitrate. Isocitrate then undergoes oxidative decarboxylation. As we saw for pyruvate, removal of CO_2 yields energy to transfer $2H^+ + 2e^-$ to form NADH + H^+, producing 2-oxoglutarate (alpha-ketoglutarate).

Step 3. 2-oxoglutarate undergoes oxidative decarboxylation to release CO_2 and make another NADH + H^+. In this case, CoA is incorporated, making succinyl-CoA.

Step 4. Succinyl-CoA releases CoA, providing energy to phosphorylate ADP to ATP. To form fumarate, $2H^+ + 2e^-$ are transferred to FAD to form $FADH_2$, a reaction involving negligible free energy change.

Step 5. Fumarate incorporates water across its double bond, forming the hydroxy acid malate. The increasing stability from fumarate to malate and from malate to oxaloacetate releases enough energy to form the final NADH + H^+. Oxaloacetate is the intermediate of lowest energy in the cycle, now ready to accept the next acetyl-CoA.

NOTE: Many textbooks state that the enzyme catalyzing step 4, succinyl-CoA synthetase, phosphorylates GDP $\rightarrow$ GTP. According to the primary literature, ADP phosphorylation predominates in *E. coli* (Margaret Birney et al., 1996), whereas in *Pseudomonas* species, various nucleotide diphosphates are phosphorylated (Vinayak Kapatral et al., 2000). Human mitochondria have two forms of the enzyme, which form ATP and GTP, respectively (David Lambeth et al., 2004).

1. Cleavage of acetyl-CoA by H_2O provides energy for condensing the acetyl group with oxaloacetate.

2. Oxidative decarboxylation of isocitrate.

3. Oxidative decarboxylation; CoA is incorporated into succinyl-CoA.

4. $2H^+ + 2e^-$ are transferred to form $FADH_2$; succinate converts to fumarate.

5. Water is incorporated, $2H^+ + 2e^-$ are transferred to $NADH + H^+$, and malate converts to oxaloacetate.

Some microbes make GTP.

Figure 13.26 The tricarboxylic acid (TCA) cycle. Acetyl-CoA derived from pyruvate and other catabolic pathways enters the TCA cycle. Blue highlights show the fate of labeled acetate incorporated into the TCA cycle. (1) The acetyl group condenses with four-carbon oxaloacetate to produce citrate, a tricarboxylic acid. (2) Citrate rearranges to isocitrate, which is decarboxylated and transfers $2H^+ + 2e^-$ to form $NADH + H^+$. (3) 2-Oxoglutarate is decarboxylated and transfers $2H^+ + 2e^-$ to form $NADH + H^+$ while incorporating CoA to form succinyl-CoA. (4) Succinate is symmetrical; thus, the "old" and "new" carbons are now indistinguishable. Succinate transfers $2H^+ + 2e^-$ to form $FADH_2$, yielding fumarate. (5) Water is incorporated, and $2H^+ + 2e^-$ is transferred to form $NADH + H^+$, yielding oxaloacetate, ready to take up another acetyl group.

to guess at dozens of short-chain acids known to exist in cells, then add each individually to an enzyme preparation and test for TCA cycle activity. In aerobic organisms, the TCA cycle is tightly tied to respiration, so an increase in uptake of oxygen signaled a TCA intermediate. A major experimental advance was the use of tracer isotopes such as ^{14}C, discovered in the 1930s.

Radioisotope tracers answered an important question about the TCA cycle. As the two acetyl carbons cycle through, which two carbons of each intermediate are removed as CO_2? Are the acetyl carbons lost first, or those of the original oxaloacetate? This question was answered using substrates radiolabeled with ^{14}C (**Fig. 13.26**, highlighted in blue). In the experiment, bacteria are fed ^{14}C-radiolabeled acetate, which enters the TCA cycle. The radiolabeled carbons are captured by the TCA intermediates and retained into the next cycle, whereas two COOH carbons from the original oxaloacetate are lost. Thus, the four-carbon intermediate does not recycle intact, but breaks down and re-forms each time it passes through the cycle.

After loss of the second CO_2, the third CH_2 of the carbon skeleton is oxidized to COOH, generating succinate. Succinate is a symmetrical molecule; thus, the former identities of the acetyl and oxaloacetate moieties are now erased, and the carbons are equally likely to disappear from either half of the molecule. Further conversion steps regenerate oxaloacetate—half its carbon from the acetyl group and half from the original oxaloacetate.

THOUGHT QUESTION 13.13 Suppose a cell is pulse-labeled with ^{14}C-acetate (fed the ^{14}C label briefly, then "chased" with unlabeled acetate). Can you predict what will happen to the level of radioactivity observed in isolated TCA intermediates? Plot a curve showing your predicted level of radioactivity as a function of number of rounds of the cycle.

The TCA cycle and oxidative phosphorylation. In all, each acetate generates three NADH molecules, one $FADH_2$, and one ATP; and all the carbons from pyruvate (ultimately from glucose) have been released as waste CO_2. From the standpoint of the carbon skeleton, the glucose breakdown is now complete. But do we have a completed metabolic pathway? No, because all of the NADH and $FADH_2$ need to be recycled by donating their electrons onto a terminal electron acceptor.

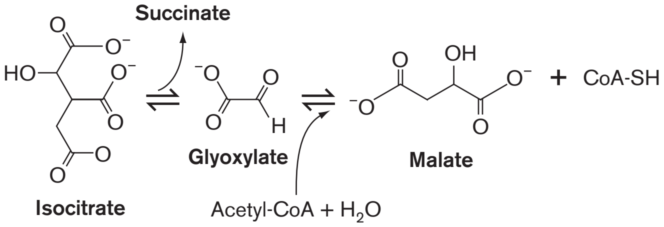
The process of electron transfer from NADH and $FADH_2$ is mediated by a series of cell membrane proteins called the electron transport system (ETS) or electron transport chain (introduced in Section 13.3). The membrane proteins use the energy of electron transfer to pump protons, generating a gradient of hydrogen ions across the membrane (**Fig. 13.27**), a process discussed in detail in Chapter 14. Assuming 3 ATPs generated per NADH and 2 ATPs per $FADH_2$, the hydrogen ion gradient then drives the membrane ATP synthase to synthesize as many as 34 ATPs. Another 4 ATPs came from glucose breakdown and the TCA cycle (38 total per glucose). Under actual conditions, however, fewer ATPs are made; about 20 ATP per glucose are made by a well-aerated culture of *E. coli*.

The overall process of electron transport and ATP generation is termed **oxidative phosphorylation**. The overall process of oxidative catabolism from substrate breakdown to oxidative phosphorylation is called respiration. The overall equation for the respiration of glucose is

$$C_6H_{12}O_6 + 6H_2O + 6O_2 \rightarrow 12H_2O + 6CO_2$$

Glucose respiration can generate a relatively large number of ATPs per glucose, far more than fermentation. In bacteria, however, the actual number of ATPs generated varies widely with availability of carbon source and oxygen. For example, as oxygen decreases in the environment, the ability to oxidize NADH decreases, so the cell may make only one or two ATPs per NADH (discussed in Chapter 14).

Regulation of the TCA cycle. The enzymes of the TCA cycle are regulated extensively by substrate induction and product inhibition, and their expression is induced at high oxygen and carbon source availability. At very low levels of glucose, alternative pathways are favored, particularly the **glyoxylate bypass**. The glyoxylate bypass consists of two enzymes that divert isocitrate to glyoxylate and incorporate a second acetyl-CoA to form malate:



The glyoxylate bypass cuts out all the generation of ATP, $FADH_2$, and NADH, with the exception of one NADH from malate to oxaloacetate. Thus, limited energy is released; but, like the low gear of a bicycle, the cycle keeps turning under tough conditions. The glyoxylate bypass can also be used to regenerate TCA cycle intermediates as needed, a process known as anaplerosis (discussed in Chapter 15).

TCA cycle intermediates as substrates for biosynthesis. Analysis of pathway evolution indicates that the TCA cycle originally evolved to provide substrates for biosynthesis. For example, the TCA cycle intermediate

Figure 13.27 Complete oxidation of glucose. Glucose catabolism generates ATP through substrate-level phosphorylation and through the electron transport system pumping H^+ ions to drive the ATP synthase. The complete oxidative breakdown of glucose to CO_2 and H_2O could theoretically generate up to 38 ATPs. Under actual conditions, the number is smaller.

2-oxoglutarate (alpha-ketoglutarate) is aminated to form glutamate, which leads to glutamine. Oxaloacetate is aminated to form aspartate, entering pathways to purines and pyrimidines as well. The TCA cycle, like glycolysis, is an amphibolic pathway that provides substrates for biosynthesis. Many bacteria use the TCA cycle and glycolytic enzymes to build their sugars and amino acids, as discussed in Chapter 15. Others, such as *Treponema pallidum,* the cause of syphilis, have lost the TCA cycle by reductive evolution. They must obtain amino acids from their host organism (see **Special Topic 13.3**).

TO SUMMARIZE:

- **The pyruvate dehydrogenase complex (PDC)** removes CO_2 from pyruvate, generating acetyl-CoA. Two electrons are transferred to NAD^+, forming $NADH/H^+$. PDC activity is a key control point of metabolism, induced when carbon sources are plentiful and repressed under carbon starvation and low oxygen.
- **The tricarboxylic acid cycle (TCA cycle)** converts the acetyl group to $2CO_2$ and $2H_2O$ in the presence of a terminal electron acceptor such as O_2 to receive the electrons associated with the hydrogen atoms.
- **Acetyl-CoA enters the TCA cycle by condensing with oxaloacetate to form citrate.** A series of enzymes sequentially remove carbon dioxide and water molecules and generate 2NADH, $FADH_2$, and ATP. Each reaction step couples energy-yielding to energy-storing events.
- **NADH and $FADH_2$ transfer electrons to the electron transport system** and ultimately the terminal electron acceptor such as O_2. Electron transport generates a proton gradient that powers the membrane-bound ATPase to make ATP.
- **Respiration** consists of substrate catabolism plus oxidative phosphorylation, the process of electron transport and ATP generation.

13.7 Aromatic Catabolism

In forest environments, bacteria and fungi catabolize aromatic molecules such as benzene derivatives. Aromatic catabolism is crucial to recycle lignin, the main component of woody biomass. Today, aromatic catabolism has growing applications for bioremediation of soil pollutants such as nitrate explosives, aniline dyes, and industrial solvents such as toluene. Aromatic molecules are notoriously difficult to catabolize because of the stability associated with the benzene ring. The benzene ring breaks down slowly in natural environments and was once thought to require aerobic digestion. We now know, however, that soil bacteria catabolize a wide range of aromatic molecules, anaerobically as well as aerobically. These microbial processes have major industrial and environmental importance. Here we explore bacterial catabolism of benzene derivatives such as benzoate (benzene carboxylate). Benzoate has a central role in aromatic catabolism, comparable to that of glucose in sugar catabolism.

Benzoate Derivatives Are Degraded to Catechol

Bacteria such as *Pseudomonas* and *Rhodococcus* species degrade benzoate and related molecules aerobically or anaerobically. The catabolic enzymes are often encoded on a large plasmid, of 100–450 kb. The aerobic pathways (**Fig. 13.28**) share key features:

- Removal of substituents such as chlorides or nitrates
- Oxidation to form the dihydroxy derivative catechol
- Ring cleavage and catabolism to acetyl-CoA, which may enter the TCA cycle

Aerobic benzoate catabolism. Aerobic degradation typically proceeds through the key intermediate **catechol**, a benzene ring bearing two adjacent hydroxyl groups. Benzoate and various related compounds, such as toluene (methyl benzene) and nitrobenzene, are each converted to catechol by a specific **dioxygenase**, an enzyme that coordinately oxygenates two adjacent ring carbons.

The intermediate catechol then undergoes another key oxidation by a **catechol dioxygenase**, which adds two more oxygens while cleaving the ring. In different bacterial species, the enzyme may oxidize either the 1, 2 positions, or the 2, 3 positions as shown. The product is either a monocarboxylate or a dicarboxylate. In either case, the carbon skeleton is further oxidized, and its constituents are directed into the TCA cycle for full degradation to CO_2.

Genetic analysis of toluene catabolism. Many pathways of aromatic catabolism are still being discovered. To study unknown metabolism, we must identify the genes that encode the enzymes responsible. These genes lie waiting in the sequenced microbial genomes, where a large proportion of genes remains unidentified. How are their functions discovered?

The dissection of the TCA cycle required decades of painstaking experiments in biochemistry and genetic analysis on model organisms such as *E. coli*. Now that so much metabolism is understood in model organisms, much of the metabolic capacity of other organisms can be deduced by comparison of their genomes. Genome analysis can be especially useful in characterizing pathogens that are difficult to culture and study, such as *Treponema pallidum*, the causative agent of syphilis.

The sequence of a microbial genome typically reveals a high percentage of genes whose function can be identified based on homology with known genes in other species (discussed in Chapter 8). For example, the components of the pyruvate dehydrogenase complex show highly similar sequences in all organisms. Thus, it is possible to survey an annotated microbial genome and predict much of the microbe's metabolic capacities.

The genome of *T. pallidum* was sequenced by Claire Fraser-Liggett and colleagues at The Institute for Genomic Research (TIGR) (**Fig. 1**). The genome encodes key enzymes of glycolysis (red arrows, central) as well as those of fermentation to lactate or acetate. However, enzymes of the TCA cycle are completely absent, as are the proteins of electron transport. Thus, *T. pallidum* can only generate ATP by substrate-level phosphorylation. The genome does encode a small number of sugar transporters (yellow symbols) for entry to glycolysis, as well as amino acid transporters (red symbols). It does not encode enzymes of amino acid catabolism or of their biosynthesis. Thus, the organism can ferment a limited number of sugars but can neither catabolize nor form its own amino acids. It must depend on its host to supply many fundamental nutrients. The general loss of major metabolic systems from *T. pallidum* is typical of ancient pathogens that have evolved over a long period in obligate association with their host.

Figure 1 Genome of *Treponema pallidum* reveals metabolic pathways. The *Treponema* genome encodes key enzymes of glycolysis and fermentation (red arrows, central). However, enzymes of the TCA cycle and electron transport are absent. Thus, *Treponema* is capable of little or no oxidative respiration. The genome does show sugar transporters (yellow symbols) and amino acid transporters (red symbols) but no enzymes for amino acid catabolic or biosynthetic pathways.

The genes encoding metabolism can be identified through use of clone libraries, as discussed in Chapter 12. For example, clone complementation was used by Hyung-Yeel Kahng and colleagues to reveal new genes encoding degradation of toluene and its derivatives associated with petroleum pollution (**Fig. 13.29**).

Kahng and coworkers obtained a strain of the soil bacterium *Burkholderia*, which degrades toluene, benzene, and chlorobenzene. A genomic library was generated to contain plasmids carrying cloned segments from throughout the *Burkholderia* genome. The library of clones was used to transform a strain of *Pseudomonas aeruginosa* that cannot degrade the toluene derivatives. Each transformed strain contained a plasmid with a different segment of the *Burkholderia* genome. One clone, pHYK2000, conferred the ability to catabolize toluene, benzoate, and chlorobenzoate. The plasmid in this clone was mapped by restriction enzymes to delimit the range of DNA sequence needed for catabolism. Ultimately, the plasmid was shown to contain two previously unknown operons for aromatic catabolism, *tbc1* and *tbc2*. Some of the genes in the operons showed homology to known genes in other organisms that encode oxygenases for aromatic catabolism. Other *Burkholderia* genes showed little relatedness to known genes. The functions of their gene products were tested subsequently by biochemical assays. These genes point to a potential new microbial route for biodegradation of petroleum waste.

Anaerobic benzoate catabolism. Anaerobic catabolism is especially desirable for cleanup of contamination underground, where oxygen levels are extremely low. Yet the pathways of anaerobic degradation of aromatic molecules remain poorly understood. An anaerobic pathway of

benzoate catabolism was observed in the soil bacterium *Azoarcus evansii* (**Fig. 13.30**). In *Azoarcus*, under anaerobic conditions, benzoate undergoes reductive degradation instead of oxidation. First, the benzoate is activated by CoA, then it is reduced by NADPH. The NADPH reduction eliminates aromaticity before ring cleavage.

The reduction of benzoyl-CoA by NADPH was demonstrated by Christa Ebenau-Jehle and colleagues at the University of Freiburg by separating radiolabeled intermediates. Ring carbons of benzoyl-CoA were labeled with ^{14}C, and reaction products from *Azoarcus* species were analyzed using thin-layer chromatography (TLC), a method that separates molecules based on different solubilities in a solvent mixture (**Fig. 13.30B**).

The chromatogram shows radiolabeled spots of [ring-^{14}C] benzoyl-CoA and its products, which are carried different distances by the chromatographic solvent. In the presence of NADPH, the labeled benzoyl-CoA steadily disappears, while products of catabolism emerge. If the nonreductive NADP$^+$ substitutes for NADPH, no loss of benzoyl-CoA occurs. Thus, benzoyl-CoA degradation was shown to require NADPH. This anaerobic route of aromatic degradation differs from that of the oxidative process, in which benzoate is oxidized and decarboxylated to catechol.

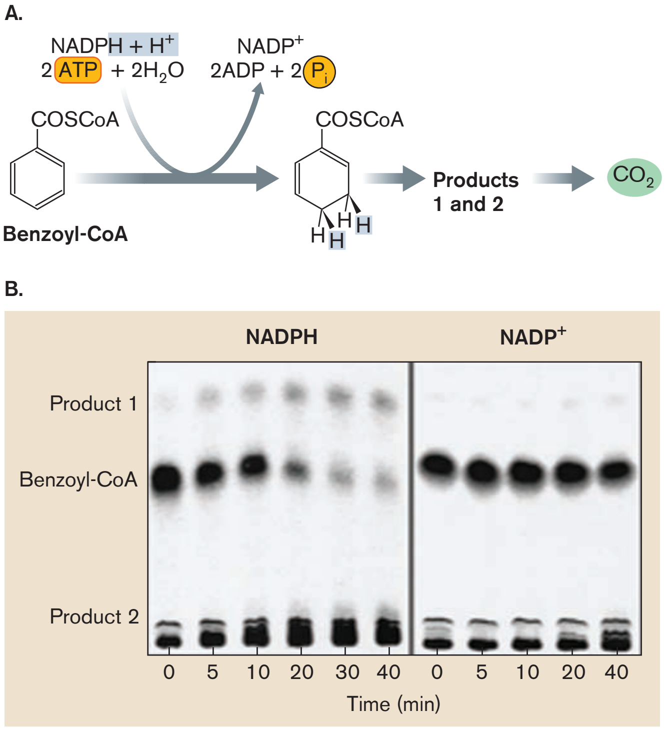

Figure 13.30 Anaerobic catabolism of benzoate: analysis by thin-layer chromatography. A. Under anaerobic conditions, benzoate is activated by coenzyme A, then reduced (hydrogenated) by NADPH. **B.** The reduction of benzoyl-CoA in *Azoarcus evansii* was observed by thin-layer chromatography (TLC). In the presence of the reducing agent NADPH, the spot due to benzoyl-CoA disappears, while those due to two products of catabolism increase. In the presence of NADP$^+$, with no reducing power, no reaction occurs. *Source:* Modified from Christa Ebenau-Jehle, et al. 2003. *J. Bacteriol.* 185:6119.

Polynuclear Aromatic Hydrocarbons (PAHs) Are Degraded Slowly

A particularly challenging class of catabolic substrates is the polynuclear aromatic hydrocarbons (PAHs). The multiple fused rings of PAH compounds may take years to biodegrade in natural environments. PAHs are found in coal tar products such as creosote, a preservative widely used to protect wood from insects and fungal decomposition. Creosote leaks from wood structures such as railway ties (**Figs. 13.31A** and **B**) and contaminates wetland environments. Many PAHs are teratogenic and carcinogenic, and their increase in our environment is of growing concern.

The pathways and even the microbial species responsible for PAH degradation in nature remain poorly known. In one study, the biodegradation of a PAH compound in creosote was observed by Sergey Selifonov and colleagues at the University of Minnesota. Selifonov used ^{13}C NMR to track the catabolism by *Pseudomonas* strain A2279 of ^{13}C-labeled acenaphthene, a tricyclic naphthalene derivative (**Fig. 13.31C**). The compound was labeled at a single aliphatic position so that its resonance would appear as a single peak separate from the range of aromatic carbon, where natural-abundance ^{13}C peaks appear. New peaks appeared, which were identified as various oxidized products of acenaphthene. The enzymes responsible for these products remain to be discovered. Furthermore, the completion of degradation remains unclear. It is likely that such complex molecules require a consortium of different species to complete their degradation to acetate.

THOUGHT QUESTION 13.14 How might the enzymes that catalyze acenaphthene catabolism be discovered?

TO SUMMARIZE:

- **Catabolism of aromatic molecules by bacteria and fungi recycles lignin** and other important substances within ecosystems. Toxic pollutants are also degraded.
- **Benzoate undergoes aerobic catabolism to catechol.** The catechol ring is cleaved, generating acetyl-CoA, which enters the TCA cycle.
- **Anaerobic catabolism of benzoate involves activation by HS-CoA and reduction of NADP$^+$ to NADPH.**

Microbiol.* 64:1447.

- **Polynuclear aromatic hydrocarbons (PAHs) are degraded slowly by microbes.** PAH catabolism has exciting potential applications for bioremediation of toxic pollutants.
- **Aromatic catabolism by environmental microbes is an important field of research.** Research techniques include genetic and genomic analysis, chromatography of radiolabeled substrates, and NMR spectroscopy.

Concluding Thoughts

In this chapter, we have seen how energy-yielding reactions enable living cells to generate order from disorder. In fact, the result of cell metabolism increases entropy throughout the universe, but enables local growth of complexity. Living organisms acquire energy by transferring energy from reactions with negative ΔG to cell-building reactions with positive ΔG. The fundamental energy-yielding pathways of Earth's biosphere are those of photosynthesis; and the biomass generated through photosynthesis provides materials for catabolism. Much of human civilization has been built on harnessing microbial catabolism for waste treatment, food production, and biotechnology.

All forms of metabolism involve chemical exchange of electrons through oxidation and reduction. In Chapter 14, we focus on the transport of electrons between donor and acceptor molecules, through membrane-embedded complexes that generate ion gradients across the membrane. This transport of electrons is fundamental to respiration, the oxidative completion of catabolism to CO_2 and water. It also underlies the autotrophic means of building biomass: the gain of energy from light (phototrophy) and from mineral oxidation (lithotrophy.)

CHAPTER REVIEW

Review Questions

1. Why must the biosphere continually take up energy from outside? Why can't all the energy be recycled among organisms, like the fundamental elements of matter?
2. Explain how a biochemical reaction can be driven by change in enthalpy, ΔH. Explain how a different reaction can be driven by change in entropy, ΔS. In each case, explain the role of the free energy change, ΔG.
3. Why do some biochemical reactions only release energy above a threshold temperature?
4. How do organisms determine which of their catabolic pathways to use? How does catabolism depend on environmental factors?
5. Beer is produced by yeast fermentation of grain to ethanol. Why must the process of beer production be anaerobic? Why are such large quantities of ethanol produced, with relatively small production of yeast biomass?
6. Explain the three different routes to catabolize glucose to pyruvate. Why is it necessary to start by spending one or two molecules of ATP?
7. Explain how the TCA cycle incorporates an acetyl group. How are the two CO_2 molecules removed?
8. Compare and contrast aerobic and anaerobic processes of benzoate catabolism.

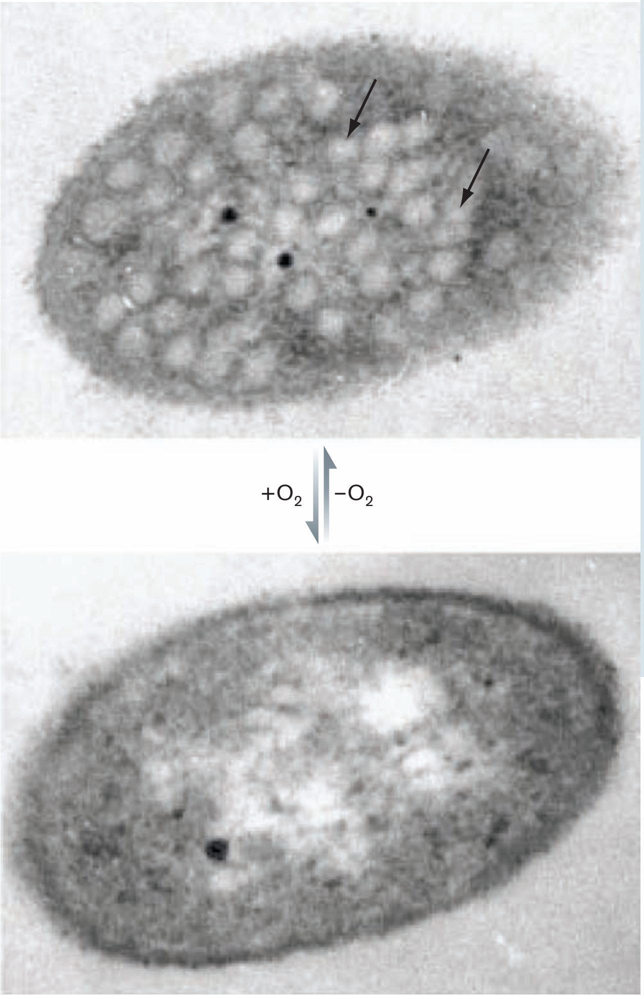
Chapter 14

Respiration, Lithotrophy, and Photolysis

14.1 Electron Transport Systems
14.2 The Proton Motive Force
14.3 The Respiratory ETS and ATP Synthase
14.4 Anaerobic Respiration
14.5 Lithotrophy and Methanogenesis
14.6 Phototrophy

Microbes transfer energy by moving electrons—the equivalent of an electric current. Electrons move from reduced food molecules onto energy carriers, from energy carriers onto membrane proteins called cytochromes, and from cytochromes onto oxygen or oxidized minerals. Some bacteria can actually donate electrons to an electrode and power a fuel cell. In the soil, bacteria donate electrons to metals such as iron, gold, and uranium. Bacteria in Earth's crust have deposited most of the iron mined today, and possibly the gold as well.

A special kind of electron current flows between proteins and cofactors of an electron transport system in a cell membrane. The electron transport system generates a "proton motive force" that drives protons across the membrane. The proton motive force stores energy to make ATP. Similar electron transport systems power our own mitochondria and the photosynthetic membranes of plant chloroplasts.



Rhodobacter sphaeroides grows by oxidative respiration (lower panel), but under oxygen limitation the bacterium forms tubes of photosynthetic membranes to harvest light (upper panel, shown by arrows; cell width, approx. 0.5 μm). The genes regulating photosynthetic membrane formation were revealed by microarray and genomic analysis.

Electric current in living organisms has fascinated scientists ever since the eighteenth century when Luigi Galvani (1737–1798) showed that a voltage potential caused a dead frog limb to flex. The idea of biological electricity inspired Mary Shelley's famous science fiction novel *Frankenstein: or, the Modern Prometheus*, in which a physician is imagined to "create life" by jolting body parts with an electric shock.

Today, electric currents and voltage potentials are understood to be fundamental aspects of all cells. Nevertheless, it came as a surprise to discover that bacteria could directly power an electrical fuel cell. Bacteria commonly found in soil can oxidize organic nutrients using iron ions (ferric ion, Fe^{3+}) instead of oxygen. The organic molecules transfer electrons to the iron. But Fe^{3+} is usually present as insoluble grains of iron oxide, outside the cell; so how do cells reach the iron? Derek Lovley and colleagues at the University of Massachussetts, Amherst, wondered how bacteria gained access to iron oxide—and whether they might also transfer electrons to an iron electrode. They found that *Geobacter metallireducens* transfers electrons to a metal electrode, generating enough power to run an electric clock. A related species of *Geobacter* may transfer electrons through its pili (**Fig. 14.1**). The pili act as nanowires conducting electricity to iron oxide, thus generating a charge difference across the bacterial membranes.

The source of electrons for *Geobacter* metabolism can include hard-to-digest organic molecules, even aromatic compounds such as benzoates that often contaminate soil. Thus, bacteria may combine electricity generation with organic waste remediation. In fact, the bacterial community of our entire biosphere acts as a battery in which underground bacteria continually transfer electrons from Earth's reduced interior to the oxidizing atmosphere. Useful electricity can be obtained simply by placing electrodes at appropriate depths in the ocean floor. While the amount of power obtained at present is small, in the future subterranean microbes may contribute significantly to our energy supply.

As we saw in Chapter 13, biochemical reactions can provide energy in different ways (see **Table 13.1**). Catabolism provides energy through breakdown of complex molecules (increasing entropy) and through electron transfer converting molecules to more stable forms (releasing heat energy). Electron transfer also yields energy from inorganic minerals (lithotrophy) and from light capture (phototrophy). Microbial electron transfer reactions have profound consequences for ecosystems; they acidify or alkalinize soil and water, and they can contribute or remove nitrogen and minerals.

Chapter 14 develops a unified view of electron transfer reactions, or oxidation-reduction reactions, in respiration, lithotrophy, and phototrophy. In all kinds of metabolism, some of the energy from electron transfer is stored in the form of an electrochemical potential (voltage) across a membrane. The voltage potential includes a concentration gradient of ions (H^+ or Na^+) plus the charge difference across the membrane. Voltage potentials drive ATP synthesis and nutrient uptake, mediate pathogenesis of infective microbes, and shape the chemistry of our environment.

14.1 Electron Transport Systems

As we learned in Chapter 13, energy to support life is obtained through reactions that convert substrates to products of lower energy—that is, reactions in which ΔG is negative. Most such reactions involve transfer of electrons from a reduced **electron donor** to an oxidized **electron acceptor**. The simplest path of electron flow occurs in fermentation, where electrons from the fermented substrate, such as glucose, are transferred onto NAD^+ to make NADH, then returned to the glucose breakdown products. More complex kinds of metabolism, such as aerobic respiration, transfer electrons through a series of membrane-soluble carriers called an **electron transport system (ETS)**, also known as an **electron transport chain**. A membrane-embedded ETS, unlike cytoplas-

Lovley discovered that *G. metallireducens* could donate electrons to a metal electrode, generating electricity to power electromechanical devices.

mic redox reactions, can convert its energy into an ion potential or electrochemical potential between two compartments separated by the membrane. The ion potential is most commonly a proton (H^+) potential, also known as proton motive force (PMF). The proton motive force drives essential cell processes such as synthesis of ATP (discussed in Section 14.2).

Electron Transport Systems Use Different Electron Donors and Acceptors

Different types of metabolism use electron transport systems with different components embedded in the bacterial membrane. Each ETS must accept electrons from an initial electron donor consisting of an organic "food" molecule, such as glucose, or a reduced mineral, such as Fe^{2+}. The ETS proteins and cofactors act sequentially as electron donors and acceptors, whose oxidation-reduction reactions are coupled to proton transport across the membrane. Each ETS finally transfers its electrons to a terminal electron acceptor molecule, whose product may exit the cell.

Metabolism using an ETS is classified based on the nature of the initial electron donors and terminal electron acceptors. In this chapter, we cover three major classes of prokaryotic energy acquisition involving an ETS (their relationships are summarized in Table 13.1):

- **Respiration** is the oxidation of electron donors such as sugars, lipids, or amino acids to CO_2 and H_2O. (Oxidation of minerals is a form of respiration called lithotrophy, discussed below.) Organic molecules donate electrons associated with hydrogen atoms, a process known as dehydrogenation. Additional hydrogen atoms are donated by water molecules. The oxidant (terminal electron acceptor) may be O_2, for aerobic respiration, or an anaerobic alternative, for anaerobic respiration. The anaerobic electron acceptor may be inorganic (such as NO_3^-) or organic (such as fumarate, $^-O_2C{-}CH{=}CH{-}CO_2^-$.
- **Lithotrophy** (or **chemolithotrophy**, or chemoautotrophy) is the oxidation of inorganic electron donors, such as Fe^{2+} or H_2. The electron acceptor may be O_2 or an anaerobic alternative, such as NO_3^-. A few inorganic electron donors, such as H_2, can be used with organic electron acceptors. Most lithotrophs are autotrophs, fixing CO_2 for biosynthesis (discussed in Chapter 15).
- **Phototrophy** involves light capture by chlorophyll, usually coupled to splitting of H_2S or H_2O (photolysis) or organic molecules (photoheterotrophy). Alternatively, light absorption drives a proton pump without photolysis. Photoautotrophs couple photolysis to CO_2 fixation for biomass (discussed in Chapter 15). Photoheterotrophs use photolysis to supplement catabolism.

NOTE: Distinguish these prefix terms:

Organo-	Organic electron donors for energy
Litho-	Inorganic electron donors for energy
Chemo-	Chemical reactions yield energy
Photo-	Light absorption drives or supplements chemical reactions for energy
Hetero-	Organic molecules for carbon source
Auto-	Inorganic carbon source, usually CO_2

An Electron Transport System Stores Energy

In Chapter 13, we showed how the free energy change ΔG determines whether energy can be obtained from a given reaction of substrates to products. Similar considerations of ΔG govern the reactions of electron flow through an ETS and the storage of energy in transmembrane ion gradients.

The reduction potential. To obtain energy, biochemical reactions require a negative ΔG overall. In oxidation-reduction reactions (redox reactions), the ΔG values are proportional to the **reduction potential** (***E***) between the oxidized form of a molecule (electron acceptor) and its reduced form (electron donor). The reduction potential represents the tendency of a molecule to accept electrons, measured in volts (V) or millivolts (mV). The oxidized and reduced states together form a **redox couple**. An example of a redox couple is the electron acceptor O_2 and the electron donor H_2O. Because O_2 is a strong electron acceptor, the redox couple O_2/H_2O has a high positive value of E.

Standard values of E at equilibrium ($E°$) are known as the **standard reduction potential**. The reduction potential $E°'$ (assuming a concentration of 1 M for all components at pH 7) for H_2 formation from $2H^+ + 2e^-$ is –0.42 volts (V). This large negative reduction potential means that it takes a lot of energy to add the two electrons to $2H^+$. Thus, the reverse reaction donating $2e^-$ from H_2 to an appropriate electron acceptor yields a lot of energy. Hydrogen-oxidizing bacteria grow in our intestines, using H_2 made by fermenting bacteria.

Reduction potentials represent a form of the standard free energy change, $\Delta G°'$. The value of $\Delta G°'$ (in kJ/mol) between reactants and products is given by

$$\Delta G°' = -nFE°'$$

where n is the number of electrons transferred, F is Faraday's constant ($F = 96.4$ kJ/V · mol) and $E°'$ is the reduction potential at 1 M concentration, 25°C, and pH 7. Note

[b] Voltage potentials for redox couples when all species are 1 M at pH 7.

[c] This value is for free FAD; FAD bound to a specific flavoprotein has a different $E°'$ that depends on its protein environment.

that the reaction is favored by positive values of *E*, which yield negative values of ▯*G*.

> **NOTE:** A higher reducing potential (more positive $E°'$) means a stronger electron acceptor (stronger oxidant). A lower reducing potential (more negative $E°'$) means a stronger electron donor (stronger reductant).

The standard reduction potential $E°'$ gives the potential difference between the oxidized and reduced states at equilibrium, when both oxidized and reduced species are at equal concentrations, namely, 1 M. Assuming equal concentrations at 1 M, we may compare $E°'$ of various molecules available in the environment for microbial respiration. Such a comparison generates an “electron tower” representing the reduction potential $E°'$ of molecules that may act as electron acceptors or donors (**Table 14.1**). The oxidized state of each redox couple in the table is shown in *red*, the reduced state in blue.

In the electron tower, the more negative values represent couples (half reactions) with a stronger electron donor (H_2, NADH), whereas the more positive values represent stronger electron acceptors (O_2, NO_3^-). For example, in the redox couple NAD^+/NADH + H^+, the oxidized form is NAD^+ and the reduced form is NADH. The reduction potential is strongly negative (–320 mV), so NADH is a strong electron donor; that is, the reverse reaction, NADH + H^+ ▯ NAD^+ goes forward releasing a lot of energy (+320 mV).

A complete redox reaction combines two redox couples, one accepting electrons (arrow forward), the other donating electrons (arrow reversed). Redox couples with more negative values of $E°'$ (higher in the tower) can provide electron donors (blue column) for electron acceptors with more positive values of $E°'$ (lower in the tower, red column). The $E°'$ for the overall reaction is then given by the subtraction of the donor $E°'$ from the acceptor $E°'$. A positive value of $E°'$ means that the reaction may proceed to provide energy. For example, the oxidation of NADH by O_2 results from combining two couples:

Acceptor:
$½O_2 + 2e^- + 2H^+$ ▯ H_2O $\quad E°' = 820$ mV

Donor:
$NADH + H^+$ ▯ $NAD^+ + 2e^- + 2H^+$ $\quad E°' = -320$ mV

$NADH + H^+ + ½O_2$ ▯ $H_2O + NAD^+$ $\quad E°' = 1{,}140$ mV

The aerobic oxidation of NADH pairs a strong electron donor (NADH) with a strong electron acceptor (O_2). Thus, NADH oxidation via the ETS provides the cell with a huge amount of potential energy (comparable to a 1-V battery cell) to make ATP and generate ion gradients. NADH is oxidized by many electron transport systems of bacteria and archaea, as well as mitochondria.

Bacteria and archaea have evolved many alternative donor-acceptor systems; the one they use depends on what their environment provides. For example, in the absence of oxygen, *Escherichia coli* can oxidize NADH with fumarate, which is reduced to succinate. From **Table 14.1**, we find that

NADH + H^+ + fumarate ▯ NAD^+ + succinate

$E°' = 320 \text{ mV} + 33 \text{ mV} = 353 \text{ mV}$

When oxygen reappears in the environment, the succinate can donate electrons back to fumarate and water:

$½O_2 + 2H^+$ + succinate ▯ H_2O + fumarate

$E°' = 820 \text{ mV} - 33 \text{ mV} = 787 \text{ mV}$

> **THOUGHT QUESTION 14.1** *Pseudomonas fluorescens*, a soil bacterium, oxidizes NADH with nitrate (NO_3^-) at neutral pH. What is the value of $E°'$?

Concentrations of electron donors and acceptors. The standard reduction potential $E°'$ assumes 1 M concentrations of reactants and products at pH 7. Actual values of E within cells depend on actual reactant concentrations. In Chapter 13, we noted that ΔG includes a term incorporating the ratio of product concentrations (C and D) to reactant concentrations (A and B):

$$\Delta G = \Delta G°' + 2.303\,RT \log \frac{[C][D]}{[A][B]}$$

where R is the gas constant (8.315 J/mol), and T is the temperature in Kelvins. The reduction potential E of a redox reaction depends on the ratio of reduced products to oxidized reactants:

$$\begin{aligned} E(\text{mV}) &= \frac{-\Delta G}{nF} \\ &= E°' - \frac{2.303\,RT}{nF} \times \log \frac{[C][D](\text{reduced})}{[A][B](\text{oxidized})} \\ &= E°' - 60 \log \frac{[C][D](\text{reduced})}{[A][B](\text{oxidized})} \end{aligned}$$

where n is the number of electrons transferred and F is the Faraday constant. As the ratio of reduced products to oxidized reactants increases, E decreases; in other words, there is less potential to do work. At moderate temperatures (25–40°C), the constants in the concentration term (2.303 RT/F) combine to yield approximately 60 millivolts (mV) per electron for a tenfold ratio of products to reactants. Thus, a tenfold ratio of products to reactants subtracts about 60 mV from ΔE (decreases energy yield), whereas a tenfold excess of reactants adds 60 mV to E (increases energy yield).

A high concentration of an electron donor can drive metabolism using reactions with small values of $E°'$. For example, *Gallionella* species use the reduction potential between Fe^{3+}/Fe^{2+} and O_2/H_2O to oxidize Fe^{2+}. *Gallionella* bacteria grow in drainage from iron mines, where high concentrations of reduced iron (Fe^{2+}) support growth of thick bacterial biofilms.

THOUGHT QUESTION 14.2 Could a bacterium obtain energy from succinate as an electron donor with nitrate (NO_3^-) as an electron acceptor?

Electron Transport Systems Function within a Membrane

An electron transport system transfers electrons onto membrane-embedded carriers in a series of increasing reduction potential. Some of these steps yield energy to pump ions across the membrane. To store this energy, the ETS must maintain an ion gradient across a membrane that fully separates two aqueous compartments. For example, a bacterial cell membrane separates the cytoplasm and external medium. Gram-negative bacteria such as *E. coli* have their ETS in the inner cell membrane, which separates the cytoplasm from the periplasm. The gram-negative outer membrane surrounding the periplasm is permeable to protons and other small molecules; thus, the outer membrane does not store energy.

Figure 14.2A shows the inner membrane of *Sulfurospirillum barnesii*, a respiring bacterium isolated from farm drainage in Nevada. *S. barnesii* can respire using O_2 as a terminal electron acceptor—or it can use one of several alternative electron acceptors, such as selenium oxyanions (SeO_3^{2-} or SeO_4^{2-}). The oxyanions are reduced to pure selenium (Se), which collects in solid granules within the cell. Whether with O_2 or with an alternative electron acceptor, electrons are transferred from a reduced nutrient molecule (electron donor) through ETS components that pump protons across the membrane.

A similar structure is found in the ETS of our own mitochondria (**Fig. 14.2B**). Mitochondrial respiration uses only O_2 as a terminal electron acceptor. The ETS proteins are embedded in folds of the mitochondrial inner membrane called cristae. The inner membrane separates the inner mitochondrial space from the intermembrane space (between the inner and outer membranes). The mitochondrial inner membrane, including its electron

Figure 14.2 **Respiratory membranes.** **A.** Electron transport occurs in the inner membrane of *Sulfurospirillum barnesii* (TEM). Reduction of selenium oxyanions (SeO_3^{2-} or SeO_4^{2-}) generates granules of selenium (Se^0). **B.** Mitochondria in a human pancreatic acinar cell (TEM). The inner membrane containing the electron transport system is organized in pockets called cristae, about 40 nm thick.

transport proteins, evolved from the cell membrane of an endosymbiotic bacterial ancestor. Among modern bacteria, the closest relatives of mitochondria are the rickettsias, obligate intracellular parasites that cause serious diseases, such as Rocky Mountain spotted fever. Like mitochondria, the rickettsias show evidence of extensive evolutionary degeneration of genes no longer required for intracellular survival. Mitochondrial evolution is discussed further in Chapter 17.

The electron carrier molecules include proteins and small organic molecules called cofactors, which are loosely or tightly bound to the proteins. The protein components of an ETS were first discovered in the 1930s at Cambridge University by Russian scientist David Keilin (1887–1963). Keilin was an entomologist who studied insect mitochondria. The mitochondrial inner membranes contained proteins called **cytochromes**, which were named for their deep colors, typically red to brown.

In prokaryotes, cytochromes are often found in the cell membrane. **Figure 14.3** shows the absorbance spectrum of a cytochrome from the cell membrane of *Haloferax volcanii*, a halophilic archaeon isolated from the Dead Sea. In the reduced cytochrome, light absorption peaks in the blue range (440 nm) and in the red (607 nm). Upon oxidation, however, the cytochrome loses its absorption peak at 607 nm, and the 440-nm peak shifts to a shorter wavelength; its reflected color shifts red. Different species of bacteria make many different cytochromes, with different absorption peaks, but all cytochromes show spectral change with change in reduction state.

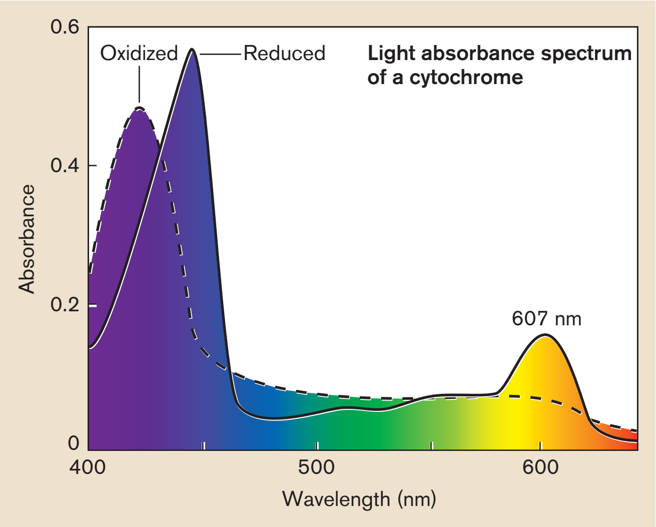

Figure 14.3 Light absorbance spectrum of a cytochrome. Absorption peaks shift between the oxidized and reduced forms of a cytochrome from the electron transport system of *Haloferax volcanii*, a halophilic archaeon.

A membrane ETS typically includes several different cytochromes with different reduction potentials. Keilin proposed that the cytochromes pass electrons sequentially from each protein complex to the next stronger electron acceptor, with each step providing a small amount of energy to the organism (**Fig. 14.4**). The electron transport proteins are now generally known as **oxidoreductases** because they oxidize one substrate (removing electrons) and reduce another (donating electrons). Thus, they couple different half-reactions in the electron tower (**Table 14.1**). Oxidoreductases consist of multiple-protein complexes that include cytochromes as well as noncytochrome proteins. The structure and function of ETS oxidoreductase complexes are discussed in Section 14.3.

TO SUMMARIZE:

- **An electron transport chain (ETS)** consists of a series of electron carriers that sequentially transfer electrons to the carrier of next higher reduction potential (that is, next stronger electron acceptor). Electron flow through the ETS begins with an initial electron donor from outside the cell and ultimately transfers all electrons to a terminal electron acceptor that leaves the cell.
- **The reduction potential *E*** for a complete redox reaction must be positive to yield energy for metabolism. The standard reduction potential $E°'$ indicates the voltage potential at which both members of a redox couple are present in equal concentration.
- **Concentrations of electron donors and acceptors** in the environment influence the actual reduction potential *E* experienced by the cell.

Figure 14.4 Electron transport system. Keilin's model for electron transfer through cytochromes. Each cytochrome in turn receives the electrons from a stronger electron donor and transfers it to a stronger electron acceptor.

- **The ETS is embedded in a membrane that separates two compartments.** Two aqueous compartments must be separate to maintain an ion gradient generated by the ETS.
- **The ETS is composed of protein complexes and cofactors.** Protein complexes called oxidoreductases include cytochromes and noncytochrome proteins. Cytochromes are colored proteins whose absorbance spectrum shifts when there is a change in redox state.

14.2 The Proton Motive Force

The sequential transfer of electrons from one ETS protein to the next yields energy to pump ions (in most cases H^+) across the membrane. Proton pumping generates a **proton motive force** (or **proton potential**) composed of the H^+ concentration difference plus the charge difference across the membrane. The proton motive force (PMF) can be used to drive many different cell processes, including ATP synthesis, flagellar rotation, and nutrient transport.

The Electron Transport System Pumps Protons

The ion pumped by most ETS complexes is H^+. In this book, we use *hydrogen ions* and *H*$^+$ interchangeably with *protons*. In fact, we do not know the precise form of the ion that crosses the membrane. In water solution, H^+ never occurs as such because it combines with a water molecule to form hydronium ion, H_3O^+. Current data, however, are consistent with the passage of isolated hydrogen nuclei (protons) across the proton pumps of the electron transport system.

The proton pump generates an H^+ concentration difference across the membrane. Also, the separation of charge generates a charge difference across the membrane. The H^+ concentration gradient (ΔpH) plus the charge difference ($\Delta\Psi$) make a proton potential (Δp), or proton motive force. The proton potential (in volts) equals the electrochemical proton gradient (in joules) multiplied by Faraday's constant.

The discovery of the proton potential radically changed the field of biochemistry. Early in the twentieth century, Keilin and other scientists knew that the energy acquired by electron transport proteins was used to make ATP, but they did not know how. Most were convinced that electron transport was somehow directly coupled to ATP synthesis. The actual means of coupling was discovered by a student of Keilin's, Peter Mitchell (1920–1992). In 1961, Mitchell proposed an astonishing explanation for the coupling of electron transport to ATP synthesis (**Fig. 14.5**). The **chemiosmotic hypothesis** states that the energy from electron transfer between membrane proteins is used to pump protons across the membrane, accumulating a higher H^+ concentration in the compartment outside. The pump generates the proton motive force Δp, which stores energy that can be used to make ATP (discussed in Section 14.3).

Figure 14.5 The chemiosmotic hypothesis. The chemiosmotic hypothesis states that the electron transport system pumps protons out of the cell. The resulting electrochemical gradient of protons (proton motive force) drives conversion of ADP to ATP through ATP synthase, as well as transport of various substrates such as sugars.

At first, many biologists found it difficult to understand how a proton potential could be coupled to ATP synthesis at an enzyme complex separate from the ETS, at a distant location on the membrane. The explanation is that the H^+ concentration gradient and charge difference exist everywhere on the membrane separating the two compartments. Because the membrane is impermeable to hydrogen ions, the H^+ current can only flow back through a proton-driven complex such as the membrane ATP synthase (discussed in section 14.3). In effect, the proton potential is a "proton battery," analogous to the electron potential of an electrical battery. The concept of cellular electricity proved highly controversial among scientists, who devised many experiments to test it before it was accepted (see **Special Topic 14.1**).

Special Topic 14.1 Testing the Chemiosmotic Hypothesis

In 1961, as a young researcher at the University of Edinburgh, Peter Mitchell (**Fig. 1A**) first developed the chemiosmotic theory. He developed the idea of vectorial metabolism—that metabolic energy could be stored in a directional form, in an ion gradient. The energy stored in a gradient of ions across a membrane could be interconverted with the energy of chemical interactions, such as oxidation of glucose. Through vectorial metabolism, the oxidation-reduction reactions of the electron transport system could drive the pumping of protons across a membrane, as well as transport of other ions and nutrients. The proton gradient could then drive protons back through the F_1F_o ATP synthase, driving synthesis of ATP.

Mitchell's ideas were largely rejected for several reasons. Established colleagues had spent many years discovering the molecular "intermediates" of metabolism, and they expected to find one or two more between the ETS and the ATP synthase. Furthermore, most biochemists lacked sufficient training in physics to appreciate Mitchell's ideas, and Mitchell's communication skills did not cross the gap. Eventually, private family wealth enabled Mitchell to leave Edinburgh and form the Glynn Research Foundation. The foundation supported a bioenergetics laboratory at Glynn House, a country estate in Cornwall that Mitchell restored and equipped (**Fig. 1C**). At Glynn, Mitchell developed a research program to test various principles and predictions of the chemiosmotic theory.

During his graduate studies at Cambridge, Mitchell had collaborated with an outstanding experimentalist, Jennifer Moyle (**Fig. 1B**). Moyle was a student of the Cambridge biochemist Marjorie Stephenson, the first woman to be selected as a Fellow of the Royal Society. Stephenson suggested that Moyle work with Mitchell, and it was Moyle who performed most of the early experiments testing the chemiosmotic theory. Moyle continued working with Mitchell at Edinburgh, and she moved with him to Glynn, where they worked together for the next 30 years.

In the 1960s, Mitchell and Moyle devised several experiments to test the chemiosmotic theory. A key requirement was to show that the ETS generates a proton potential. Moyle showed that respiration of mitochondria was associated with proton efflux: Mitochondria isolated from rat livers were exposed to oxygen, causing efflux of hydrogen ions. The H^+ efflux occurred as electrons were transferred across the ETS and hydrogen ions were expelled by the proton pumps. In Moyle's experiments, the number of protons extruded per electron transferred down the ETS was consistent with the chemiosmotic model. Similar results were obtained using vesicles made first from mitochondrial membranes and later from the membranes of chloroplasts and bacteria.

A greater challenge was to demonstrate that a proton motive force could in fact drive the ATP synthase and other ion transporters without any undiscovered intermediate. Many researchers attempted to show this, often with conflicting results. The first successful experiment was reported in 1966 by André Jagendorf, a colleague from Johns Hopkins University who had visited Mitchell at Glynn. Jagendorf and his postdoctoral fellow Ernest Uribe tested the effect of a proton gradient imposed on spinach chloroplasts (**Fig. 2A**). Chloroplasts, unlike mitochondria and bacteria, contain ATP synthase directed outward (that is, driven by proton flow from inside to outside). The chloroplasts were partly opened by osmotic shock, then suspended in medium containing concentrated hydrogen ions (pH 4). With the osmotic balance restored, the chloroplast membranes closed again, with increased $[H^+]$ trapped inside. When the pH outside was raised to pH 8.3 (that is, lower $[H^+]$), protons from the acidic interior of the

vesicles flowed out through the ATP synthase, and ADP and inorganic phosphate were converted to ATP. Jagendorf interpreted this result as consistent with Mitchell's chemiosmotic hypothesis for the mechanism of phosphorylation.

Figure 2 **Either ΔpH or $\Delta\psi$ drives ATP synthesis.** **A.** A pH difference imposed across the chloroplast inner membrane drives a proton current through an outwardly directed ATP synthase. **B.** A charge difference generated by K^+ influx drives a proton current through ATP synthase.

Other researchers showed that ATP synthesis could be driven by a charge difference across a vesicle membrane (**Fig. 2B**). An artificial electrical potential ($\Delta\psi$) was applied by loading vesicles with potassium ions (K^+). The potassium ions were conducted across the membrane by an ionophore, a small organic molecule that binds to an ion and solubilizes it in the membrane. The K^+ ionophore was the antibiotic valinomycin, a cyclic peptide of 12 amino acids produced by the bacterium *Streptomyces fulvissimus*. Valinomycin specifically binds K^+, while its hydrophobic side chains solubilize it in the membrane; thus the molecule conducts K^+ across the membrane down its concentration gradient (see **Fig. 2B**). In the experiment shown, the vesicles are "inside-out" bacterial membrane vesicles, in which the ATP synthase points outward instead of inward. The K^+ influx adds positive charge, which drives H^+ out through ATP synthase, catalyzing formation of ATP. Thus, $\Delta\psi$ drives formation of ATP.

The preceding experiments, however, could not definitively rule out the existence of an undetected component of the membrane that somehow energized ATP synthase. A more compelling experiment was performed in 1975 by Efrem Racker and colleagues at Cornell University. Racker developed a process to make artificial vesicles called "liposomes," composed of purified phospholipids in the absence of any membrane proteins. He then purified a proton pump called bacteriorhodopsin from a halophilic archaeon, a *Halobacterium* species. Bacteriorhodopsin acts as a single-protein proton pump driven by light absorption. The bacteriorhodopsin was combined with phospholipids and with ATP synthase purified from mitochondria to obtain "reconstituted liposomes" with functional bacteriorhodopsin and mitochondrial ATP synthase. When the liposomes were exposed to light, the bacteriorhodopsin pumped protons and the ATP synthase made ATP. Thus, a proton pump and a proton-driven ATP synthase from two completely different organisms could work together in a membrane, connected solely by the proton motive force.

In 1978, Mitchell received the Nobel Prize in Chemistry, and the scientific community fully embraced the role of ion currents in metabolism. Today the chemiosmotic principle is firmly established as the basis of energy transduction in respiration, lithotrophy, and photosynthesis. Nevertheless, interesting questions remain, some of which were addressed by Peter Rich (now at University College, London), who succeeded Mitchell as director of research at Glynn in 1987. Rich introduced modern forms of spectrophotometry to investigate the mechanisms of proton transport by specific ETS components, such as cytochrome oxidase. Other researchers are now investigating how extreme acidophiles and alkaliphiles manage to grow at pH values as low as pH 1 or as high as pH 14 while maintaining internal pH within two units of neutrality. Medical researchers, meanwhile, investigate how pathogenic bacteria and tumor cells use proton-driven efflux pumps to expel antibiotics from the cell.

The Proton Potential Includes the Electrical Potential and the H^+ Concentration Gradient

When protons are pumped across the membrane, energy is stored in two different but energetically equivalent forms: the separation of charge, or electrical potential (because H^+ carries a positive charge), and the gradient of H^+ concentration, or pH difference, as shown in **Figure 14.6**. Either form (or both) can drive Δp-dependent cell processes.

Thus, the Δp contains two different components:

- **The electrical potential** ($\Delta\psi$) arises from the separation of charge between the cytoplasm (more negative) and the solution outside the cell membrane (more positive). For many bacteria, this "battery" potential is about –50 to –150 mV.
- **The pH difference** (ΔpH) is the log ratio of external to internal chemical concentrations of H^+. For example, if the bacterial internal pH is 7.5 and the external pH is 6.5, the ΔpH is 1.0, and the ratio of $[H^+]_{out}$ to $[H^+]_{in}$ is 10. A ΔpH of 1.0 corresponds to a proton chemical concentration potential of approximately –60 mV.

The relationship between electrical and chemical components of the proton potential Δp is given by:

$$\Delta p = \Delta\psi - (2.3RT/F)\ \Delta \text{pH}$$

or approximately

$$\Delta p = \Delta\psi - 60\Delta \text{pH}$$

For cells grown at neutral pH, all three terms (Δp, $\Delta\psi$, and -60ΔpH) usually have a negative value, meaning that their force drives protons inward from outside.

In living cells, the relative contributions of $\Delta\psi$ and -60ΔpH vary depending on other sources of charge difference and protons, as shown in **Figure 14.6**. Both the $\Delta\psi$ and ΔpH components of Δp are influenced by other factors besides ETS proton transport. For example:

- **The charge difference $\Delta\psi$** includes charges on other ions, such as K^+ and Na^+. These ions are pumped or exchanged by ion-specific membrane transport proteins.
- **The pH difference ΔpH** is affected by metabolic generation of acids, such as fermentation acids, or by pH changes outside the cell. Permeant acids can run down the gradient through the membrane, collapsing the ΔpH to zero.

Overall, the cell uses its various membrane pumps and metabolic pathways to adjust and maintain its proton motive force at a size sufficient to drive ATP synthesis but not so great as to disrupt the membrane.

THOUGHT QUESTION 14.3 What do you think happens to $\Delta\psi$ as the cell's external pH increases or decreases? What happens to Δp in bacteria growing at a pH two or three units above their internal pH?

How are the Δp and its two components actually measured? In larger cells, such as those of eukaryotes, a microelectrode can be inserted into the cell to measure voltage potentials directly. Most bacterial cells are too small to insert electrodes, but $\Delta\psi$ and ΔpH can be measured by the uptake of molecules whose ability to permeate the membrane depends on their ionic state.

Lipid-soluble cations measure $\Delta\psi$. Most ions carrying positive charge (cations) cannot penetrate the hydrophobic membrane. However, certain cations contain multiple hydrophobic side chains whose lipid solubility overcomes the unfavorable interaction with the positive charge. An example is triphenylmethylphosphonium (TPMP) (**Fig. 14.7**). TPMP can penetrate and cross the membrane. Because no H^+ is carried, uptake of the cation is driven

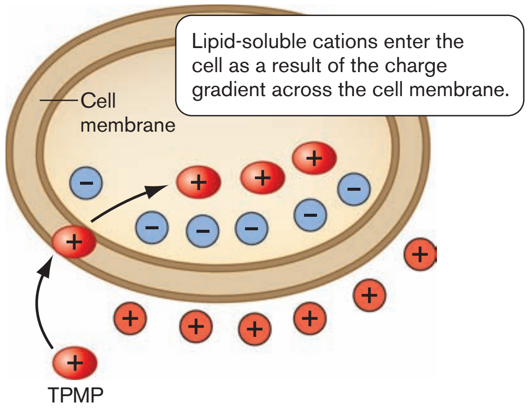
solely by the charge difference (usually negative inside the cell) and thus affects only the electrical potential. A radiolabeled TPMP will accumulate in the cell in proportion to the charge difference (**Fig. 14.8**). Thus, the cellular uptake of a lipid-soluble cation such as TPMP can be used to measure $\Delta\psi$.



Lipid-soluble cations enter the cell as a result of the charge gradient across the cell membrane.

Figure 14.8 Measuring the electrical potential, $\Delta\psi$. Uptake of lipid-soluble cations is proportional to the transmembrane charge difference, or electrical potential, $\Delta\psi$.

Membrane-permeant weak acids measure ΔpH. Weak acids such as benzoic acid cross the membrane primarily in the uncharged form (HA) (**Fig. 14.9A**), as discussed in Chapters 3 and 4. Many fermentation acids, such as acetate and lactate, are membrane-permeant weak acids. At low concentration, the weak acid acts as a proton carrier, soluble in the membrane. Inside the cell, at higher pH, the HA dissociates to H^+ plus A^-. The acid accumulates inside until the pH inside falls to the level of the pH outside. Thus, uptake of a radiolabeled weak acid can be used to measure ΔpH.

Some weak acids cross the membrane in both charged and uncharged forms. The weak acid 2,4-dinitrophenol (DNP) dissociates to an anion whose charge is relatively evenly distributed around the molecule; thus, it remains overall hydrophobic enough to penetrate the membrane (**Fig. 14.9B**). Because both protonated (uncharged) and deprotonated (negatively charged) forms cross the membrane, DNP can cyclically bring protons into the cell and collapse both $\Delta\psi$ and ΔpH (**Fig. 14.9C**). Such molecules are called **uncouplers** because they uncouple electron transport from ATP synthesis through the membrane ATP synthase. Uncouplers are highly toxic to bacteria, and in the early twentieth century, they were considered for use as antibiotics. Unfortunately, they are also highly toxic to human cells. All cells need to maintain ion gradients and voltage potentials.

The Proton Potential Drives Many Cell Functions

Besides ATP synthesis, Δp drives many cell processes directly, such as the rotation of flagellar motors (**Fig. 14.10**). Proton transport is also coupled to transport of ions

Figure 14.9 Membrane-permeant weak acids and uncouplers. A. such as K^+ or Na^+ through parallel transport (symport) or oppositely directed transport (antiport), as discussed in Chapters 3 and 4. Ion flux then drives uptake of nutrients such as amino acids or efflux of molecules such as antibacterial drugs. Drug efflux pumps are a major problem in hospitals, where the pump proteins are encoded by genes carried on plasmids that spread among virulent strains.

TO SUMMARIZE:

- **The ETS complexes generate a proton motive force** (Δp). The force is usually directed inward, driving protons into the cell.
- **The proton potential drives ATP synthase** and other functions, such as ion transport and flagellar rotation.
- **The proton potential (Δp, measured in millivolts)** is composed of the electrical potential ($\Delta\psi$) and the hydrogen ion chemical gradient (ΔpH): $\Delta p = \Delta\psi - 60\Delta\text{pH}$.
- **Uncouplers are molecules taken up by cells in both protonated and unprotonated forms.** Uncouplers can collapse the entire proton potential, thus uncoupling respiration from ATP synthesis.

THOUGHT QUESTION 14.4 Suppose that de-energized cells ($\Delta p = 0$) with an internal pH 7.6 are placed in a solution at pH 6. What do you predict will happen to the cell's flagella? What does this demonstrate about the function of Δp?

14.3 The Respiratory ETS and ATP Synthase

In the respiratory electron transport system (ETS), a series of carrier molecules harvest the reducing potential of electrons in small steps. The respiratory ETS most commonly presented is that of the mitochondrial inner membrane, in which NADH and $FADH_2$ transfer electrons ultimately to O_2, producing H_2O. Microbes, however, have evolved a diverse array of electron carriers matched to diverse electron donors and acceptors.

Cofactors Provide Small Energy Transitions

ETS proteins such as cytochromes must associate electron transfer with small energy transitions. The small energy transitions are mediated by cofactors, small molecules that associate strongly or loosely with the protein. **Figure 14.11** shows the protein structure of a cytochrome from the pathogen *Pseudomonas aeruginosa*. The protein, cytochrome *c*, transfers electrons for nitrate respiration. Its reddish color derives from the buried cofactor called **heme**, a ring of conjugated double bonds surrounding an iron atom. The heme plays a key role in acquiring and transferring electrons, with an Fe^{2+}/Fe^{3+} transition. Metal-reducing bacteria such as *Geobacter* make hundreds of different types of cytochromes in their periplasm, where electrons accumulate until the bacterium finds an oxidized metal to accept them.

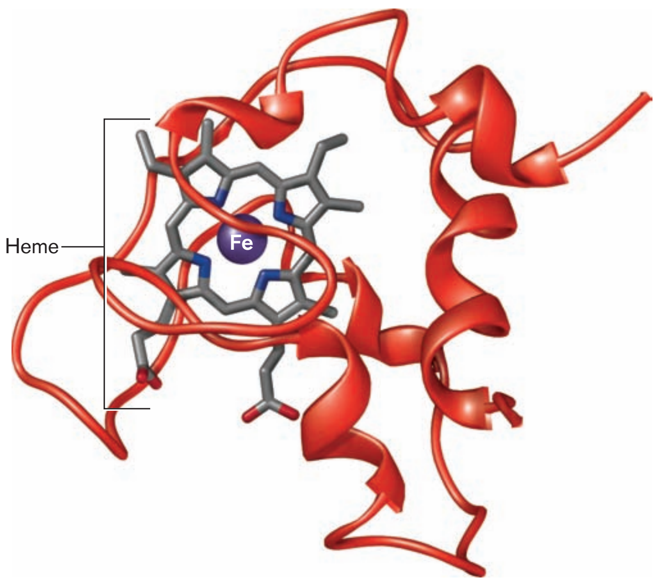

Figure 14.11 Cytochrome *c*. Portion of the protein structure of cytochrome *c* containing one heme cofactor, from the pathogen *Pseudomonas aeruginosa*. (PDB code: 2PAC)

Cofactors such as heme provide the capacity for small, reversible redox changes (**Fig. 14.12**). Examples include flavin mononucleotide (FMN) and ubiquinone. The structure of each cofactor must allow transition of an electron between orbitals with closely spaced energy levels to avoid "spending it all in one place." If all energy were spent in one transition, most of it would be lost as heat instead of conversion to several small processes, such as pumping H^+ across the membrane.

Small energy transitions are typically accomplished by these kinds of molecular structures:

- Metal ions such as iron or copper, coordinated (and hence held in place) with amino acid residues. Iron is often coordinated by sulfur atoms of cysteine residues in the protein; examples shown in **Figure 14.12B** are [2Fe-2S] and [4Fe-4S]. Transition metals make useful electron carriers because their outer electron shell has several closely spaced energy levels, facilitating small energy transitions.
- Conjugated double bonds and heteroaromatic rings, such as the nicotinamide ring of NAD^+/NADH, also provide narrowly spaced energy transitions. Membrane-soluble carriers such as **quinones** (reduced to **quinols**) allow even smaller energy transitions than does NAD^+/NADH.

The major protein complexes of electron transport each contain one or more reaction centers containing either metal ions or conjugated double bonds or both. In FMN, the conjugated double bonds allow a small energy transition (**Fig. 14.12A**). In iron sulfur clusters (Fe_2S_2 and Fe_4S_4), the metal atoms provide the site for a small energy transition, its size dependent on the cluster's connections within the associated protein (**Fig. 14.12B**). The heme group found in cytochromes and other oxidoreductases contain

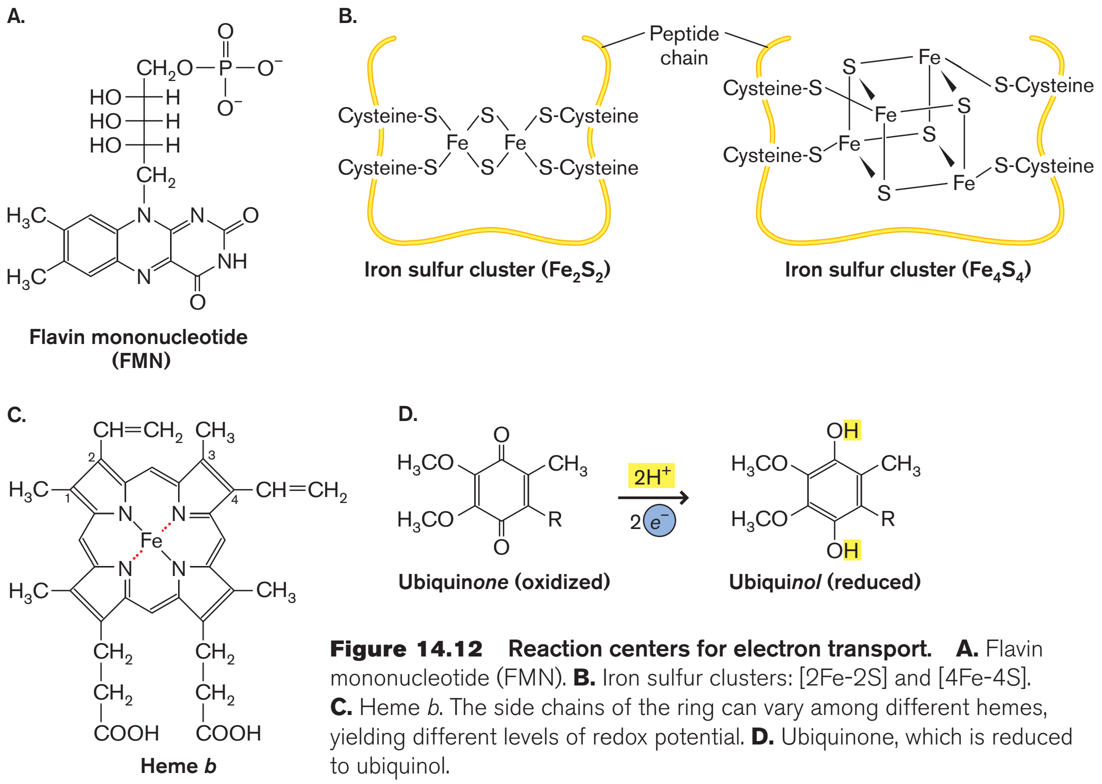

Figure 14.12 Reaction centers for electron transport. A. Flavin mononucleotide (FMN). **B.** Iron sulfur clusters: [2Fe-2S] and [4Fe-4S]. **C.** Heme *b*. The side chains of the ring can vary among different hemes, yielding different levels of redox potential. **D.** Ubiquinone, which is reduced to ubiquinol.

extensive conjugated double bonds, coordinated around the metal Fe^{3+} (**Fig. 14.12C**). Reduction by a transferred electron converts the iron to Fe^{2+}. The branching of side chains on the ring varies among different hemes, altering the magnitude of $E°'$ for the redox couple Fe^{3+}/Fe^{2+}.

Some electron carriers are small molecules that associate loosely with a protein complex, then come apart to diffuse freely throughout the membrane. Mobile electron carriers include quinones such as ubiquinone (**Fig. 14.12D**), which are reduced by hydrogenation to quinols:

$$Q + 2H^+ + 2e^- \rightarrow QH_2$$

Quinols carry electrons and protons laterally within the membrane between the proton-pumping protein complexes of the ETS. After transferring their electrons to the next protein complex, they revert to quinones, capable of accepting electrons again.

> **NOTE:** *Dehydrogenases, reductases,* and *oxidases* are all **oxidoreductases**, which oxidize one substrate (remove electrons) and reduce another (donate electrons). Oxidoreductases that accept electrons from NADH or $FADH_2$ are called dehydrogenases because their reaction releases hydrogen ions.

Oxidoreductase Protein Complexes

Here we present the molecular structures of a typical bacterial ETS conducting respiration. A respiratory electron transport system includes at least three functional components: a substrate oxidoreductase (or dehydrogenase), a mobile electron carrier, and a terminal oxidase. In some cases, alternative forms for each component allow access to alternative electron-donating substrates and terminal electron acceptors.

Substrate oxidoreductase. An ETS begins with an oxidoreductase that receives a pair of electrons from an organic substrate such as NADH, or an inorganic substrate such as H_2 or Fe^{2+}. Note that NADH arises through removal of $2H^+$ from an organic product of catabolism (designated RH_2) (**Fig. 14.13A**). The $2H^+$ are ultimately balanced by $2H^+$ from the cytoplasm combining with O_2 (or another terminal electron acceptor) at the end of the ETS.

NADH donates electrons to **NADH dehydrogenase (NADH:quinone oxidoreductase, NDH-1)** (**Fig. 14.13A**). In bacteria, the NDH-1 complex includes 14 different subunits; in mitochondria, there are 46, one of the most elaborate membrane complexes known. A bacterial complex includes the cofactor FMN as well as several iron sulfur clusters (typically $7Fe_4S_4$ and $2Fe_2S_2$). The cofactors "hand off" electrons to each other through adjacent connections; see, for example, the placement of FMN and the first Fe_4S_4 within the peptide coils of NDH-1 (**Fig. 14.13B**).

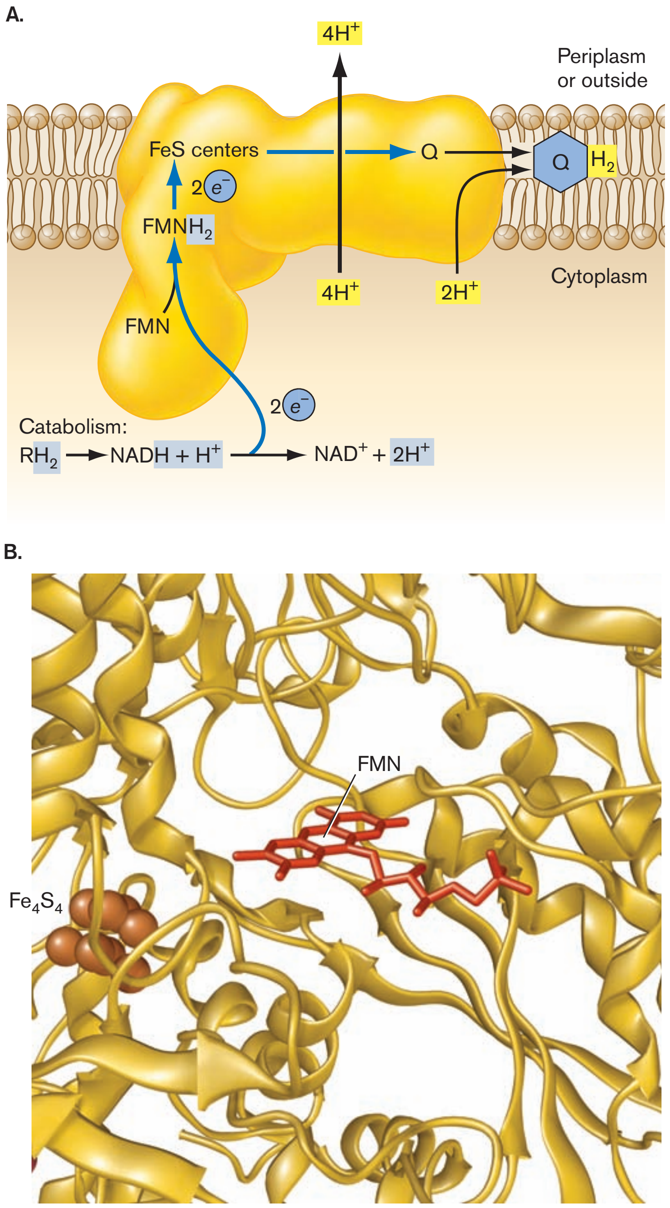

Figure 14.13 **NADH:quinone oxidoreductase complex (NDH-1).** **A.** NDH-1 transfers two electrons from NADH onto FMN ($FMNH_2$), through several FeS centers, ultimately onto a quinone, Q (forming quinol, QH_2). The energy from oxidizing NADH is coupled to pumping an additional $4H^+$ across the cell membrane. **B.** Within the NDH-1 complex, FMN lies adjacent to the first iron sulfur center, Fe_4S_4. (PDB code: 1NOX)
Source: B. L. A. Sazanov and P. Hinchliffe. 2006. *Science* 311:1430–1436.

Each electron from NADH travels individually through FMN and the iron sulfur series. At the end of the chain, the electrons are transferred to a quinone, which picks up $2H^+$ from solution and is thus reduced to quinol. Quinones are generally designated Q, and quinols QH_2.

Elsewhere within the NDH-1 complex, the oxidation of NADH and reduction of Q to QH_2 is coupled to pumping of up to $4H^+$ across the membrane, using the energy yielded by oxidation of NADH. Note that the $4H^+$ pumped across the membrane are distinct from the $2H^+$ transferred onto the quinone (Q ▯ QH_2). In some halophilic bacteria, $4Na^+$ are pumped instead of $4H^+$. The mechanism of the coupling reaction remains unknown, although it is of interest because of its contribution to the proton potential. In human mitochondria, the NADH dehydrogenase (aka complex I) is critical for health; genetic defects in complex 1 are associated with diseases such as Parkinson's disease and some forms of diabetes.

> **NOTE:** In our figures, protons that are formed and consumed without affecting the transmembrane potential are shaded gray (see **Fig. 14.13A**). Protons that cross the membrane by the end of the ETS are highlighted yellow.

Not all substrate oxidoreductases pump protons. For example, *E. coli* has an alternative NADH dehydrogenase (NDH-2) that transfers two electrons to Q without pumping additional protons across the membrane. (The unused energy is lost as heat.) NDH-2 functions during rapid growth, when the cell must limit its proton potential to avoid membrane breakdown. Other complexes, such as succinate dehydrogenase, transfer electrons from substrates that lack sufficient energy to pump extra protons.

Quinone pool. A quinone can receive $2e^-$ from the substrate oxidoreductase. When it picks up $2H^+$ from solution, the quinone is converted to a quinol (**Fig. 14.12D**). The quinols diffuse within the membrane and carry reduction energy to other ETS components. After transferring $2e^-$ to the next protein complex, $2H^+$ are released in solution, usually across the membrane (**Fig. 14.14**). Thus quinol transfer contributes $2H^+$ to the transmembrane proton potential. The reoxidized carriers then recycle back as quinones.

Each quinone can bind to a substrate dehydrogenase, pick up a pair of electrons and hydrogen ions, then diffuse away and carry the electrons to a reductase. The quinones and quinols, referred to as the **quinone pool**, diffuse freely within the phospholipids of the membrane. Thus, the quinones/quinols are able to transfer electrons between many different redox enzymes.

Note that quinones with different side chains have different names, such as ubiquinone and menaquinone. For clarity, we refer to all as quinones (Q) and their reduced forms, quinols (QH_2).

Terminal oxidase. A terminal oxidase complex receives electrons from a quinol (QH_2) and transfers them to a terminal electron acceptor, such as O_2 or NO_3^- (**Fig. 14.14**). The complex usually includes a cytochrome that accepts electrons from quinols. Cytochromes of comparable function are designated by letters, such as cytochrome *b* (*E. coli* and mitochondria) and cytochrome *c* (mitochondria). The

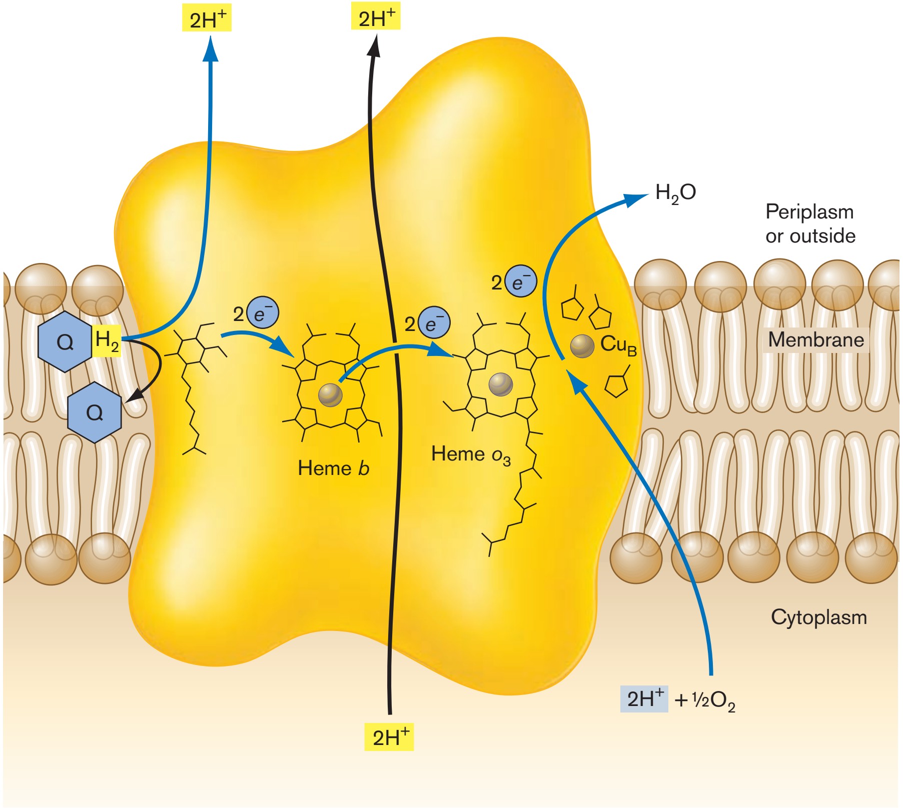

Figure 14.14 Cytochrome *bo* quinol oxidase complex. Each quinol (QH_2) transfers two electrons to heme *b*. The two H^+ from each quinol are expelled to the periplasm (or outside the bacterial cell). The $2e^-$ from the quinols are transferred to heme o_3, a step coupled to pumping of $2H^+$ across the membrane. At heme o_3, $2e^-$ combines with $2H^+$ plus an oxygen atom from O_2 to form water. *Source:* Based on the structure determined by Jeff Abramson, et al. 2000. *Nature Structural Biology* 7:910–917.

cytochrome is bound to an oxidase complex containing a series of electron-transferring carriers: two iron-centered hemes and three copper atoms. This unique center couples electron transfer and proton pumping.

The *E. coli* cytochrome *bo* quinol oxidase consists of cytochrome *b* plus oxidase complex *o*. The cytochrome *b* subunit receives two electrons from a quinol (QH_2 ▯ Q) and releases the $2H^+$ out to the periplasm. Each electron from quinol travels through the two hemes of the oxidase complex. Thus, because $2H^+$ were consumed from the cytoplasm at the NADH oxidoreductase (**Fig. 14.13**) and $2H^+$ were released outside by a quinol, there is net increase of $2H^+$ outside the cell. In addition, the transfer of $2e^-$ between the two oxidase hemes is coupled to pumping $2H^+$ from the cytoplasm across to the periplasm (**Fig. 14.14**).

The second heme of the oxidase (heme o_3) receives an atom of oxygen from O_2. Each oxygen atom in turn receives two electrons and combines with two protons ($2H^+$) from the cytoplasm to form H_2O. The $2H^+$ consumed balances the $2H^+$ released by catabolism to make NADH + H^+.

Note that the oxidase is conventionally shown as obtaining two electrons from the cytoplasm and donating them to $½O_2$, although, of course, $½O_2$ does not exist as such. A full reaction cycle of cytochrome *bo* quinol oxidase actually puts four electrons from two quinols (originally 2NADH) onto O_2, taking up $4H^+$ from the cytoplasm to make two molecules of H_2O.

Besides cytochrome *bo* quinol oxidase, bacteria express different terminal oxidases that differ with respect to the ratio of cytoplasmic protons pumped to electrons transferred. For example, the alternative cytochrome *bd* oxidase reduces O_2 to water but pumps no extra protons. Cytochrome *bd* is favored when external pH is already low and cell growth would be impaired by further acidification.

Electron Transport Pathways for Respiration

As we have seen, a respiratory ETS includes at least three phases of electron transfer: (1) Substrate electrons are donated to an oxidoreductase; (2) the electrons are transferred to a quinone, which is reduced to a quinol; and (3) the quinol electrons are transferred to a terminal oxidoreductase while its $2H^+$ are released outside. Both enzymes and quinones show considerable complexity and diversity among different species in different environments. **Figure 14.15** summarizes one example of a complete ETS for oxidation of NADH by $½O_2$ in the inner membrane of *E. coli*.

The entering carrier NADH carries two electrons with protons obtained from catabolized food molecules. The two electrons ($2e^-$) from NDH-1 and two protons ($2H^+$) from solution are transferred onto Q (quinone), converting it to QH_2 (quinol). The electrons transferred

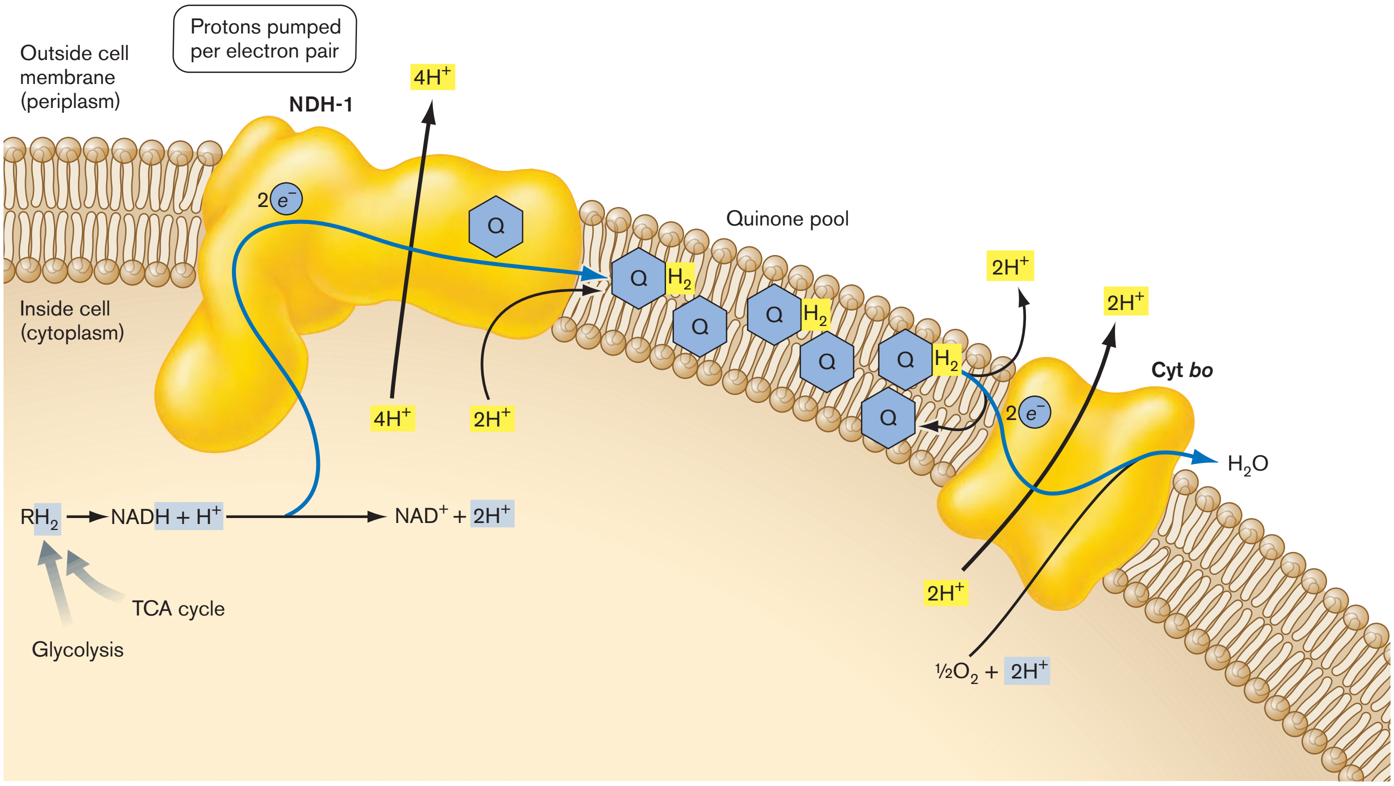

Figure 14.15 **A bacterial ETS for aerobic NADH oxidation.** In *E. coli*, electrons from NDH-1 are transferred to quinones, generating quinols. The quinols transfer electrons onto Cyt *bo*. For each NADH oxidized, up to $8H^+$ may be pumped across the membrane.

from NADH include sufficient energy to pump up to $4H^+$ across the membrane. The exact number depends on cell conditions, such as the concentrations of NADH and the terminal electron acceptor.

The hydrogenated QH_2 diffuses within the membrane until it reaches a terminal oxidase complex, such as the cytochrome *bo* quinol oxidase. The $2H^+$ from QH_2 are released outside the cell, while the $2e^-$ enter the oxidase, reducing the two hemes. The two electrons join $2H^+$ from the cytoplasm, combining with an oxygen atom to make H_2O. The reaction is coupled to pumping of $2H^+$ across the membrane plus a net increase of $2H^+$ outside through redox reactions.

Overall, the oxidation of NADH exports about $8H^+$ per $2e^-$ transferred through the ETS to make H_2O. The export of protons generates a proton potential □*p*.

NOTE: Protons (hydrogen ions, H^+) can have three different fates in the ETS:

1. Protons are pumped across the membrane by an oxidoreductase complex; contributes □*p*.
2. Protons are consumed from the cytoplasm by quinone/quinol, then released across the membrane; contributes □*p*.
3. Protons are consumed by combining with the terminal electron acceptor (O_2). Balances protons released by catabolism; does not affect □*p*.

THOUGHT QUESTION 14.5 What is the advantage of the oxidoreductase transferring electrons to a pool of mobile quinones, which then reduce the terminal reductase (cytochrome complex)? Why does each oxidoreductase not interact directly with a cytochrome complex?

THOUGHT QUESTION 14.6 Why are most electron transport proteins fixed within the cell membrane? What would happen if they "got loose" in aqueous solution?

Environmental modulation of the ETS. The ETS just described represents optimal conditions, when food and oxygen are unlimited. What happens in tough conditions, when food (that is, electron donors) or oxygen is scarce? Under varying environmental conditions, bacteria adjust the efficiency of their ETS by expressing alternative oxidoreductases. This adjustment depends on available concentrations of electron donors (such as NADH) and electron acceptors (such as O_2). Available concentrations of substrates determine the actual reduction potential *E* for NADH oxidation and hence the proton motive force □*p*.

The overall equation for NADH oxidation by O_2 is

$$2\mathrm{NADH} + 2\mathrm{H}^+ + \mathrm{O}_2 \ \square\ 2\mathrm{NAD}^+ + 2\mathrm{H}_2\mathrm{O}$$

The reduction potential *E* depends on the concentrations of reactants and products.

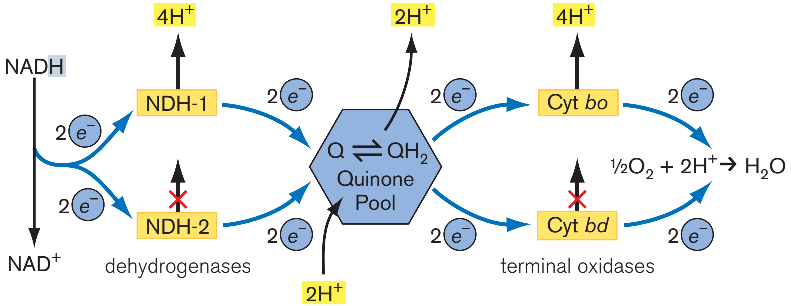
$$E \ \square\ E\square\ \square\ \frac{2.303\,RT}{nF}\ \square\ \log\frac{[\mathrm{NAD}^{\square}]^2}{[\mathrm{NADH}]^2[\mathrm{H}^{\square}]^2[\mathrm{O}_2]}$$

At low concentration of NADH or O_2 or at high pH (low H^+ concentration), the concentration term is negative, so the amount of energy released by the oxidation of NADH by O_2 is decreased. This means that fewer protons can be pumped per electron. Thus, it is advantageous for *E. coli* to have a range of options for its electron transport, pumping two to eight protons per NADH as needed.

The efficiency of the bacterial ETS is adjusted by making different NADH dehydrogenases and terminal oxidases under different environmental conditions (**Fig. 14.16**). In *E. coli*, the ETS components are regulated as follows:

- **High oxygen level.** When O_2 concentration is high, some electrons are donated to NDH-2 instead of NDH-1, allowing NAD^+ to be recycled without pumping extra protons. This is necessary to avoid generating too much negative potential and too high a pH in the cytoplasm.
- **Low oxygen level.** Cytochrome *bo* quinol oxidase requires a high concentration of O_2 to pump protons. At low $[O_2]$, electrons are transferred instead from cytochrome *bd* quinol oxidase, which has a higher

Figure 14.16 Alternative substrate dehydrogenases and terminal oxidases. NADH:quinone oxidoreductase complex (NDH-1) pumps $2H^+$ whereas NDH-2 pumps none. Cyt *bo* pumps an extra proton per electron, whereas Cyt *bd* only exports protons from QH_2 and consumes $2H^+$ to make H_2O.



affinity for O_2. However, the *bd* oxidase cannot pump protons. So at low oxygen level, expression of NDH-2 is repressed, allowing maximal proton pumping by NDH-1.

- **High external pH.** When external pH exceeds the pH of the cytoplasm, the cell needs to minimize proton export to maintain a constant internal pH. So the *bd* oxidase is expressed in preference to the proton-pumping *bo* oxidase.

THOUGHT QUESTION 14.7 Why would bacteria evolve dehydrogenases that fail to pump protons even when sufficient donor potential exists?

THOUGHT QUESTION 14.8 Experiments suggest that NADH dehydrogenase 2 is more often coupled with cytochrome *bo*, and dehydrogenase 1 more often with cytochrome *bd*. Why might this be the case?

Bacteria also have alternative oxidoreductases to serve different electron donors and acceptors. Some enzymes take electrons from donors lacking the potential of NADH; for example, succinate dehydrogenase catalyzes the one step of the TCA cycle that yields $FADH_2$, a step that provides not quite enough energy to produce NADH (discussed in Chapter 13). Succinate dehydrogenase is the only TCA enzyme embedded in the membrane as an ETS component. Other complexes donate electrons to anaerobic electron acceptors such as nitrate, or they accept electrons from inorganic electron donors (discussed in Sections 14.4 and 14.5).

Mitochondrial respiration. In contrast to bacteria, mitochondria have only a single ETS, optimized for a relatively uniform intracellular environment (**Fig. 14.17**). Protected by the eukaryotic cytoplasm, mitochondria do not need to maintain alternative versions of their respiratory ETS. Instead, a set of just four electron-carrying complexes has evolved so as to maximize the energy obtained from NADH, minimizing energy lost as heat. This highly efficient mitochondrial respiration is nearly universal throughout the cells of animals, plants, and most eukaryotic microbes.

The mitochondrial ETS differs from that of *E. coli* in these respects:

- **An intermediate cytochrome oxidase complex.** Besides NADH dehydrogenase (complex I) and cytochrome *c* oxidase (complex IV), both of which have homologs in *E. coli*, mitochondria show an intermediate step of electron transfer to ubiquinol-cytochrome *c* oxidoreductase (complex III, shown in **Fig. 14.17**). The intermediate electron transfer step pumps an

additional $2H^+$. Another $2e^-$ may come from succinate dehydrogenase (complex II), which forms $FADH_2$ through the TCA cycle.

- **The mitochondrial ETS pumps more protons per NADH.** As many as 10–12 protons may be pumped per NADH, in contrast to 2–8 protons in *E. coli*.
- **Homologous complexes have numerous extra subunits.** The mitochondrial homologs of bacterial enzymes generally have evolved additional nonhomologous subunits specific to eukaryotes. For example, the homologous subunits of cytochrome *c* complex are enveloped by a series of eukaryotic-specific proteins.

The Proton Potential Drives ATP Synthesis

The proton potential drives synthesis of ATP by the membrane ATP synthase, also known as the F_1F_o ATP synthase. The proton-driven synthesis of ATP completes the cycle of oxidative phosphorylation, in which hydrogen atoms from organic foods are transferred to NADH + H^+. The same type of ATPase can use the proton potential generated by lithotrophy (see Section 14.5) or by phototrophy (see Section 14.6).

The F_1F_o ATP Synthase

The F_1F_o ATP synthase is a protein complex highly conserved in the bacterial cell membrane, the mitochondrial inner membrane, and the chloroplast thylakoid membrane. An elegant molecular machine, the ATP synthase is composed of two rotating complexes, F_o and F_1 (**Fig. 14.18**). The F_o complex translocates protons across the membrane. Twelve *c* subunits form a cylinder embedded in the membrane, stabilized by subunits *a* and *b*. The F_1 complex consists of six alternating subunits of types alpha and beta surrounding a gamma subunit that acts as a drive shaft. Each "third" of the F_1 complex (an alpha plus a beta subunit) interconverts ADP + P_i with ATP + H_2O. The gamma subunit connects the tripartite "knob" of F_1 to the membrane-bound F_o. Proton transport through F_o drives ATP synthesis by F_1.

One proton at a time enters the subunit *a* channel and moves into a subunit *c* of F_o (**Fig. 14.19**). The proton potential directed inward ensures that protons more often enter from the outside than from the cytoplasm. Each entering proton causes a subunit *c* to rotate around the axle, with release of a bound proton to the cytoplasm. The flux of three protons through F_o is coupled to forming one molecule of ATP by one alpha-beta-gamma unit of F_1. During each cycle generating ATP, the 12 c subunits of the F_o rotor rotate in the membrane one-third of one turn relative to the F_1 in the cytoplasm.

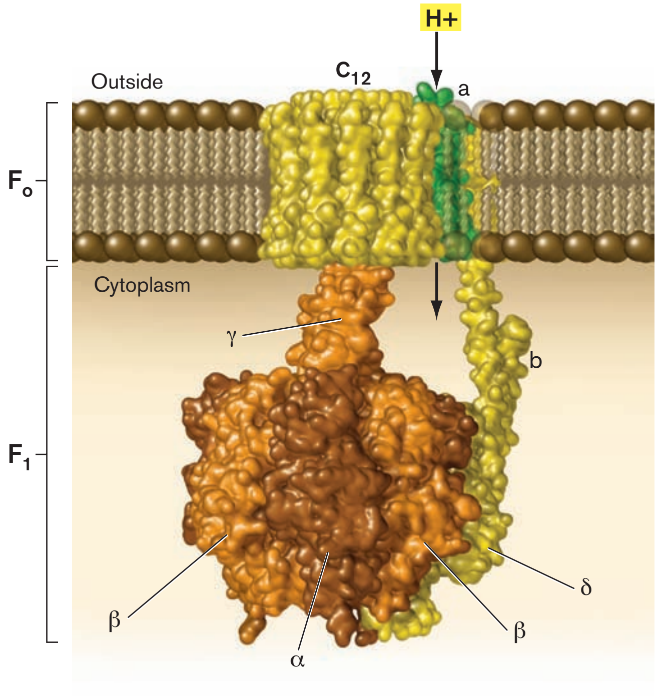

Figure 14.18 Bacterial membrane-bound ATP synthase (F_1F_o ATPase). The F_1F_o complex plugged into the *E. coli* plasma membrane. The three pairs of alpha and beta subunits rotate around the gamma axle, catalyzing formation and hydrolysis of ATP. The ring of *c* subunits rotates while translocating three protons. (PDB codes: 1B9U, 1C17, 1E79, 2CLY)

Note that the generation of ATP is completely reversible, so that ATP hydrolysis by F_1 can pump protons back through F_o across the membrane. In the absence of a proton potential, a high ATP concentration can drive the F_o in reverse, actually pumping protons to generate Δp. This reversal of ATP synthase is used, for example, by *Enterococcus faecalis*, enteric gram-positive cocci that have no electron transport system but generate ATP entirely by fermentation and substrate phosphorylation. *E. faecalis* can operate the membrane-bound F_1F_o ATP synthase in reverse, consuming ATP and thus generating a proton potential for nutrient uptake and ion transport.

How do alkaliphilic bacteria make ATP and maintain a proton potential when growing in a high pH environment, such as the Dead Sea? Their ATP synthase looks surprisingly similar to that of bacteria living at neutral pH, but its peptide sequences differ at key amino acid positions (see **Special Topic 14.2**).

THOUGHT QUESTION 14.9 How might the bacterial cell compensate for environmental conditions in which Δp falls below 100 mV, a suboptimal level for ATP synthesis?

THOUGHT QUESTION 14.10 Would *E. coli* be able to grow in the presence of an uncoupler that eliminates the proton potential supporting ATP synthesis?

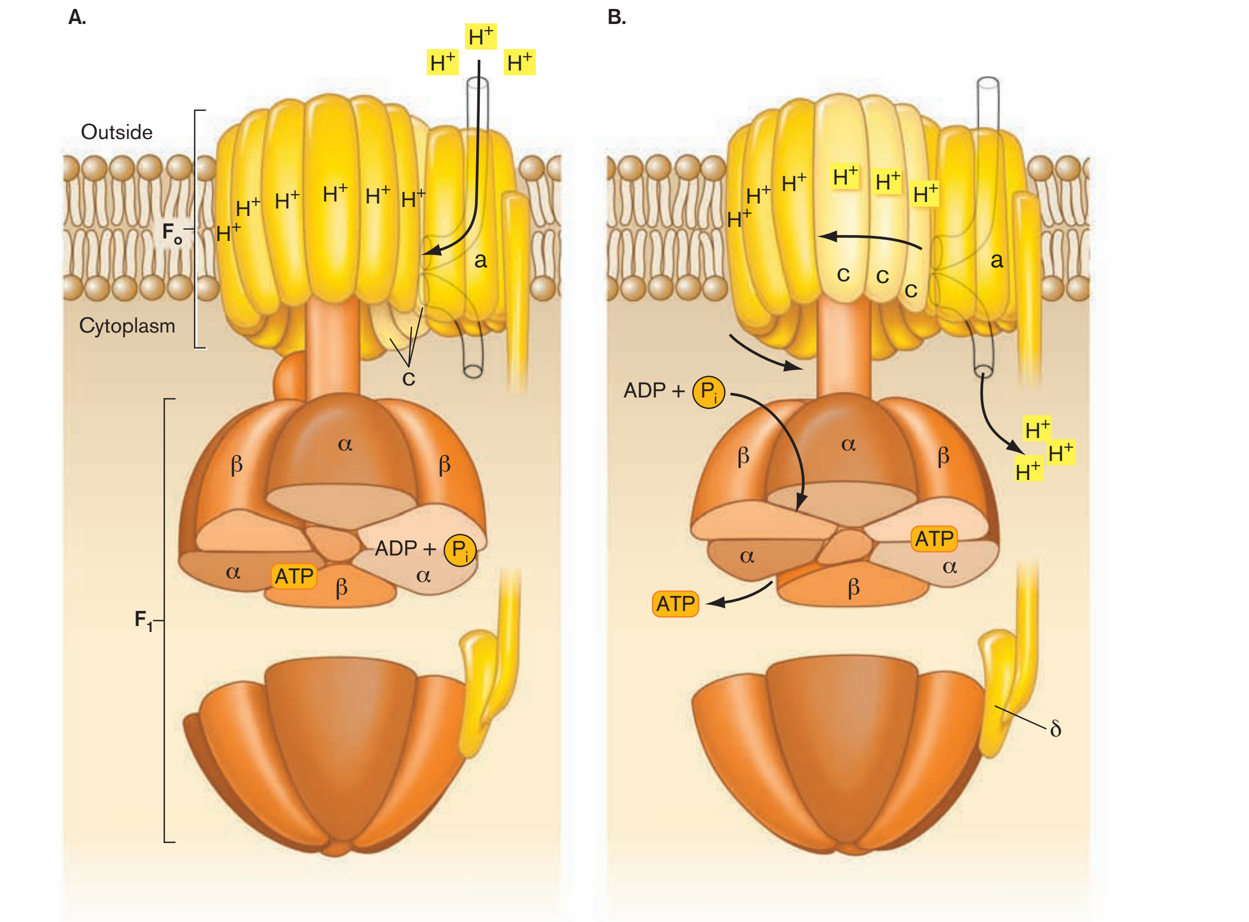

Figure 14.19 **H^+ flux drives ATP synthesis.** **A.** Three protons enter *c* subunits of the F_o complex. **B.** The three *c* subunits rotate ⅓ turn relative to the F_1. Flux of three protons through F_o is coupled to F_1 converting ADP + P_i to ATP. ⏯ *Source:* Animation by Don Nicholson.

Na^+ Pumps: An Alternative to H^+ Pumps

While a proton potential provides primary energy storage for most species, some bacteria generate an additional potential of sodium ions. A sodium motive force (□Na^+) is analogous to the proton motive force in that it includes the electrical potential □□ plus the sodium ion concentration gradient (log ratio of the Na^+ concentration difference across the membrane). In extreme halophilic archaea, which grow in concentrated NaCl, the sodium potential entirely substitutes for the proton potential to drive ATP synthesis. These "haloarchaea" make use of the high external Na^+ concentration to store energy in the form of a sodium potential.

In some bacteria, an ETS oxidoreductase pumps Na^+ instead of H^+. For example, the proton-pumping NADH dehydrogenase can be supplemented by an NADH dehydrogenase that pumps Na^+. This primary sodium pump is found in many pathogens, including *Vibrio cholerae*, the cause of cholera, and *Yersinia pestis*, the cause of bubonic plague. These pathogens use the sodium-rich circulatory fluids of their hosts to store energy in a sodium potential.

TO SUMMARIZE:

- **Electron carriers** containing metal ions and/or conjugated double-bonded ring structures are used for electron transfer. Cytochrome *c* quinol oxidase has two hemes and three copper ions.
- **A substrate dehydrogenase** receives a pair of electrons from a particular reduced substrate such as NADH. NADH dehydrogenase (NADH:quinone oxidoreductase) typically has an FMN carrier and nine iron sulfur clusters.
- **Quinones receive electrons** from the substrate dehydrogenase and become hydrogenated to quinols. Typically, a quinol receives $2H^+$ from the cytoplasm, then releases $2H^+$ across the membrane upon transfer of $2e^-$ to an electron acceptor complex.
- **Protons are pumped** by substrate dehydrogenases (oxidoreductases) and terminal oxidases. The bacterial cytochrome *bo* oxidase pumps $4H^+$ across the membrane, coupled to transfer of $4e^-$ onto O_2 to generate $2H_2O$.
- **Protons are consumed** by combining with the terminal electron acceptor, such as combining with oxygen to make H_2O.

- **The number of protons pumped by a bacterial ETS** is determined by environmental conditions, such as the concentrations of substrate and terminal electron acceptor.
- **The proton potential drives ATP synthesis** through the membrane-bound F_1F_o ATP synthase. Three protons drive each F_1F_o cycle, synthesizing one molecule of ATP.
- **An Na^+ potential (ΔNa^+) can drive ATP synthesis**, replacing or supplementing the proton potential for some bacteria and archaea.

14.4 Anaerobic Respiration

Nearly all multicellular animals and plants require electron transport to oxygen. Bacteria and archaea, however, sample an extraordinary menu of terminal electron acceptors, including metals, oxidized ions of nitrogen and sulfur, and chlorinated organic molecules. This **anaerobic respiration** generally occurs in environments where oxygen is scarce, such as in wetland soil and water and within the human digestive tract.

Alternative Electron Acceptors and Electron Donors

Respiratory bacteria usually possess several different terminal oxidoreductases to reduce alternative electron acceptors, as shown for *E. coli* in **Figure 14.20**. These enzymes, although comparable to cytochrome quinol oxidases, are conventionally termed "reductases" to emphasize reduction of the alternative electron acceptor. Some of the electron acceptors are inorganic, such as nitrate (NO_3^-) reduced to nitrite (NO_2^-), or NO_2^- reduced to NO. Others are organic products of catabolism; for example, the TCA cycle intermediate fumarate can be reduced to succinate. Organic electron acceptors play important roles in food decomposition. For example, the substance trimethylamine oxide, used by fish as an osmoprotectant against sea salt, is reduced by bacteria to trimethylamine—the main cause of the "fishy" smell.

At the top of the ETS, alternative dehydrogenases receive electrons from different organic electron donors as well as from molecular hydrogen (H_2). The various dehydrogenases all "connect" to various terminal reductases through the pool of quinones. Note that the various electron donors differ greatly in their reduction potential and hence in their capacity to generate proton potential (see **Table 14.1**). In a given environment, the strongest electron donor and the strongest electron acceptor available may be used. The best donor and best acceptor usually induce expression of genes encoding their respective redox enzymes. For example, in the presence of nitrate, genes encoding nitrate reductase are expressed. At the same time, nitrate represses the expression of reductases for poorer electron acceptors, such as fumarate. (The mechanisms of gene induction and repression are discussed in Chapter 10.)

Nitrogen and Sulfur: Oxidized Forms Accept Electrons

Oxidized forms of nitrogen and sulfur, usually anions such as nitrate or sulfate, can accept electrons from many species of soil and water bacteria. The nitrogen series offers an abundant source of strong electron acceptors. Reduction of oxidized states of nitrogen for energy yield is called **dissimilatory denitrification**. Dissimilatory nitrate reduction contributes to respiration, whereas assimilatory reduction of nitrate leads to ammonia for fixation into biomass (discussed in Chapters 15 and 22).

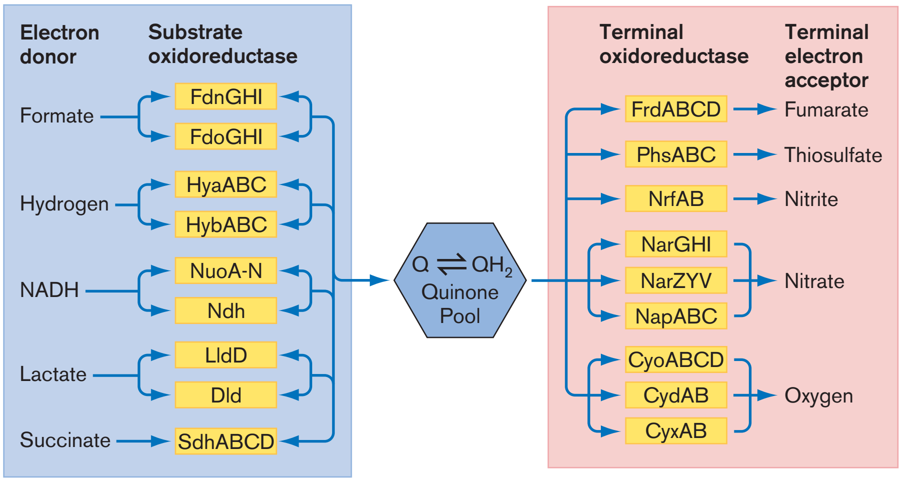

Figure 14.20 Alternative electron donors and electron acceptors. *Escherichia coli* can oxidize various foods (electron donors) while reducing various electron acceptors. Each electron donor may utilize alternative dehydrogenases, depending on the environmental conditions. Each dehydrogenase sends protons through the quinol pool to the terminal reductases.

Special Topic 14.2 ATP Synthesis at High pH

Alkaliphilic bacteria isolated from soda lakes, such as Lake Natron in Tanzania, grow at pH values as high as pH 14 while maintaining internal pH at 9–10. Thus, their ΔpH is inverted, with 10,000-fold higher H^+ concentration inside the cell. How do these alkaliphiles maintain a proton motive force driving protons inward? Maintaining internal pH several units lower than outside the cell seems incompatible with generation of a proton potential that runs ATP synthase. So how do these organisms make ATP?

One model to explain ATP synthase coupling at high pH was proposed by Terry Krulwich, at Mount Sinai School of Medicine (**Fig. 1**). Krulwich proposed that protons pumped by the electron transport system are sequestered just outside the membrane and directed into the ATP synthase (**Fig. 1B**). This model (as yet unproven) would require a cell compartment, or trap, for protons outside the cell membrane or some kind of direct connection between the ETS proton pumps and the ATP synthase.

Figure 1 Alkaliphiles maintain an inverted pH gradient. At external pH several units higher than internal pH, how do alkaliphilic bacteria make ATP? **A.** Terry Krulwich, researcher on alkaliphilic bacteria. **B.** Proposed model for how protons pumped by the electron transport system might be sequestered just outside the membrane and directed into the ATPase.

Oxidized forms of nitrogen. In the nitrogen redox series, a given oxidation state can serve as an acceptor in one redox couple but as a donor in the next. The redox couples are summarized here:

$$\underset{\text{Nitrate}}{NO_3^-} \xrightarrow{2e^-} \underset{\text{Nitrite}}{NO_2^-} \xrightarrow{e^-} \underset{\text{Nitric oxide}}{NO} \xrightarrow{e^-} \underset{\text{Nitrous oxide}}{\tfrac{1}{2}N_2O} \xrightarrow{e^-} \underset{\text{Nitrogen gas}}{\tfrac{1}{2}N_2}$$

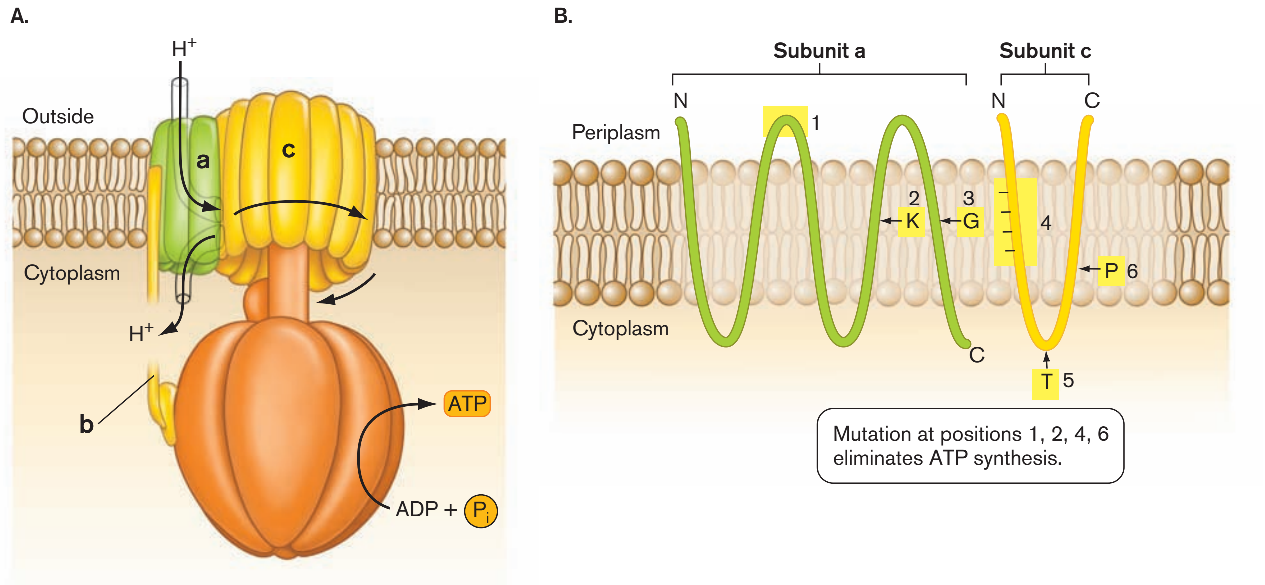
In general, a single bacterial species expresses the terminal reductase for only one or two transformations in the series, such as reduction of nitrate and nitrite, while growing in communities that include species conducting the next steps. Each nitrogen state requires a specialized reductase, such as nitrate reductase or nitrite reductase, to receive electrons from the ETS. The full series of nitrate reduction to N_2 plays a crucial role in producing the nitrogen gas of Earth's atmosphere (discussed in Chapter 22).

An alternative option for many soil bacteria, such as *Bacillus* species, is to reduce nitrite to ammonium ion:

$$NO_2^- + 8H^+ + 6e^- \rightarrow NH_4^+ + 2H_2O$$

The structure of the hypothetical proton coupling connection is unclear, but one prediction from the model is that the membrane-bound F_o component of ATP synthase, which transduces proton flow, would have a form specialized for alkaliphilic conditions. Krulwich and colleagues compared the peptide sequences of F_o from an alkaliphilic species, *Bacillus pseudofirmus* OF4, with that of a neutralophilic species of the same genus, *B. megaterium*. Six amino acid differences were observed in the sequences of the membrane-bound *a* and *c* subunits, which mediate the proton flux.

Mutant strains of the alkaliphile *B. pseudofirmus* were obtained, each of which had an amino acid substitution at one of the sites 1–6 OF4 (**Fig. 2**). Four of the respective mutants failed to synthesize ATP when grown at high pH (mutation sites 1, 2, 4, and 6). This observation shows that the alkaliphile has evolved a form of ATP synthase specifically adapted to function at high external pH. It is consistent with a model that the alkaliphile's cell membrane contains a special proton compartment or coupling device to drive ATP synthesis, although other explanations are possible.



Mutation at positions 1, 2, 4, 6 eliminates ATP synthesis.

Figure 2 Mutations that inactivate ATP synthase in an alkaliphile. A. ATP synthase structure in the alkaliphile *B. pseudofirmus* OF4, showing membrane location of subunits *a* and *c*. **B.** Location of mutant residues in subunits *a* and *c* that inactivate the ATP synthase at high pH.

Dissimilatory nitrate and nitrate reduction to ammonia can increase the soil pH, precipitating metals such as iron.

The presence of a particular reductase can be used as a diagnostic indicator for clinical isolates of bacteria. For example, the chemical test for nitrate reduction is a key step in the diagnosis of *Neisseria gonorrheae*, the causative agent of gonorrhea. *N. gonorrheae* happens to lack the terminal reductase for nitrate; hence, it tests negative, whereas several closely related species test positive.

Respiration using oxidized forms of nitrogen is widespread among bacteria and has been found in a growing number of archaea. Most eukaryotes must breathe oxygen, but some eukaryotic microbes respire on nitrate and nitrite. In anaerobic soil, many yeasts and filamentous fungi can reduce nitrate to nitrite, and nitrite to nitrous oxide. In the digestive tract of termites and of ruminant vertebrates, many fungi and protists grow anaerobically.

Oxidized forms of sulfur. A similar series of oxidized sulfur molecules serve as electron acceptors for bacteria that synthesize appropriate reductases:

$$\underset{\text{Sulfate}}{SO_4^{2-}} \xrightarrow{2e^-} \underset{\text{Sulfite}}{SO_3^{2-}} \xrightarrow{2e^-} \underset{\text{Thiosulfate}}{\tfrac{1}{2}S_2O_3^{2-}} \xrightarrow{2e^-} \underset{\text{Elemental Sulfur}}{S^0} \xrightarrow{2e^-} \underset{\text{Hydrogen Sulfide}}{H_2S}$$

Their redox potentials are generally lower than those for oxidized nitrogen forms. Nevertheless, sulfate and sulfite receive electrons from many kinds of electron donors, including acetate, hydrocarbons, and H_2. Sulfate-reducing bacteria and archaea are widespread in marine habitats, from the arctic waters to submarine thermal vents. The ubiquity of sulfate reduction may be related to the high sulfate content of seawater, in which SO_4^{2-} is the most common anion after chloride.

Dissimilatory Metal Reduction

An important class of anaerobic respiration involves the reduction of metal cations, or **dissimilatory metal reduction**. The term *dissimilatory* indicates that the metal reduced as a terminal electron acceptor is excluded from the cell. This is in contrast to minerals reduced for the purpose of incorporation into cell components (assimilatory metal reduction). The metals most commonly reduced through anaerobic respiration are iron ($Fe^{3+} \rightarrow Fe^{2+}$) and manganese ($Mn^{4+} \rightarrow Mn^{2+}$), but virtually any metal with multiple redox states can be reduced or oxidized by some bacteria.

Metal electron acceptors require a specific oxidoreductase (or reductase). Metal ions in solution interact directly with reductases; but oxidized metals such as Fe^{3+} are often barely soluble in water. How does a bacterial reductase interact with an insoluble source of metal outside the cell? One way that soil bacteria reduce metals is to "shuttle" electrons using quinone-like degradation products of lignin, a complex aromatic substance that forms the bulk of wood and woody stems. Lignin degradation products are also called "humics" from their presence in humus, the organic components of soil. Humics accumulate in anaerobic environments, where decomposition is slow. Some are quinones (or their reduced counterparts, quinols). The extracellular quinols can shuttle electrons from the cell's ETS to extracellular metals.

Anoxic or anaerobic environments, such as the bottom of a lake or wetland sediment, offer a series of different electron acceptors (**Fig. 14.21**). The stronger electron acceptors will be consumed, in turn, by species that have the terminal oxidases to use them. For example, as oxygen grows scarce, nitrate is reduced to nitrogen gas ($NO_3^- \rightarrow N_2$) by nitrifying bacteria. As nitrate is used up, other species reduce manganese ($Mn^{4+} \rightarrow Mn^{2+}$), iron ($Fe^{3+} \rightarrow Fe^{2+}$), and sulfate ($SO_4^{2-} \rightarrow H_2S$). At the bottom of the lake or sediment, carbon dioxide is reduced to methane by methanogenesis. Methanogenesis is conducted by archaea (see Section 14.5). Microbial reduction of minerals plays a critical role in every ecosystem and participates in the geochemical cycling of elements throughout Earth's biosphere (discussed in Chapter 22).

The reduction of Fe^{3+} is of great interest from the standpoint of early evolution of the biosphere. The biosphere of early Earth lacked molecular oxygen but had plenty of iron, the most abundant element in our planet. Most of the iron would have existed in the reduced, soluble form, Fe^{2+}. Without the ozone layer, however, ultraviolet rays may have reacted with Fe^{2+}, removing an electron to produce Fe^{3+}. Fe^{3+} could have been used by early hydrogenotrophs and even phototrophs as a terminal electron acceptor. Cycles of microbial iron reduction and oxidation are believed to have generated the major iron ores we mine for iron metal worldwide (discussed in Chapter 17).

A particularly interesting family of metal-reducing microbes is Geobacteraceae, whose members reduce metals such as iron and manganese as well as uranium ($U^{6+} \rightarrow U^{4+}$). Reduced uranium is insoluble in water, precipitating as uranite (UO_2). *Geobacter metallireducens* can use uranium reduction to respire on simple organic substrates such as acetate, providing a way to remediate uranium-contaminated water. The U.S. Department of Energy has used uranium-reducing bacteria for remediation at Rifle, Colorado, where uranium contamination has threatened the Colorado River. In this process, acetate is pumped into the water table, where *G. metallireducens* oxi-

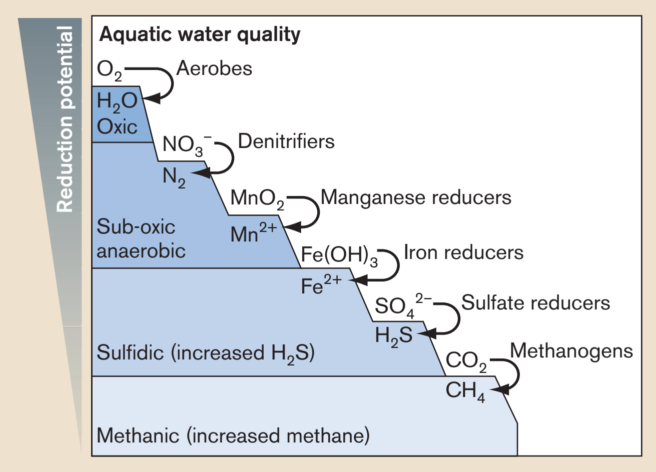


Figure 14.21 Anaerobic respiration in a lake water column. As each successive terminal electron acceptor is used up, its reduced form appears. The next best electron acceptor is then used, generally by a different species of microbe.

dizes the substrate to CO_2 by reducing U^{6+} to U^{4+}. The reduced uranium then precipitates out of the water into the soil, where it can be collected and removed, while the cleansed water flows through.

THOUGHT QUESTION 14.11 The proposed scheme for uranium removal requires injection of acetate under highly anoxic conditions, with less than 1 part per million (ppm) dissolved oxygen. Why must the acetate be anoxic?

Another intriguing type of metal reduction associated with anaerobic respiration is that of gold ($Au^{+3} \rightarrow Au^0$). The gold ion is soluble in water, but gold metal precipitates on the surface of gold-reducing bacteria. It is speculated that bacterial gold respiration may have formed much of the gold metal deposits found on Earth.

TO SUMMARIZE:

- **Anaerobic terminal electron acceptors**, such as nitrogen and sulfur oxyanions, oxidized metal cations, and oxidized organic substrates, accept electrons from a specific reductase complex of an ETS.
- **Nitrate** is successively reduced by bacteria to nitrite, nitric oxide, nitrous oxide, and ultimately nitrogen gas. Alternatively, nitrate and nitrite may be reduced to ammonium ion, a product that alkalinizes the environment.
- **Sulfate** is successively reduced by bacteria to sulfite, thiosulfate, elemental sulfur, and hydrogen sulfide. Sulfate reducers are especially prevalent in seawater.
- **Oxidized metal ions** such as Fe^{3+} and Mn^{4+} are reduced by bacteria in soil and aquatic habitats, a form of anaerobic respiration also known as dissimilatory metal reduction.
- **The geochemistry of natural environments** is largely shaped by anaerobic bacteria and archaea.

14.5 Lithotrophy and Methanogenesis

Many reduced minerals can serve as electron donors for an ETS, in the energy-yielding form of metabolism known as lithotrophy (or chemolithotrophy). Lithotrophy is distinguished from organotrophy, metabolism that derives energy from breakdown of organic compounds (compounds with at least one carbon-carbon bond.) Only prokaryotes can grow by metabolizing inorganic compounds without photosynthesis. Thus, bacteria and archaea fill many key niches in ecosystems that eukaryotes cannot.

As summarized in the previous chapter in Table 13.1, lithotrophs may share common components of ETS with organotrophs. The electron-accepting oxidoreductase, however, needs to be specialized for the electron donor, such as H_2, NH_4^+, or Fe^{2+}. Most inorganic substrates other than H_2 are relatively poor electron donors compared to organic donors such as glucose. Therefore, the terminal electron acceptor is usually a strong oxidant, such as O_2, NO_3^-, or Fe^{3+}. Obligate lithotrophs (organisms that conduct only lithotrophy) consume no organic carbon source; they build biomass by fixing CO_2. Other bacteria, however, possess alternative metabolic pathways for lithotrophy and heterotrophy.

Nitrogen Oxidation

A form of lithotrophy of great importance to the environment is oxidation of nitrogen compounds:

$$\underset{\text{Ammonium}}{NH_4^+} \xrightarrow{\frac{1}{2}O_2} \underset{\text{Hydroxylamine}}{NH_2OH} \xrightarrow{O_2} \underset{\substack{\text{Nitrous acid}\\ \text{(nitrite)}}}{HNO_2} \xrightarrow{\frac{1}{2}O_2} \underset{\substack{\text{Nitric acid}\\ \text{(nitrate)}}}{HNO_3}$$

Reduced forms of nitrogen, such as ammonium ion derived from fertilizers, support growth of **nitrifiers**, bacteria that generate nitrites or nitrates (forming nitrous acid or nitric acid, respectively). Acid production can degrade environmental quality. In soil treated with artificial fertilizers, nitrifiers decrease the reduced nitrogen content and produce toxic concentrations of nitrites, which leach into groundwater. Still, nitrifiers can be useful in sewage treatment, where they eliminate ammonia that would harm aquatic life (discussed in Chapter 22).

Ammonia and nitrite are relatively poor electron donors compared to organic molecules. Thus, their oxidation through the ETS pumps fewer protons, and the bacteria must cycle relatively large quantities of substrates to grow. Nevertheless, where reduced carbon supplies are exhausted, ammonium is oxidized rapidly.

What happens to ammonium from detritus that accumulates in anaerobic regions, such as the bottom of lakes? Surprisingly, ammonium can yield energy through oxidation by nitrite produced from nitrate respiration:

$$NH_4^+ + NO_2^- \rightarrow N_2 + 2H_2O \qquad E°' = 430 \text{ mV}$$

Under conditions of high ammonium and extremely low oxygen, this metabolism supports ample growth of bacteria. Known as the **anammox reaction**, anaerobic ammonium oxidation plays a major role in wastewater treatment, and it cycles tremendous amounts of nitrogen back to the atmosphere. Anammox is conducted by planctomycetes, irregularly shaped bacteria with unusual nucleus-like membranes enclosing their nucleoid (discussed in Chapter 18).

Sulfur and Metal Oxidation

Major sources of lithotrophic electron donors are minerals containing reduced sulfur, such as hydrogen sulfide and sulfides of iron and copper. As we saw for nitrogen compounds, each sulfur compound that undergoes partial oxidation may serve as an electron donor and be further oxidized.

$$\underset{\substack{\text{Hydrogen}\\\text{sulfide}}}{H_2S} \xrightarrow{\frac{1}{2}O_2} \underset{\substack{\text{Elemental}\\\text{sulfur}}}{S^0} \xrightarrow{\frac{1}{2}O_2} \underset{\text{Thiosulfate}}{\tfrac{1}{2}S_2O_3^{2-}} \xrightarrow{O_2 + H_2O} \underset{\substack{\text{Sulfuric}\\\text{acid}}}{H_2SO_4}$$

Sulfur oxidation produces the strong acid sulfuric acid, which dissociates to produce an extremely high H^+ concentration. In the early twentieth century, no one would have believed that living organisms could live in concentrated sulfuric acid, much less produce it. The *Star Trek* science fiction episode "The Devil in the Dark" portrayed an imaginary alien creature, the Horta, that produced sulfuric acid in order to eat its way through solid rock (**Fig. 14.22A**). In actuality, of course, no creatures beyond the size of a microbe are yet known to grow in sulfuric acid. But archaea such as *Sulfolobus* species oxidize hydrogen sulfide to sulfuric acid and grow at pH 2, often in hot springs at near-boiling temperatures (**Figs. 14.22 B** and **C**). *Sulfolobus* makes irregular Horta-shaped cells without even a cell wall to maintain shape; how it protects its cytoplasm from disintegration is not yet understood.

The result of microbial sulfur oxidation can be severe environmental acidification, causing deterioration of concrete structures and stone monuments. The problem is compounded by sulfur oxidation in the presence of iron, such as in iron mine drainage. For example, the sulfur-oxidizing archaeon *Ferroplasma acidarmanus* was discovered in the huge abandoned mine Iron Mountain, in northern California, by Katrina Edwards of the Woods Hole Oceanographic Institution and colleagues from the University of Wisconsin–Madison. *Ferroplasma* oxidizes ferrous sulfide (FeS_2) with ferric iron (Fe^{3+}) and water:

$$FeS_2 + 14Fe^{3+} + 8H_2O \rightarrow 15Fe^{2+} + 2SO_4^{2-} + 16H^+$$

This reaction generates large quantities of sulfuric acid. The acidity of the mine water is near pH 0, one of the most acidic environments found on Earth. As *Ferroplasma* grows, it forms biofilms of thick streamers in the mine drainage, which poisons aquatic streams.

Anaerobic reactions between sulfur and iron cause hidden hazards for human technology, such as the corrosion of steel in underwater bridge supports. Anaerobic corrosion was long considered a mystery, since iron was known to rust through spontaneous oxidation by O_2. In anaerobic conditions, however, corrosion can be caused by two alternative pathways involving sulfur-reducing bacteria (**Fig. 14.23**). In one pathway, the bacteria reduce elemental sulfur (S^0) with H_2 to hydrogen sulfide (H_2S).

H_2S then combines with iron metal (Fe^0), which gives up two electrons to form Fe^{2+}, precipitating as iron sulfide (FeS). The displaced $2H^+$ combine with the $2e^-$ from iron, regenerating H_2—now available to reduce sulfur once again. In an alternative mechanism, bacteria use Fe^0 to reduce sulfate directly to FeS. These damaging processes may resemble the iron-based metabolism of Earth's most ancient life-forms.

Nevertheless, like the imaginary Horta that ended up helping miners with their excavations, acid-producing microbes are now used to supplement commercial mining. Lithotrophs such as *Thiobacillus ferrooxidans* oxidize sulfides of iron and copper found in minerals such as chalcopyrite ($CuFeS_2$), chalcocite (Cu_2S), and covellite (CuS). The oxidation of Cu^+ to Cu^{2+}, as well as the acidification resulting from production of sulfate, dissolves the metal from the rock. Oxidation of Cu^+ can occur either aerobically with O_2 or anaerobically with NO_3^- present in the soil. Other metals oxidized by *T. ferrooxidans* include selenium, antimony, molybdenum, and uranium. The process of metal dissolution from ores is called **leaching**. Leaching of minerals has been a part of mining since ancient times, long before the existence of microbes was known. Today, over 10% of the copper supply in the United States is provided by microbial leaching from ores too low in copper to smelt directly (**Fig. 14.24**). A similar process is being developed to mine gold, and special strains of *T. ferrooxidans* are being engineered to optimize gold recovery.

In the absence of sulfur, reduced metal ions such as Fe^{2+} and Mn^{2+} provide energy through oxidation by O_2 or NO_3^-. These lithotrophic processes occur commonly in soil where weathering exposes reduced minerals. They generate metal ions with higher oxidation states (such as Fe^{3+} or Mn^{4+}), which other bacteria use for anaerobic respiration. Environments such as ponds and wetlands that experience frequent shifts between oxygen availability and oxygen depletion are likely to host a variety of metal-oxidizing lithotrophs as well as metal-reducing anaerobic heterotrophs. Lithotrophy in ecology is discussed further in Chapters 21 and 22.

Hydrogenotrophy Uses H_2 as an Electron Donor

The use of molecular hydrogen (H_2) as an electron donor for electron acceptors is known as **hydrogenotrophy** (**Table 14.2**). An example is oxidation of H_2 by sulfur to form H_2S, performed by *Pyrodictium brockii*, a species of archaea that grows at thermal vents above 100°C. Hydrogen gas is a stronger electron donor than most organic foods, so it can be oxidized with the full range of electron acceptors. It is available in anaerobic communities as a fermentation product.

Hydrogenotrophy is hard to categorize. Because H_2 is inorganic, oxidation by O_2 is considered lithotrophy; yet many species that oxidize H_2 with molecular oxygen are heterotrophs that also respire on organic foods. When hydrogen reduces an organic electron acceptor, such as fumarate, the process is considered a form of fermentation or (more correctly) anaerobic respiration. When hydrogen reduces a mineral such as sulfur or sulfate, the process is anaerobic lithotrophy.

A form of hydrogenotrophy with enormous potential for bioremediation is **dehalorespiration**, the reduction of halogenated organic molecules by H_2 (**Fig. 14.25A**). Chlorinated molecules such as chlorobenzenes, perchloroethene, and polyvinylchloride (known as PVC) are highly toxic environmental pollutants. In dehalorespiration, the chlorine is removed as chloride anion and replaced by hydrogen, a reaction requiring input of two electrons from H_2. Many soil bacteria conduct dehalorespiration; a particularly unusual cell wall-less bacterium was discovered to dechlorinate chlorobenzene, a highly stable aromatic molecule (**Fig. 14.25B**).

Table 14.2 Hydrogenotrophy: examples.

Specific reaction	General description
$O_2 + 2H_2 \rightarrow 2H_2O$	Aerobic oxidation of H_2
Fumarate + $H_2 \rightarrow$ succinate	Organic + $H_2 \rightarrow$ organic
$2CO_2 + 4H_2 \rightarrow CH_3COOH + 2H_2O$	Mineral + $H_2 \rightarrow$ organic
$2H^+ + SO_4^{2-} + 4H_2 \rightarrow H_2S + 4H_2O$	Mineral + $H_2 \rightarrow$ mineral
$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$	Methanogenesis–only in archaea

Methanogenesis and Methane Oxidation

Hydrogen is such a strong electron donor that it can even reduce the highly stable carbon dioxide to methane. Reduction of CO_2 and other single-carbon compounds to methane is called **methanogenesis**. Methanogenesis supports a major group of archaea known as **methanogens**, many of which grow solely by autotrophy, generating methane. The availability of methane then provides a niche for methane-oxidizing bacteria.

Methanogenesis. The simplest form of methanogenesis involves hydrogen reduction of CO_2:

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$$

Because both sides of the equation contain a weak electron acceptor (CO_2, H_2O) and a strong electron donor (H_2, CH_4), it is surprising that such a reaction can yield energy for growth, but in the presence of sufficient carbon dioxide and hydrogen, enormous communities of methanogens are supported. Such conditions prevail wherever bacteria grow by fermentation, and their gaseous products are trapped, such as in landfills, where methane can be harvested as natural gas, as well as in the digestive systems of cattle and humans. Variants of methanogenesis also include pathways by which H_2 reduces various one-carbon and two-carbon molecules, such as methanol, methylamine, and acetic acid. Methanogens include a variety of archaeal species nearly as diverse as an entire domain.

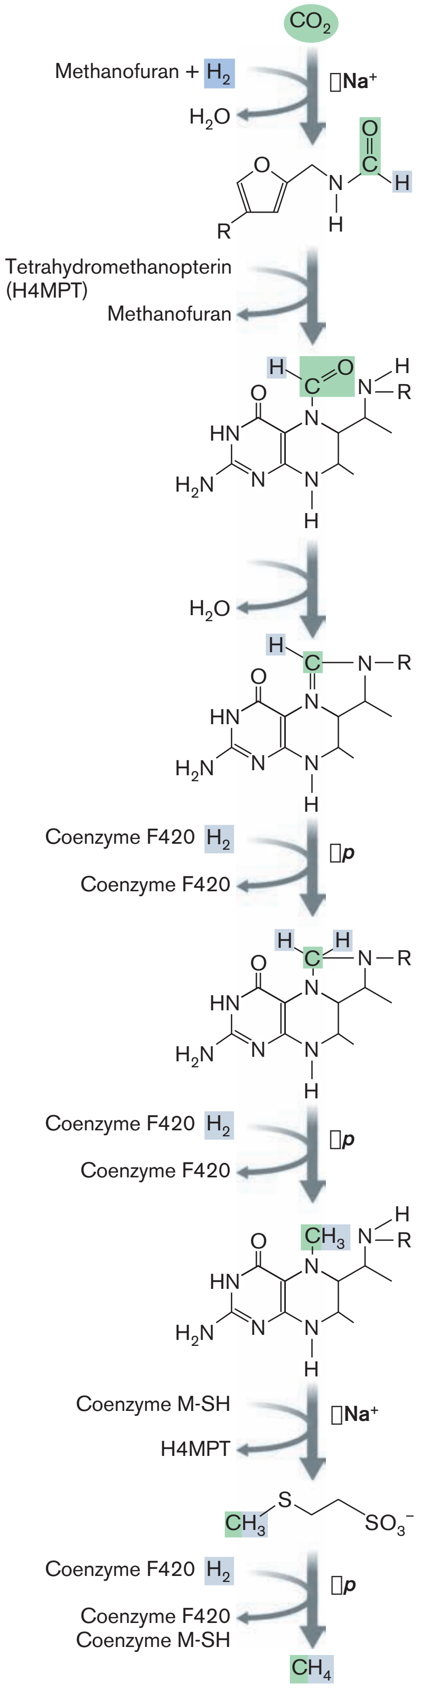

Figure 14.26 Methanogenesis. A methanogen reduces carbon dioxide with hydrogen, generating methane. The incorporation of hydrogen is driven both by a proton potential and by a sodium potential (discussed in Chapter 19).

A simplified pathway of methanogenesis from CO_2 is shown in **Figure 14.26**. The CO_2 undergoes stepwise hydrogenation, and each oxygen is reduced to water. The increasingly reduced carbon is transferred through a series of unique cofactors (methanofuran, tetrahydromethopterin, coenzyme M-SH). Three of the hydrogenation steps involve a membrane ETS complex including the carrier coenzyme F_{420}, whose reaction generates a proton potential. Note, however, that the initial hydrogenation step and the final step of methane production generate a transmembrane sodium potential (□Na^+). The use of a sodium potential is consistent with genetic evidence that methanogens evolved from ancient halophiles, organisms living in a high-salt environment (discussed in Chapter 19).

THOUGHT QUESTION 14.12 Hydrogen gas is so light that it rapidly escapes from Earth. Where does all the hydrogen come from to be used for hydrogenotrophy and methanogenesis?

Methane oxidation. Methanogenesis provides a niche for methanotrophs, bacteria and archaea that oxidize methane with a terminal electron acceptor. In deep-ocean sediment, the activity of methanogens is so high that enormous quantities of methane become trapped on the seafloor in the form of water-based crystals known as methane hydrates. If all the methane were to be released at once, it would greatly accelerate global warming. How is this methane recycled? Until recently, it was thought that most methane oxidation, or **methanotrophy**, required O_2; indeed, many bacteria are aerobic methanotrophs. The deep-ocean sediments reveal other species of bacteria and archaea that oxidize methane using nitrate or sulfate. This anaerobic methane oxidation may be critical for the global carbon cycle, as it suggests a mechanism for removal of submarine methane.
